WORKING PAPER 7

Impact Evaluation and Interventions to Address Climate Change: A Scoping Study

Martin Prowse
Birte Snilstveit
March 2010

About 3ie

The International Initiative for Impact Evaluation (3ie) works to improve the lives of people in the developing world by supporting the production and use of evidence on what works, when, why and for how much. 3ie is a new initiative that responds to demands for better evidence, and will enhance development effectiveness by promoting better informed policies. 3ie finances high-quality impact evaluations and campaign to inform better program and policy design in developing countries.

3ie Working Paper series covers both conceptual issues related to impact evaluation and findings from specific studies or synthetic reviews.

This Working Paper was written by Martin Prowse, Institute of Development Policy and Management and Birte Snilstveit, 3ie.

Foreword

Substantial and increasing amounts of funding are available for climate change interventions. This paper argues that to ensure effective allocation of these resources, the selection and design of climate change mitigation and adaptation interventions should be based on evidence of what works, what doesn't, under what circumstances and at what cost. Currently the evidence base for bringing about behaviour change in the context of climate change interventions is minimal and there is a need for wider application of rigorous impact evaluation (IE) in the field. Climate change interventions have much to learn from experiences in the related fields of international development and conservation. The paper highlights some of the challenges faced when conducting IEs of climate change interventions and how these can be tackled. We argue that there are ample opportunities to conduct IE of climate change interventions. Increased financing of climate change interventions is urgently needed to mitigate global warming and enable countries and communities to adapt to its impact. However, if calls for increasing financing of climate change mitigation and adaptation by hundreds of billions of dollars a year are to remain credible, and gain and maintain support, evidence of the effectiveness of current spending is essential.

1. Introduction and background to study

Climate change is at the top of the international policy agenda. While differences in interests and negotiating positions make ongoing negotiations challenging, there is broad agreement on the need to tackle the causes and consequences of global climatic change. But although the evidence base on the science of climate change is overwhelming, there is less of a consensus around the effectiveness of policies and interventions designed to bring about behaviour change for mitigation and adaptation. So far very few rigorous impact evaluations of climate change interventions have been undertaken: the evidence base to guide policy-makers needs strengthening.

This paper argues that to support the effective allocation of substantial climate funds, the selection and design of climate change interventions (both mitigation and adaptation) should be based on evidence of what works, what doesn't, under what circumstances and at what cost. This paper is intended to be of relevance to climate change professionals on the one hand, and impact evaluators on the other. However, as the applicability of IE techniques to climate change interventions has not been widely considered, the paper does not purport to be comprehensive or exhaustive. Instead, it sketches out the terrain on which future studies might build.

Section 2 of the paper provides an introduction to climate change, policy responses and sources of funding. We briefly summarise the science of climate change and its physical impacts, provide some background on what is meant by mitigation and adaptation, and provide an overview of the main financial resources available through the United Nations Framework Convention on Climate Change (UNFCCC) and other multilateral sources.

The remaining sections of the paper discuss impact evaluation in relation to climate change interventions. Section 3 provides a brief introduction to IE, a summary of how it has been applied to climate change and related environmental interventions in developing countries to date, and a brief discussion of the limits and opportunities in applying rigorous IE to climate change interventions. The fourth and fifth sections focus on some of the key areas relevant for mitigation and adaptation interventions, respectively, and suggest ways in which IEs could be implemented, using evaluations in other policy fields as examples. As stated above, there is ample scientific evidence of the fact of climate change, and of the science behind proposed interventions for mitigation and adaptation. But underlying the success of these interventions is behaviour change, and it is this behaviour change which has been inadequately evaluated. The sixth section concludes.

2. Overview of climate change, policy responses and funding streams

Climate change is shorthand for anthropogenic global warming, caused by higher concentrations of greenhouse gases in the atmosphere, especially carbon dioxide from the combustion of fossil fuels. These gases insulate and warm the earth by preventing infrared radiation from escaping back into space. The evidence that human activity is causing the earth's temperature to increase is overwhelming (see IPCC 2007a, 2007b; Liverman, 2007, 2008; Anderson and Bows, 2008). Higher temperatures are having a profound effect on environmental systems, increasing sea levels, thawing glaciers and permafrost, and changing the spatial distribution of plant and animal species.

In addition to the impact on environmental systems, climate change has become one of the most pressing international development issues. Anthropogenic global warming threatens, *inter alia*, to alter the spatial distribution of infectious and respiratory diseases, increase weather-related mortality, increase the salinity and temperature of oceans (altering fish stocks), modify the supply, demand and quality of freshwater, radically alter crop yields and the area of arable land, and increase the frequency and severity of natural hazards (IPCC 2007b; FAO 2007, 2008; Cline, 2007; Fischer *et al.*, 2002; Warren *et al.*, 2006; Dasgupta *et al.*, 2007; Kahn, 2005; Dell *et al.*, 2009; World Bank, 2009e). It is hard to disagree with the Human Development Report 2007/2008 assertion that climate change is "the defining human development issue of our generation" (UNDP 2007, p.1). A statement supported by the attendance of 119 heads of state and government (representing 89 per cent of global GDP) in Copenhagen for the 15th Conference of Parties in December 2009.

Whether we look at the projected impacts of climate change on crop yields, areas of arable land, natural hazards, or sea-level rise, it is clear that the consequences of climate change will be distributed unequally, affecting the poorest countries disproportionately, not least as they are more likely to rely on natural resources and economic sectors that are vulnerable to climate change, such as agriculture, fisheries and forestry (see Reid and Swiderska, 2008). Moreover, climate change is likely to have the greatest negative impact on the poorest sections of populations. We know that the poorest citizens are most likely to be: found in remote and unconnected rural areas; derive most of their income, directly or indirectly, from agriculture or natural resources; live in insecure environments and have few assets or entitlements to cope with shocks and stresses; have limited political voice and representation; and have little access to decent work opportunities (CPRC, 2008). It is likely that the physical effects of climate change will make these poverty traps more severe and "create a vicious cycle of poverty and vulnerability" (Ibarrarán *et al.*, 2009, p. 563).

In sum, the risks from climate change are greatest for the poorest countries and for the poorest sections of societies, and there is a profound sense of injustice if the poorest are forced to suffer most from the physical impacts of climate change (see Paavola and Adger, 2006; Thomas and Twyman, 2005). We thus have a moral as well as an economic case for global interventions to finance climate change interventions to reduce emissions and limit the adverse effects of global environmental change.

Climate change mitigation

Climate change interventions are divided into two broad categories: mitigation and adaptation. Mitigation interventions are designed to tackle the causes of climate change, while adaptation refers to interventions designed to assist people and countries in tackling the effects of climate change.¹ We give a brief summary of each, with particular reference to developing countries.²

Climate change *mitigation* refers to policies that reduce greenhouse gas (GHG) emissions and preserve/expand carbon sinks.³ Because of the large number of human activities that contribute to emissions, interventions to mitigate climate change are implemented across a range of sectors and industries, such as energy, transport, industrial production, waste management, and agriculture and forestry (UNFCCC, 2008b).

Barker *et al.* (2007) estimate that in 2004 the most important sources of GHG emissions were energy supply (26%), industry (19%) and forestry (17%). In addition, current GHG emissions from agriculture are estimated at around 14 per cent, with high emission increases expected for the future (UNFCCC, 2009). The sources of emissions vary widely between developed (Annex 1) and developing (non Annex 1) countries. For example, a breakdown of CO₂ emissions by sector in 2000 shows us that for OECD countries emissions stem mainly from electricity and heat, manufacturing and construction, transportation and other fuel combustion (WRI, 2009). This is also the case for China and India. However, for much of the rest of Asia, sub-Saharan Africa and South and Central America the majority of emissions come from land use change and forestry. For instance, a breakdown of emission sources in 2000 for sub-Saharan Africa shows that 75 per cent come from this source (*ibid.*).

In contrast to the previous century when developed countries emitted the vast bulk of (non land use) emissions, the distribution of emissions has changed radically in the past two decades. Due to the global shift in manufacturing and rapid industrialisation in parts of Asia, developing countries now have the majority of energy-intensive industry, and account for a greater proportion of final energy use by industry than the developed world, with this proportion set to increase (Barker *et al.*, 2007). Moreover, transport energy use in the developing world is projected to increase by 3 to 5 per cent per year in the coming decades, bringing its share of total energy use on a par with the developed world by around 2030 (Barker *et al.*, 2007).

But despite the shift in (non land use) emissions from developed to developing countries, and the position of China as the world's largest annual emitter of CO₂, developed countries will continue to owe a greater 'ecological debt' than developing

¹ In practice there may be some overlap between these two types of interventions, notably in sectors like agriculture and forestry (see Dodman *et al.*, 2009). However, as the main aims of mitigation and adaptation interventions are different, we discuss the possible role of impact evaluation in assessing interventions separately.

² The terms 'developing countries' and 'non Annex 1 countries' are treated as synonyms, as are the terms 'developed countries' and 'Annex 1 countries'.

³ The UNFCCC defines a sink as 'any process, activity or mechanism which removes a greenhouse gas, an aerosol or a precursor of a greenhouse gas from the atmosphere' (United Nations, 1992, p. 4). Examples of sinks include the forests, ocean, peat, permafrost and soil (IETA, n.d). Sinks can be preserved or enhanced to increase their role in reducing GHG emissions to the atmosphere.

countries for some time to come. There are two main reasons: population size; and the length of time CO₂ stays in the atmosphere. On a per capita basis, (non land use) emissions from Canada, the US and Russia are projected to be at least double China's emissions in 2030 (at a similar level to EU levels) (Financial Times, 2009). Since CO₂ remains in the atmosphere for around 100 years (IPCC, 2007a) we can better compare (non land use) per capita cumulative emissions, instead of annual emissions, by which by 2030 Chinese emissions will still be less than a fifth of emissions from the US, Canada and Russia and a third of EU emissions (Financial Times, 2009).

A post-Kyoto climate regime needs to reach a fair and just balance between emission reductions in developed and developing countries to avert dangerous climate change. The levels of CO₂ in the atmosphere in 2008 were 385.2 ppm, increasing by 2 ppm from 2007 (World Meteorological Organisation, 2009). The IPCC's best estimates are that if levels reach 450 ppm CO₂e⁴, there is a 50 per cent chance of a 2 °C temperature increase. If we reach 550ppm and 650ppm there is a 50 per cent chance of 3 and 4°C temperature increases respectively (see also Anderson and Bows, 2008). And as CO₂ stays in the atmosphere for at least 100 years, even if emissions peak in the next 25 to 50 years stocks in the atmosphere will only stabilise in 100 to 300 years (IPCC, 2001). This means that temperature stabilisation will only take place over a few centuries, and that due to thermal expansion and ice melt, sea levels will continue to rise for much longer. In other words, reducing greenhouse gas emissions now will influence the climate for hundreds, if not thousands, of years (IPCC, 2001).

Concomitant with the greatest sources of GHG emissions, a large proportion of mitigation activities have so far been focused in the energy and transport sectors, including energy efficiency measures, fuel switching, the use of renewable energy and biofuels (World Bank, 2009d).⁵ In addition to reducing carbon emissions, climate change mitigation also takes the form of preserving and expanding carbon sinks such as forests. Global forest cover equates to around 30 per cent of global land area, but is shrinking rapidly due to the pressures of agriculture, infrastructure and urbanisation. Forests play a particularly important role in climate change. On the one hand, forests act as a store which contains twice the amount of carbon present in the atmosphere. On the other hand, each year forests actively remove up to one third of all carbon dioxide emissions from fossil fuel combustion and land use change (McMullen and Jabbour, 2009). This vital role in maintaining the globe's carbon cycle can be supported in a number of ways. For example, through increasing a forest's carbon density and through utilising sustainably-harvested forest products in place of items with a large carbon footprint (see McMullen and Jabbour, 2009). Most importantly, though, forests' vital role can be supported through reducing deforestation. Estimates suggest that around one fifth of global greenhouse gas emissions stem from tropical deforestation, concentrated particularly in Indonesia and Brazil (see Porrúa et al., 2007).

In common with adaptation, many mitigation interventions share similarities with development activities. For example, the introduction of new technologies, sustainable agricultural practices, the production of new products and services, such

⁴ Includes other greenhouse gases such as methane and nitrous oxide.

⁵ For transport, mitigation options are relatively limited because of dependence on oil as a fuel (although alternatives include fuel-cell vehicles, hydrogen power and biofuels).

as biofuels and environmental services, all of which can provide new sources of income and wellbeing in addition to reducing GHGs.

Climate change adaptation

Despite receiving less attention than mitigation in recent years, adaptation is now also at the forefront of climate policy, as the impacts of climate change are already being observed and worse impacts are inevitable – see McGray *et al.*, 2007; Parry *et al.*, 2007; Rosenzweig *et al.*, 2007. As Smit and Wandel (2006) note, while there are countless definitions of adaptation in the conceptual literature, most definitions refer to a common theme, namely the adjustment of individual groups, systems and institutions to a changing climate, including an increase in external shocks, in order to reduce vulnerability and thus improve the capacity to cope with and reduce the negative impacts of climate change. For instance, the IPCC (2001, p. 982) defines adaptation as: “adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities.”

There is an extensive literature conceptualising different types of adaptation. Distinctions are made between *ex ante* (anticipatory) or *ex post* (reactive) adaptation, and *planned* and *autonomous* adaptation (Mitchell and Tanner, 2007).⁶ As the purpose of this paper is to discuss practical aspects of interventions, we do not detail the conceptual debate here (for the wider literature see for example Adger *et al.*, 2003, 2005, 2009; Paavola and Adger, 2006; Pielke *et al.* 2007).

Despite developing countries having the greatest adaptation need (as they face the greatest risks from climatic change), a relatively small number of adaptation activities have been implemented to date (due in part to low levels of funding and a lack of knowledge of climate data and data processing skills). Those that have been undertaken have mainly focused on preparing for adaptation through capacity building and assessments of vulnerability and options for adaptation (Burton *et al.*, 2006; GEF, 2007b).

Hence, there are signs of a slow move towards implementation of adaptation activities on the ground and a number of GEF funded projects are now underway, focusing on enhancing food security, access to water, public health and coastal infrastructure (GEF, 2007b).⁷ Other examples include crop and livelihood diversification, seasonal climate forecasting, community-based disaster risk reduction, famine early warning systems, insurance, natural resource management, water storage and supplementary irrigation (Adger *et al.*, 2007; Hedger *et al.*, 2008; Huq and Reid, 2004; World Bank, 2009d).

⁶ For example, initial attempts at adaptation appear to have been planned using large-scale modelling to inform policy choices, whilst more recent approaches are based on community-based activities which emphasise the existing coping strategies of communities and individuals (Huq and Reid, 2007). This has led to calls that “approaches to adaptation must be turned upside down to focus on local adaptation strategies as the point of departure for engagement” (Christoplos, *et al.* 2009, p.31).

⁷ Examples of specific adaptation interventions in the GEF portfolio include sustainable management of water resources in Argentina, market-led small holder development in Mozambique, adaptation using agro-biodiversity in Yemen, participatory coastal zone restoration in Sri Lanka, and piloting of community-based adaptation in ten different countries (GEF, 2007b).

A recent review study identified 135 adaptation activities (McGray *et al.*, 2007). The results suggest the majority of interventions were implemented in rural areas, at the village or community level, with few national level interventions being identified. In terms of sectoral distribution, agriculture and disaster risk management dominate, followed by water resources management and coastal resources, with very few interventions undertaken in the human health and energy sectors.

As these findings suggest, the distinction between 'adaptation' and 'development' is rather blurred. In his Foreign Policy Centre 2008 annual lecture, Douglas Alexander, the UK's Secretary of State for International Development went as far as to argue that 'adaptation simply means development under the conditions of a changing climate' (Alexander, 2008). The overlap between adaptation and development activities is also noted by McGray *et al.* (2007) who, in identifying 12 different adaptation strategies, suggest that "if there are uniquely 'adaptive' elements to these efforts, they are those involved in defining problems, selecting strategies, and setting priorities, not in implementing solutions" (p. 15) (see also Hedger *et al.*, 2008).

It is therefore unsurprising that there are increasing calls for including adaptation in mainstream development efforts (OECD, 2006, 2009a, 2009b). For example, many strategies from the 'development toolbox' are now being promoted as adaptation activities, including microfinance services (Hamhill *et al.*, 2008), social protection (in the form of weather-indexed crop insurance, asset restocking and cash transfers) (Commission on Climate Change and Development, 2009; Oswald, 2009), agricultural extension services (Commission on Climate Change and Development, 2009), and disaster risk reduction (see O'Brien *et al.*, 2008; Thomalla *et al.*, 2006; ISDR, 2009a; Yamin *et al.*, 2005).

Financing climate change interventions

Adaptation and mitigation interventions require substantial financial resources. For example, recent estimates by the World Bank (2009e) suggest that the cost of mitigation could reach \$400 billion a year between 2010-2030, and the cost of adaptation could average \$75 billion a year between 2010-2050.⁸ Both the UNFCCC (United Nations, 1992) and the Kyoto Protocol (United Nations, 1998) acknowledge adequate financial flows and investments as an important component of a successful global strategy for climate change mitigation and adaptation.

Strengthening efforts on finance and investments is one of the four key pillars of the Bali Action Plan, guiding current negotiations for a new global treaty on climate change (UNFCCC, 2008a). Recognising the 'common but differentiated responsibilities' of countries, the UNFCCC and the Kyoto Protocol commit most developed countries (Annex II) to provide new and additional funding to support developing countries in their efforts to mitigate and adapt to climate change (United Nations 1992; United Nations 1998).⁹ In addition to the financial mechanisms

⁸ It remains difficult to provide an exact estimate of funding. The World Bank (2009) estimates are broadly similar to UNFCCC (2007) figures for mitigation (US \$200-210 billion in annual global investments by 2030), and UNDP (2007) figures for adaptation (US\$86 billion by 2015).

⁹ The UNFCCC divides parties to the Convention into three groupings, depending on their commitments under the Convention. Annex I parties include industrialised countries who were members of OECD in 1992 and economies in transition, such as Russia and the Baltic states. Annex II parties are the Annex I states that are members of OECD and these countries are obliged to provide financial assistance to

designated for this purpose under the UNFCCC and the Kyoto Protocol, provisions are also made for Annex II countries to distribute financial resources through other bilateral, regional and multilateral channels (United Nations, 1998, Article 11, paragraph 3).

As climate change has moved up the policy agenda the sources of finance directed at climate change interventions have multiplied into a mixture of bilateral and multilateral funding initiatives. In 2007 alone, 14 new climate change related financing initiatives were announced (Porter *et al.*, 2008). Financial resources now come from a range of sources, including national exchequers, foreign direct investment, official development assistance (ODA), carbon markets, as well as the financial mechanisms of the Convention (Porter *et al.*, 2008; UNFCCC, 2008b).

The proliferation of new financing initiatives has raised concerns over the lack of a coherent global financial architecture to avoid duplication and inefficient allocation of resources. For example, a recent OECD (2009b) report on climate financing highlights how existing project-based climate funds impart high transaction costs and are often not aligned sufficiently with national policies or systems, as recommended by the 2005 Paris Declaration on Aid Effectiveness and the 2008 Accra Agenda for Action. The extent to which new funds are actually additional funding and not merely a re-branding of existing ODA is also a key concern.¹⁰

The size and architecture of climate funds are changing rapidly and will continue to do so from Copenhagen onwards.¹¹ Figure 1, taken from OECD (2009b), provides a useful overview of multilateral funds (with an indication of commitments or disbursements) and their institutional affiliation as of October 2009.¹²

We now provide a brief introduction to IE, the extent to which it has been applied to climate change and related environmental interventions in developing countries, and the challenges and opportunities in applying IE to CC interventions.

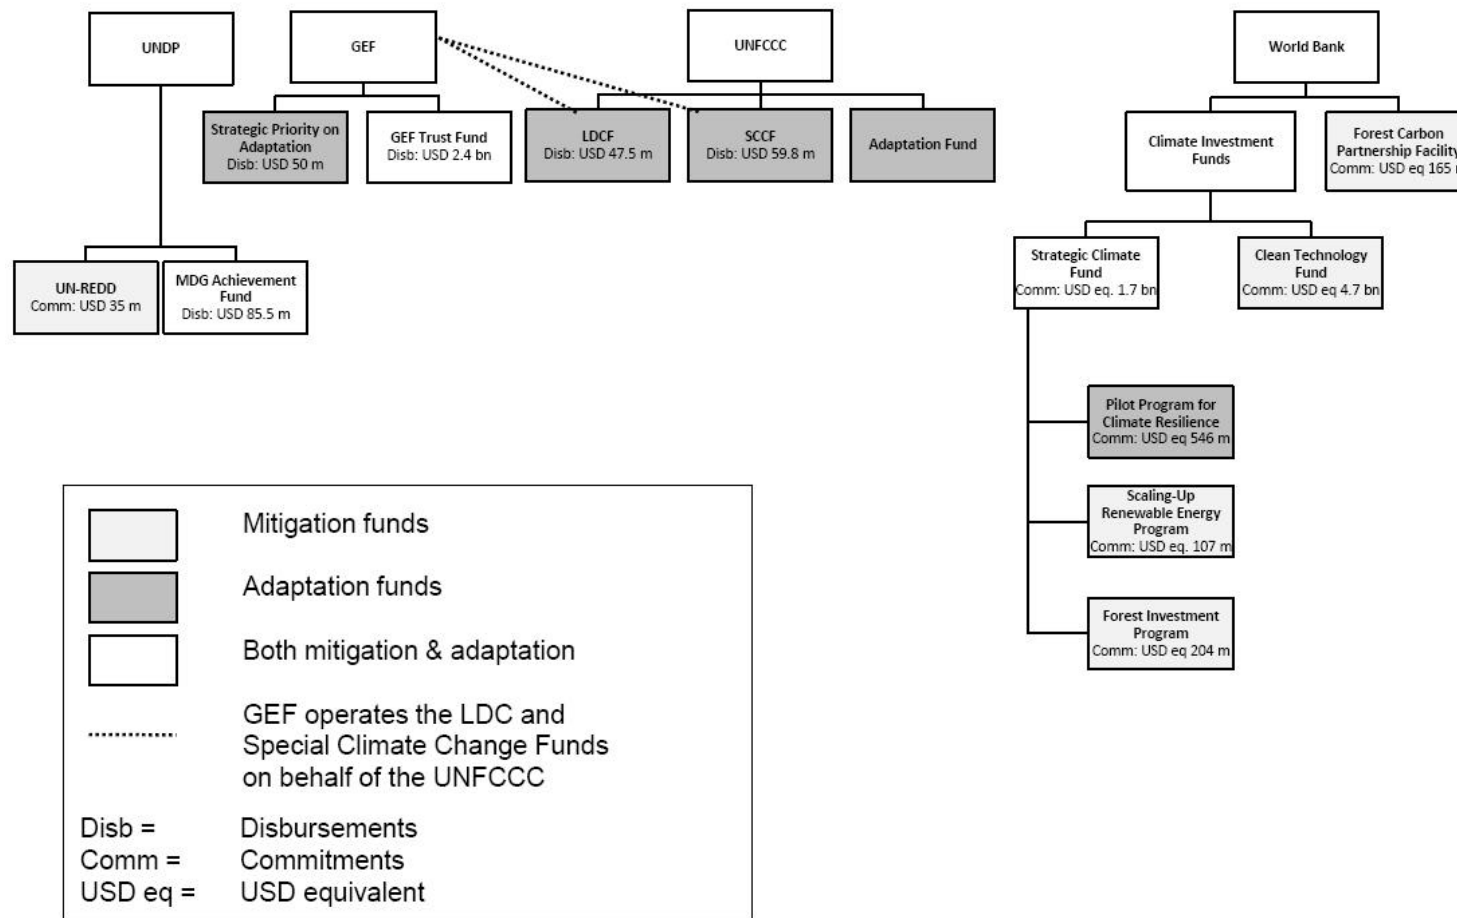

support developing countries to undertake climate change mitigation and adaptation interventions, in addition to promoting the development and transfer of environmentally friendly technologies to developing and transition economies. The last group is Non-Annex I parties and it largely includes developing countries (UNFCCC, n.d).

¹⁰ Using data in the OECD Creditor Reporting System (CRS) database, and assuming that activities in a wide range of sectors, including education, health, water resource management, governance, agriculture, infrastructure and energy are potentially relevant to adaptation, the share of ODA funding relevant to adaptation and adaptive capacity is more than 60 per cent (Levina, 2007).

¹¹ The major share of financial flows to address climate change for the year 2000 came from domestic funds (60%), followed by 22 per cent from FDI and 18 per cent from foreign debt (UNFCCC, 2007). The estimated ODA of US\$ 16 billion is too small to show up in the overall distribution of the total of US\$ 7,750 billion invested.

¹² Recent details can be gleaned from climatefundsupdate.org

3. Impact evaluation and climate change interventions

What is impact evaluation?

Recent years has seen a vibrant debate on the increasing use of Impact Evaluation (IE) in international development (see White 2009a, 2009c). Broadly speaking, IE is structured to answer the question: how would participants' welfare have altered if the intervention had not taken place? This counterfactual analysis involves "a comparison between what actually happened and what would have happened in the absence of the intervention" (White, 2006, p. 3). Since it is not possible to collect data on what would have happened if the intervention was not implemented, IE uses different methods to create a robust comparison group who is not directly exposed to the intervention, and whose outcomes would have been similar to participants if the intervention had not taken place (White, 2006). Such counterfactual analysis enables researchers to attribute the changes in outcome to particular interventions. Methods for establishing a valid counterfactual include experimental (randomisation), and quasi-experimental approaches; there may also be opportunities to exploit 'natural experiments'. In addition to overcoming attribution and selection bias issues, IE can form the basis for cost-benefit analysis to assess the efficiency of different interventions (see White 2009c)

This paper follows the International Initiative for Impact Evaluation (3ie) in defining rigorous impact evaluations as: "analyses that measure the net change in outcomes for a particular group of people that can be attributed to a specific program using the best methodology available, feasible and appropriate to the evaluation question that is being investigated and to the specific context" (3ie, 2008, p. 2). See Box 1 for a brief description of these methods.

Box 1 - Impact evaluation methodology

IE assesses the impact of an intervention using counterfactual analysis. The estimated impact of the intervention is calculated as the difference in mean outcomes between a 'treatment group' (those receiving the intervention) and a 'control group' (those who don't). The single difference estimator compares mean outcomes at end-line and is valid where treatment and control groups have the same outcome values at baseline. The difference-in-difference (or double difference) estimator uses baseline and end-line data to calculate the change in outcomes over time across the two groups. There are various approaches to determining an appropriate comparison group for counterfactual analysis.

Randomisation: the experimental approach to impact evaluation involves the random selection of participants into the intervention and control groups. When this method is well implemented over a sufficiently large sample the only difference between the two groups is that the control group does not receive the intervention. The experimental approach is held up by some as the 'gold standard' of evaluation, but is not applicable to all interventions; see Skoufias (2001) for an example.

Pipeline: This approach uses people, households, communities or businesses already chosen to participate in a project at a later stage as the comparison group. The assumption is that as they have been selected to receive the intervention in the

future they are similar to the treatment group, and therefore comparable in terms of outcome variables of interest. See for instance Edmonds (2002) for an example.

Matching: This approach involves matching programme participants to non-participants based on a number of observed criteria. One such approach is that of propensity score matching (PSM), which uses a statistical model to calculate propensity of participation on the basis of the set of observable characteristics. Participants and non-participants are then matched on the basis of similar propensity scores. A second approach is regression discontinuity design, which exploits a decision rule as to who does and does not get the intervention to compare outcomes for those just either side of this cut-off. See for instance Kassie et al. (2009) for an example of a study using matching.

Other techniques of IE include interrupted time-series and regression-based designs.

For a discussion of IE approaches see White (2006). Additionally, 3ie has recently launched an online database with a range of impact evaluations conducted in low- and middle income countries. Available from www.3ieimpact.org

As with all social research methods, experimental and quasi-experimental approaches have potential limitations. For example, the merging of control and treatment groups (such as when a control unit forces itself into the treatment group), spillover effects (when the direct or indirect effects of the intervention leaks over from the treatment group into the control), and a lack of compliance by an implementing agency which compromises the study (for a discussion of some of the pitfalls see Ravallion 2001, 2005; Chen *et al.*, 2006; see also Prowse and Camfield, 2009). Moreover, Bamberger and White (2007) highlight some of the difficulties in applying experimental approaches to development interventions. These include the often heterogeneous and changing contexts of interventions, logistical and practical challenges and difficulties with monitoring service delivery, and estimate that experimental designs are only applicable to five per cent of development finance (Bamberger and White, 2007). However, a range of quasi-experimental approaches are applicable to a greater number of interventions and these can provide valid impact estimates when applied rigorously.

Impact evaluation as defined here has thus far been dominated by (quasi-) experimental analysis of the counterfactual, often based on random sample survey data. While formal sample surveys are ideally suited to generate evidence of what works, on their own they are usually less able to improve our understanding of why interventions work or not (see Prowse, 2007b), and under which circumstances. Moreover, evidence on the effectiveness of an intervention in achieving its intended outcomes “does not tell us enough to inform program improvement or policy revision” (Weiss, 2007, p. 77). Most interventions within the realm of public policy are of a voluntary, rather than coercive nature, and will therefore be successful to the extent that people are incentivised to change their behaviour favourably. Therefore we *need* to know why and how interventions work.

The application of a theory-based approach to impact evaluation is one way of improving our understanding of why an intervention is successful or not, and to increase the policy relevance of IEs (see Birkmayer and Weiss, 2000; Cook, 2000; Rogers, 2007; White, 2009b). This approach combines rigorous counterfactual impact analysis, as outlined above, with other methods, emphasising analysis of the ‘factual’ using both quantitative and qualitative methods, to examine the causal

chain and shed light on the 'why' and 'how' questions (Leeuw and Vaessen, 2009; White, 2009b). In the case of climate change interventions, if the reduction of carbon-emitting behaviours is known one can to some extent rely on technical coefficients to calculate carbon reductions from practices like kerosene consumption and air travel. But as behavioural changes and take up of new technologies are difficult to assess, data from impact evaluations are extremely valuable. Evidence provided by theory-based impact evaluations can improve our understanding of these processes. Box 2 outlines six key principles of the theory-based approach as set out by White (2009b).

Box 2 - Principles of theory-based impact evaluation

Map out the causal chain (programme theory): This involves outlining the theory of how the intervention is expected to lead to the intended impact, enabling the evaluation to test the underlying assumptions along the causal chain. The theory should be flexible and ready to adapt to changing circumstances in the field, unforeseen consequences and surprises in the data.

Understand context: The context of the intervention, including the social, political and economic setting, is critical for understanding the impact of the intervention and designing the evaluation. Doing so would involve reading project documents and the broader literature before designing the evaluation.

Anticipate heterogeneity: This would assist in identifying sub-groups and adjusting the sample size to account for the levels of disaggregation to be used in the analysis. Examples of sources of impact heterogeneity are socio-economic status and the timing of impact measurement. Understanding context can assist in anticipating possible impact heterogeneity.

Rigorous evaluation of impact using a credible counterfactual: As many links in the causal chain as possible to be examined using a credible counterfactual (recognising time and resource constraints, the feasibility of constructing a counterfactual, and the significance of these links in the overall chain).

Rigorous factual analysis: Many of the links in the causal chain call for factual analysis to supplement the counterfactual analysis. Examples that would require such analysis is targeting and output analyses, for instance; did the training lead to improved knowledge and was the knowledge put into practice?

Use mixed methods: A combination of quantitative and qualitative methods in the same evaluation to provide information on the environmental, political or social context of interventions and provide essential insights into 'why' or 'how' an intervention succeeded or failed. The qualitative data can be generated through a range of activities, including focus groups, in-depth interviews, reading of anthropological and political literature, PRA and field visits.

Source: White (2009b).

Thus, a theory-based approach to IE (TBIE) includes collecting data at different points along the causal chain to test the underlying assumptions of the program theory. This provides data on mechanisms between activities and outcomes, enabling

evaluators to draw conclusions about the points in the causal chain that led to the measured outcomes (Birkmayer and Weiss, 2000). As Birkmayer and Weiss (2000) highlight, TBIE helps to plan evaluations; mapping out the program theory can act as 'the scaffolding of the study' and assist the researcher in deciding which key assumptions in the program theory warrants testing and data collection.

As argued by Ferraro (2009), IEs of climate change interventions can benefit from adopting a theory-based approach, not least as evaluations of both mitigation and adaptation interventions include measuring intermediate outcomes and in such cases a theory-based approach can improve validity. Moreover, as TBIE can provide insights into how and why interventions are effective or not, including evidence on causal mechanisms and contextual factors, this approach can improve the external validity and thus wider policy relevance of evaluations.¹³

Applying impact evaluation to climate change interventions

In this sub-section we examine how approaches to impact evaluation have been applied to climate change interventions and environmental interventions more broadly. Despite the increased attention on climate change mitigation and adaptation, most of the literature focuses on the physical science of climate change, conceptual issues and potential policies and frameworks related to mitigation and adaptation. To assess the current state of the literature we searched databases and websites to identify IEs of climate change interventions undertaken in developing countries.¹⁴

Apart from a few recent impact evaluations in the conservation literature, the results of our searches were disappointing. It seems the application of rigorous IE techniques to assess the effectiveness of climate change interventions has so far been limited. This is also noted by a number of recent publications. For instance, Jones *et al.* (2008) find that there are significant gaps in the application of IE and they particularly highlight the lack of studies on environmental protection, agriculture and health. Likewise, a recent desk review (Hedger *et al.*, 2008) assessed the current state of climate change adaptation evaluations and found high-quality impact evaluations lacking. Reviewing eleven evaluations of adaptation interventions in the GEF database, Hedger *et al.* (2008) note that evaluations generally depend on qualitative methods such as stakeholder interviews, tend to lack baselines, and are not integrated into projects.

An assessment of the evaluations of mitigation interventions included in the GEF database leads to similar conclusions: the evaluation methodologies are largely based on desk review, interviews and short field visits. White (2009c) also laments the lack of IEs of climate change mitigation interventions as this approach can be

¹³ The multi-tier framework presented by Ostrom (2007) can provide a useful starting point for theory-based IEs of climate change interventions and suggests a range of different variables researchers might want to consider when designing IEs.

¹⁴ We limited our attention to studies estimating impact using counterfactual analysis, based on the techniques discussed in Box 1 above, and did not review studies using structural modelling techniques. We used key word combinations such as climate change AND evaluation, clean development mechanism AND evaluation, climate change AND mitigation, climate change AND adaptation, 'payment for environmental services', 'risk management' AND environment AND evaluation, 'disaster risk reduction' AND evaluation, 'crop insurance' AND evaluation. Our sources included Google and Google scholar, Science Direct, JOLIS, IDEAS and BLDS. The Cochrane and Campbell Collaboration libraries were searched using the keywords climate change OR clean development mechanism and all results including any of these keywords were scanned. The websites of various organisations, such as the Global Environment Facility, IIED, UNEP and J-PAL were also searched and screened for any relevant results.

used to conduct cost-benefit analysis to assess the efficacy of investments. Moreover, noting the scarcity of counterfactual analysis in the related fields of biodiversity conservation and environmental economics more broadly, both Ferraro and Pattanayak (2006) and Greenstone and Gayer (2007) call for more widespread application of IE in these fields.

While there is a clear lack of rigorous IEs of climate change interventions, a few notable examples of IE of conservation interventions stand out. These studies are focused on three types of interventions, namely: protected areas; payment for environmental services; and decentralised forest management. In the past these strategies have been applied to biodiversity and forest conservation, but they are also relevant for climate change interventions, most notably under the rubric of Reduced Emissions from Deforestation and Degradation and the conservation and sustainable management of existing forest carbon stocks (REDD+).

Protected areas have long been used for environmental conservation and Andam *et al.* (2008), Gaveau *et al.* (2009) and Sims (2008) are recent examples of rigorous impact evaluations of these policies in Costa Rica, Indonesia and Thailand, respectively. All three studies use matching techniques to construct a counterfactual and evaluate the impact of the protected area on avoided deforestation. While Gaveau *et al.* (2009) found the protected areas policy has not led to a complete halt in logging and deforestation in the intervention areas in Sumatra, all the three studies suggest a reduction of deforestation in protected areas. Moreover, the importance of using rigorous methods and controlling for potential sources of bias to avoid distorted estimates of impact is highlighted by a comparison with results obtained from other methods (Andam *et al.*, 2008). Andam *et al.* (2008) estimate a substantially lower impact of protected areas on avoided deforestation in Costa Rica than estimated by conventional approaches and suggest the lack of random allocation of protected areas, in addition to the lack of control for spillovers, as potential sources of bias in studies using conventional methods. In addition to evaluating the environmental impact of protected areas, Sims (2008) is a rare example of a study assessing impact on both environmental and development outcomes. Combining new consumption, poverty and inequality estimates from the sub-district level and remote sensing data on forest cover, Sims uses matching and regression techniques to estimate the impact of the protected areas on socio-economic outcomes and land use. The results suggest that there are no causal links between the protected areas and the high poverty levels found in the communities nearby. Indeed, the analysis shows an increase in consumption and a reduction in poverty for those with land in national parks, although the distributional impacts of the protected areas may have been uneven.

Payment for environmental services (PES) programs is another conservation policy where rigorous IEs are starting to emerge. Arriagada (2008), Pfaff *et al.* (2008) and Robalino *et al.* (2008) all evaluate the impact of Costa Rica's payment for environmental services (PES) program, while Uchida *et al.* (2007) evaluate China's land conservation program, 'Grain for Green'. The PES program in Costa Rica tries to reduce deforestation by providing forest owners with financial compensation for the services their forests provide. The 'Grain for Green' PES program in China provides farmers with compensation in the form of grain, cash and seedlings if they set aside all or parts of their land to grow trees. The program's primary objective is to avoid soil erosion by increasing forest cover, but further objectives also include poverty alleviation and sustainable agriculture.

To control for the non-random allocation of the PES program Pfaff *et al.* (2008) and Robalino *et al.* (2008) use both covariate and propensity score matching techniques

to estimate the program's impact on avoided deforestation, while Arriagada (2008) uses multivariate and propensity score matching. While Robalino *et al.* (2008) suggest there was a small increase in the avoided deforestation resulting from the PES program in the 2000-2005 period, compared to 1997-2000, both studies of the PES program in Costa Rica suggest the scheme has failed to have much impact on deforestation and it is suggested this limited effect could be due to a significant reduction in deforestation across the whole country as a result of current and previous policies aimed at reducing deforestation. Hence, both studies argue better targeting of the payments to areas with the highest risks of deforestation has the potential to improve the effectiveness of the program (Pfaff *et al.*, 2008; Robalino *et al.*, 2008). Arriagada (2008) found little impact on forest loss, but found a small positive impact on forest re-growth and net deforestation. In China, Uchida *et al.* (2007) collected survey data on a randomly selected sample of 359 households, matching participants with non-participants using difference-in-difference estimation. The evaluation of 'Grain for Green' in China concluded the programme had been successful both in providing environmental services in the form of reduced soil erosion and in increasing the wealth of the mostly poor participants.

Lastly, decentralised forest management has become a widespread approach to forest conservation. Here we present two studies. First, Edmonds (2002) employed a pipeline approach and instrumental variable analysis to evaluate the impact of forest management by forest user groups in Nepal. National forest management was abandoned by the government in 1993 and field staff were instructed to start building forest user groups to manage forests without outside intervention. Three years later over 4000 forest user groups had been established. As this included less than 10 per cent of Nepal's forests it enabled a comparison between areas with and without forest user groups. Thus, Edmonds (2002) matched data from a census of forest user groups in the Arun Valley with the location of communities included in a Living Standards Measurement Survey data from the same area and estimated impact on fuel wood collection (as this is a major driver of deforestation in Nepal). The results showed that forest user groups reduced fuel wood extraction by around 14 per cent. Similarly, Somanathan *et al.* (2009) also employ a quasi-experimental design to evaluate the impact of decentralised forest management. This study used multiple regression analysis and propensity score matching to compare the impact and cost-effectiveness of the devolution of forest management to village councils from local government. The results suggest that village councils were at least as effective as local government in conserving forests. However, the expenditures by local government were more than nine times greater than village councils, leading the authors to conclude that 'substantial savings could be realized by decentralizing management' (Somanathan *et al.*, 2009, p. 4146).

While there appears to be few IEs on behaviour change in support of climate change interventions, this is not to say that evaluations of the environmental impact of projects have not used counterfactual types of analysis. For example, there has been recent interest in increasing the use of scenario planning when conducting *ex ante* environmental impact assessments (see Dunker and Greig, 2006). Here, either quantitative techniques (such as cross-impact analysis, statistical modelling techniques or trend analysis) or qualitative approaches (such as Delphi techniques or horizon scanning) are used to define a baseline against which the impact of an intervention is judged (see Ramalingam and Jones, 2008, for a range of futures planning tools). But this type of counterfactual analysis differs from IE: it utilises a constructed vision of a future baseline, in contrast to IEs concern with utilising an actual or reconstructed control against which an intervention is judged.

While this brief review of existing IEs of environmental protection interventions in developing countries found some good examples of the application of quasi-experimental methodologies to evaluate conservation interventions, it is perhaps surprising that the application of rigorous IE techniques to climate change interventions has not become more widespread. With substantial volumes of finance necessary for climate change interventions in the coming decades, impact evaluation could play an important role in promoting the efficient use of these resources.

The challenges of conducting IEs of climate change interventions

Numerous reasons help account for the lack of rigorous impact evaluations of climate policies. First, a number of common challenges faced by researchers when conducting IE are especially pronounced when attempting to evaluate environmental programs. For instance, some programmes lack baseline data, include a long time lag between intervention and measurable impact (Chomitz, 2008; Ferraro, 2009, Hedger *et al.*, 2008), lack an appropriate counterfactual for attribution (Chomitz, 2008; Hedger *et al.*, 2008), and include confounding factors and selection bias (Ferraro, 2009). Adaptation interventions can be particularly challenging as they can include a diversity of interventions, and lack agreement on indicators and the definition of adaptation success (see Hedger *et al.*, 2008).

Second, many climate policies are at a relatively early stage of implementation. For example, many adaptation initiatives have so far focussed on governance and institutional processes not appropriate for IE designs (such as consultations, capacity building exercises, needs assessments and policy development). And third, Ferraro (2009) suggests that many environmental practitioners and scientists may lack experience in IE designs and methods.

This is not to say that counterfactual analysis has not been considered when evaluating climate interventions. For instance, the independent evaluation unit of Global Environment Facility (which manages four large climate funds, see Figure 1) has discussed the possible use of counterfactual analysis in evaluating some programs (see Todd and Brann, 2007). However, the challenges of conducting such evaluations, as highlighted above, the possible cost, as well as difficulties encountered when conducting a counterfactual evaluation of one energy efficiency program, led Todd and Brann (2007, p. 9) to suggest that ‘the rigorous impact evaluation model is neither appropriate nor affordable’ for the GEF.

Impact evaluations of climate interventions can be a challenging undertaking, but that is not a compelling argument for not doing so. The examples of quasi-experimental evaluations of conservation programs cited above illustrate that rigorous evaluation of environmental programs are possible. Moreover, there are good reasons for pursuing them. As Ferraro argues:

“Counterfactual thinking is critical to building the evidence base in environmental policy about what types of interventions work and under what conditions... Despite the barriers and paucity of examples, there are substantial opportunities to elucidate causal relationships through experimental and quasi-experimental designs” (Ferraro, 2009: 76).¹⁵

¹⁵ Ferraro (2008) lists four elements that are required for a study of the impact of protected areas on welfare to be credible in attributing effects to the intervention: 1) Indicators of human welfare at a relevant unit of analysis (for example, individual, household, community and region) that can be objectively measured; 2) Data on applicable indicators before and after establishment of the protected

In addition, and as Greenstone and Gayer (2007, p. 42) note, estimating the costs and benefits of emissions reductions on the basis of associational evidence “can be highly misleading and can therefore lead to poor policies”. Triangulating such findings with studies that overcome selection bias problems and attribution issues is clearly desirable. The argument presented in this paper is that there appears to be a need to add to the existing evidence base.

In addition to the common challenges faced by researchers when conducting an IE, IEs of climate mitigation interventions are complicated because of difficulties in establishing baselines and measuring environmental outcomes. De Boer (2009) highlights how the lack of sufficient scientific capacity to measure the carbon sequestration in land use, land-use change and forestry (LULUCF) was one of the reasons for the exclusion of these sectors from the Kyoto Protocol. For example, for some mitigation interventions in the agriculture and forestry sectors environmental outcomes will be highly dependent on the local environmental context (as the amount of carbon sequestered in the soil depends on climatic zone, local climatic conditions, characteristics of the soil, type of crop and cultivation practices – see Muller, 2009). While progress has been made on addressing this issue, more work is needed, such as improving the measurement of carbon sequestration and emissions from modes of agricultural production (Muller, 2009).¹⁶

An alternative approach to direct measurement of environmental outcomes is to use behavioural change as a proxy. In other words, to measure environmental outcomes in a smaller sub-sample of units and then use observation or survey data on behavioural outcomes, or modelling, to extrapolate the environmental outcomes for the larger sample (Conant and Paustian, 2002; Ogle *et al.*, 2007).

Similarly, Ferraro (2009) points out that measuring the intermediate impact on behavioural changes might be a more feasible approach when direct measurement of environmental outcomes is difficult. This approach could potentially be used for a wide range of mitigation interventions, especially those involving a shift away from carbon intensive technologies to alternative, tried and tested low carbon technologies. Although if using proxy indicators one clearly needs to recognise that “there may be a temporal aspect to their emergence; for example, positive behavioural outcomes might occur prior to the observation of positive ecological outcomes” (Brooks *et al.*, 2006, p. 1529). In addition, as with all forms of evaluation, IEs need an explicit understanding of “the shape of the impact trajectories associated with [an intervention’s] projects, and ... how these trajectories vary for different kinds of projects operating in different contexts, at different scales and with varying degrees of implementation effectiveness” (Woolcock, 2009, p.1).

There is also a further set of challenges when conducting IEs of climate interventions: evaluations of climate mitigation measures in developing countries should ideally also assess impact on welfare. There are two good reasons for this. First, to ensure the mitigation efforts do not cause harm. And second, to maximise any adaptation co-benefits from mitigation actions. However, only two of the IEs

area (if baseline observations are not available another way of controlling for the initial situation and trends in social welfare has to be established); 3) Observations of the relevant indicators from treatment and control groups with similar characteristics; 4) Observations of characteristics affecting location of protected areas and human welfare trends in both groups before the establishment of the protected areas.

¹⁶ A systematic review entitled ‘Comparison of methods for the measurement and assessment of carbon stocks and carbon stock changes in terrestrial carbon pools’ (Petrokovsky *et al.*, 2009) is under preparation and its findings should provide an important resource to evaluators of LULUCF interventions.

reviewed in this paper measured both environmental and welfare outcomes (Sims, 2008, Uchida *et al.*, 2007).¹⁷

IEs of adaptation interventions will not always face the same challenges associated with measuring and establishing a counterfactual for environmental outcomes. Nevertheless, establishing a counterfactual for measuring people's capacity to adapt to and cope with the consequences of climate change can be problematic, especially if the intervention aims to reduce the risks associated with natural hazard events predicted to occur in the future (Dodman *et al.*, 2009). However, the similarities between adaptation and conventional development activities means there is more experience to draw on: evaluators can use similar methodologies as those used in development evaluations (Hedger *et al.*, 2008). Indeed, research by Adger *et al.* (2007 cited in Commission on Climate Change and Development) suggests indicators commonly used to measure human development have a statistically strong relationship with ability to deal with climate related events.¹⁸ Similarly, Hedger *et al.* (2008) suggest that many of the indicators used for measuring development effectiveness will also be related to adaptation and can be used to assess impact on adaptive capacity. They highlight the importance of building on existing indicator frameworks to avoid duplication of efforts and 'indicator overload'.¹⁹

As this discussion has illustrated evaluators face numerous challenges in conducting IEs of mitigation, and to a lesser extent, adaptation initiatives. They will have to work with environmental practitioners, scientists, development practitioners and social scientists to form creative solutions, while maintaining the rigour required for constructing a valid counterfactual (Ferraro, 2009). Some of the mechanisms adopted in climate change interventions will be similar to those used to achieve other development objectives and the increasing number of IEs in other policy fields can provide useful guidance for the design of IEs of climate change interventions. We now turn to examples of key mitigation and adaptation interventions. For each area of intervention, we discuss the potential for implementing IEs and where possible, offer an example of a relevant completed IE study.

4. Mitigation interventions

Green growth strategies

International pressure to control carbon emissions is growing, with countries being encouraged to adopt 'greener growth paths' – in other words, to find ways to grow while controlling the associated increase in carbon emissions. Such policies are less likely to affect agrarian countries in sub-Saharan African countries than countries that are industrialising, such as China and India. Nevertheless, and as illustrated in the Copenhagen Accord, even countries with substantial 'ecological space' may

¹⁷ *Vice versa*, it is also important that development projects assess GHG emissions. The announcement that the World Bank and other multilateral development banks intend to assess the carbon footprint of future projects and are developing a common methodology for doing so improves the prospects that development projects will measure GHG emissions (Block, 2009).

¹⁸ Adger *et al.* (2007, cited in Commission on Climate Change and Development) identify the following 18 indicators: population with access to sanitation; literacy rate, 5-14 year olds; maternal mortality; literacy rate, over 15 years; calorific intake; voice and accountability; civil liberties; political rights; life expectancy at birth; government effectiveness; literacy ratio (female to male ratio); GDP per capita; Gini coefficient; regulatory quality; rule of law; health expenditure per capita; educational expenditure as a percentage of GDP; percentage of population employed in agriculture.

¹⁹ The Disaster Risk Index (UNDP, 2004) and the Indicators of Disaster Risk and Risk Management (Cardona, 2007) are examples of other existing tools evaluators can draw on when evaluating adaptation.

voluntarily implement low-carbon growth policies, and tighter environmental standards and regulation. It is vital to ensure that these approaches do not undermine economic growth, but stimulate it through improved energy efficiency and productivity.²⁰

In the past decade, reducing carbon emissions associated with economic growth has focussed on reducing the energy intensity of growth (World Bank, 2008). A particular concern has been the inefficient production equipment in many industries in Eastern Europe and parts of Asia (*ibid.*).²¹

Todd and Brann (2007) review studies assessing the extent to which energy efficiency measures reduced electricity consumption and GHG emissions in Thailand, Poland, Mexico and Jamaica. The studies found that energy efficiency measures resulted in major changes in the residential market for lighting, refrigeration and air conditioning, especially in Thailand. Moreover, the studies also made some estimates of the costs and environmental benefits of the projects. Annual reductions of electricity sector emissions were estimated at around 0.5 per cent, with the exception of around 3.5 per cent reductions in the case of Thailand. Costs of around US\$ 1 to US\$ 5 per ton of carbon reduction were found in Thailand, Poland and Mexico, while at around US\$ 40 per ton, costs were much higher in Jamaica. Thus, in three of the four countries in the study, the benefits were estimated to exceed costs by a factor of between 2 and 5. In Jamaica, the benefits were found to be only 40 per cent of costs. Overall, the measures were found to make a modest contribution to the integration of energy efficiency objectives into energy policies.

However, these studies suffered from a number of shortcomings: IE was not integrated into projects at the outset, so the development of a comparison group was ex post and 'highly speculative', and the IE encountered resistance from project staff. Despite the considerable deficiencies of this project (including the difficulties of obtaining good data), it does illustrate that IE can be employed, especially when qualitative forms of enquiry are included to provide some estimates of the impact of energy efficiency measures which are at the core of green growth strategies.

Clean Development Mechanism

The Clean Development Mechanism was established by the Kyoto Protocol as a means to assist Annex I countries in achieving their emission reduction commitments and to contribute to low-carbon growth in non-Annex I countries (United Nations, 1998). It provides one of three channels through which industries and companies within Annex I countries can augment their allotted emission amounts (the other two being the purchase of emission rights from other Annex I countries, or the purchase of emission-reduction credits from offset projects in Annex I countries).²² In short,

²⁰ Green growth strategies could be beneficial to the poor as well as to the environment if they support a shift to low-polluting, labour-intensive production methods, and if they improve energy efficiency and stimulate growth.

²¹ A recent report from the World Bank's IEG (2008a) argued that rural electrification shifts energy use to more efficient and usually more sustainable sources, and suggested there is great scope for investments to reduce system losses which will greatly reduce the energy intensity of growth. World Bank supported off-grid energy supply contributes to carbon emissions reductions as the majority of the projects rely on renewable energy technologies and replace non-renewable energy sources. However, as the report highlighted, there is a need for further analyses of the environmental impacts of grid extensions.

²² The Kyoto Protocol stipulates that emissions reductions from CDM project activities must provide '[r]eal, measurable and long-term benefits related to the mitigation of climate change' and '[r]eductions in emissions that are additional to any that would occur in the absence of the certified project activity (United Nations, 1998, p.12).

the CDM enables industries or companies in Annex I countries to purchase certified emission reductions (CERs) from projects in developing countries on the condition that the reductions are *additional* to any GHG reductions that would have occurred without the CDM project.

Since the Kyoto Protocol came into force in 2005 (with 55 signatories accounting for at least 55% of 1990 emissions) the CDM has become a major offset market with over 1,900 projects registered, and over 2,500 and 280 at the validation and registration stages, respectively (Fenhann, 2009). Over 60 per cent of CDM projects are in the renewable energy sector, such as hydropower or biomass energy schemes. However, industrial gas projects, where powerful greenhouse gases such as hydrofluorocarbons or nitrous oxide are sequestered, account for over 70 per cent of the Certified Emission Reductions issued (due to the potency of these emissions). This is partly due to the restrictions on the inclusion of forestry and land use change projects within the CDM (although afforestation and reforestation projects were included).²³ However, this sector could play much larger role in the CDM in the future as there was substantial progress in Copenhagen on integrating REDD+ into a global climate regime (see Phelps et al, 2010).

The geographical concentration of CDM projects remains extremely uneven: as of November 1, 2009, 78 per cent of projects in the CDM pipeline are in Asia and the Pacific (mainly in China and India), and 17 per cent in Latin America with few projects in other regions of the globe (Fenhann, 2009). There are a number of straightforward reasons for this spatial disparity: the more industrialised non Annex I countries are able to clean up existing heavy industry; that CDM projects contain large economies of scale (including substantial upfront costs for each project); and that non Annex I parties lack the financial resources and technical expertise to tackle high upfront costs and complex procedures, respectively (see Keane and Potts, 2008).

While some recent work (Huang and Barker, 2009) suggests that CDM projects have had a significant effect on emissions reductions in host countries,²⁴ the effectiveness of the CDM in achieving its twin objectives of sustainable development and emissions reductions, has also been brought into question (see Schneider, 2007; Olsen, 2007; Sutter and Parreño, 2007). In particular, the effectiveness of the CDM in achieving *additional* emissions reductions has received widespread attention in the literature, especially regarding projects in China (Paulsson, 2009; Michaelowa and Purohit, 2007; Wara and Victor, 2008).²⁵ As the CDM is an offset mechanism, the issue of *additionality* is of particular importance as a failure to reduce emissions compared against a 'business as usual' baseline can lead to a net increase in global emissions, as the purchasers buy the right to emit in their home country.

²³ The eligibility of land use, land-use change and forestry projects under the Clean Development Mechanism (CDM) was one of the most controversial issues at the Sixth Conference of the Parties in November 2000. Thus only afforestation and reforestation projects were included in the CDM, with measures to address issues around non-permanence, social and environmental effects, leakage and additionality.

²⁴ Huang and Barker (2009) reach this conclusion after estimating an environmental Kuznets curve by applying VAR modelling to panel data from 34 host countries for the period 1990-2007. However, as no method is used to control for selection bias it is possible that this study provides evidence of an associational, rather than causal, nature.

²⁵ There are different ways of assessing additionality under the CDM. The CDM's methodological tool for assessing additionality includes a four step approach for identifying alternatives to the project that are consistent with current regulation, investment analysis, barrier analysis and common practice analysis. See CDM Executive Board (2008) for details.

The CDM utilises a form of counterfactual analysis, although establishing convincing business-as-usual baselines is not straightforward for CDM project developers (see Paulsson, 2009). A baseline is defined by UNFCCC as “the scenario that reasonably represents the anthropogenic emissions by sources of greenhouse gases that would occur in the absence of the proposed project activity” (UNFCCC, 2006). These baselines can be constructed using one of three approaches: current or historical emissions; future emissions from an economically attractive course of action; and the average emissions from comparable projects implemented in the past five years when their performance is in the top quintile of their category (*ibid.*). The first of these approaches uses a static before-versus-after comparison, and the second a constructed baseline scenario; the third utilises a comparison project to calculate reduced emissions.

As project developers benefit from inflating baseline figures, accredited firms validate and verify baseline scenarios and claimed emission reductions. These firms, commonly known as Designated Operational Entities (DOEs), must utilise a UNFCCC-approved methodology for the sector in question: for example, energy, manufacturing, chemical, transport, waste, and afforestation/reforestation. Despite the use of control and treatment groups to assess some initiatives, our searches did not identify any IEs specifically on CDM projects (or at least the evaluations were not labelled impact evaluations).

Experimental and quasi-experimental approaches are not well suited to assessing investments in large-scale investment in plant or infrastructure. Other techniques including structural modelling approaches such as computable general equilibrium (CGE) models (widely applied to analyses of major policy initiatives such as trade policies - see Harrison and List, 2004) might be more appropriate for evaluating the effectiveness of major policy interventions within the CDM. A review of the methodological and applied literature on structural modelling approaches to evaluation is beyond the scope of this paper, but it is worth noting that a number of recent studies of climate change policies use this technique, e.g. Kallbekken (2006) and Sue Wing and Kolodziej (2009) which use CGE modelling to provide ex-ante estimates of the impact of CDM and the Regional Greenhouse Gas Initiative (RGGI) in the United States respectively. In other cases pipeline approaches may offer a useful way of integrating IE into CDM assessments.

Agriculture

As agriculture is a major contributor of GHG emissions, recent studies have highlighted the potential for mitigation from this sector (de Boer, 2009; FAO 2009a; FAO, 2009b; Smith *et al.*, 2007; World Bank, 2007). It has been estimated that around 74 per cent of emissions from agriculture originate in developing countries (FAO, 2009c) and there have been calls to include incentives for emissions reductions in agriculture in developing countries within a future climate change treaty (FAO, 2009b, World Bank, 2007).

Mitigation options in agriculture include interventions that contribute to the reduction, removal and avoidance or displacement of emissions (Smith *et al.*, 2007). The range of practices include organic and low-input agriculture, agro-forestry, restoration of degraded land, crop rotation, improved land and natural resource management, more efficient livestock production and capture and storage technologies for manure (FAO, 2009c; Kranjac-Berisavljevic *et al.*, 2009; Smith *et al.*, 2007; World Bank, 2007).

However, whilst it may be possible to accurately measure, report and verify the abatement of GHG emissions from agriculture in developing countries, we need to be cautious about whether there are good reasons to do so. Clearly, rural communities in developing countries have contributed least to greenhouse gases in the atmosphere and in this sense have some 'ecological space'. Moreover, we need to be keenly aware that the rural poor often, directly or indirectly, derive the majority of income from agriculture and that any mitigation measures must not reduce income or food security. The application of intensive agricultural practices have been one of the most effective forms of poverty reduction to date, as illustrated by the attempts of the Alliance for a Green Revolution in Africa (AGRA) to replicate the smallholder-led productivity gains achieved in Asia (for example, see Rosegrant and Hazell 2000; Hazell and Ramasamy 1991). In this respect, it is important to ensure that calls for organic and low-input agriculture in low income countries on the grounds of climate mitigation do not place a burden on the poor or harm developmental objectives. But that said, high-yielding seed varieties and high-input agriculture may not be the right approach in all places, and practices such as agroforestry, reduced tillage and agro-ecology are likely to be beneficial in some contexts. The challenge is to ensure that the right approach to increasing productivity is adopted in the right places by the right farmers. Thus, it is important that IEs of interventions to change agricultural practices are designed to assess both environment and human welfare outcomes.

With this important caveat in mind, the literature suggests two main reasons for the lack of progress in mitigating emissions from agriculture: first, a lack of appropriate financial mechanisms; and second, important technical issues regarding leakage, additionality, measurement, monitoring, reporting and verification (FAO, 2009c; World Bank, 2007). Whilst climate change mitigation in the agricultural sector is still at a very early stage, the FAO (2009c) suggests that one can accurately measure the role of agriculture to changes in soil carbon stocks by "applying efficient sampling designs and rigorous protocols" (pp. 3-4). For example, through combining the direct measurement of soil carbon across an intensive sample of benchmark sites to evaluate the impact of different practices, with more diffuse sampling to assess the aggregate impact of an intervention on wider soil stocks (Conant and Paustian, 2002).

The FAO (2009c) also propose that combining direct field measurement with model-based approaches could provide a cheaper alternative to intensive direct measurement. For instance, using a simulation model developed for ecosystem processes and data from 47 agricultural experiments Ogle *et al.* (2007) test the relationship between modelled and measured carbon stock values under different production systems. They found a significant relationship between modelled and measured results (and develop a statistical model to adjust for biases and quantify the precision of the results).

Such an approach requires the establishment of a database with empirical data on carbon content in the soil from a range of pilots across agro-ecological zones, with information on soil, climate, land use and management. The FAO (2009c) suggest a coordinated effort to conduct and 'pool' direct measurements obtained following a rigorous protocol so that in the future practice-based performance standards can be used instead of the more expensive direct measurements.

While we are not aware of any impact evaluations that assess the impact of agricultural mitigation strategies on wellbeing and environmental outcomes, there are a number of evaluations of interventions in agriculture which illustrate the possibilities for IE in this sector (for example Feder *et al.*, 2003).²⁶ For instance, a recent study evaluates the impact of the adoption of sustainable agricultural practices, with special focus on reduced tillage (Kassie *et al.*, 2009). The study also compares the productivity gains from reduced tillage to those resulting from chemical fertiliser use. Kassie *et al.* (2009) use propensity score matching and a switching regression framework to analyse plot level survey data from two different agro-ecological zones in Ethiopia, a low rainfall area of the Tigray region and high rainfall area of the Amhara region. They estimate the impact of fertiliser under different tillage regimes and the impact of tillage practices under different fertiliser regimes. The results from this analysis suggest reduced tillage had a significant positive impact on crop productivity in areas with lower rainfall, while chemical fertiliser had a greater significant positive impact in high rainfall areas. Thus, Kassie *et al.* (2009) conclude that in a dry land environment sustainable agricultural practices like reduced tillage can have multiple benefits for resource poor farmers by increasing yields, reducing production costs and promoting environmental benefits.

Biofuel production

Global demand for liquid biofuels more than tripled between 2000 and 2007 (Sims, *et al.*, 2008). Whilst biofuels are often couched in terms of reduced greenhouse gas emissions, production is also based on a desire for energy self sufficiency in the face of recent spikes in oil prices (for example, the US and EU set targets for biofuels within their transport energy mix).²⁷ The need for mitigation and energy self sufficiency suggest that demand for biofuels will continue to increase.

While 90 per cent of current global biofuel production is based in the US, Brazil and the EU (mainly from cereals, maize, rape seed and sugarcane), biofuel production is also taking place in many developing countries (including second generation biofuels

²⁶ Impact evaluation of related interventions, such as protected areas and payment for environmental services also provide useful examples that evaluations of mitigation interventions in agriculture can draw on.

²⁷ The EU is aiming for 10 per cent of transport fuels to come from biofuels by 2020, a substantial increase from the 3 per cent currently met through domestic production.

produced from non-food materials such as wood, energy grass and other cellulosic biomass).

The switch towards second-generation biofuels is important because continued first-generation biofuel production is likely to impact negatively on global food availability and affordability. Both the reduced supply of staple food crops for consumption, and the increased competition for factors of production, may well contribute to higher global staple food prices with the poor worst affected (see Wiggins and Levy, 2008). For example, Mitchell (2008) estimates the most important factor behind the increase in global food prices between 2002 and 2008 was expanded biofuel production in the US and EU. Such pressure on global prices looks set to stay despite farmers' supply response as it is profitable to use maize for ethanol production when oil prices are above \$55 per barrel (Piesse and Thirtle, 2009). Despite current global economic difficulties, such a scenario appears likely in coming years if one considers the increased dominance of OPEC in the oil market, political instability in key exporting nations such as Iraq, Iran, Venezuela and Nigeria, and increased demand from China and other emerging economies (see Smith, 2009).

There will also be winners and losers from biofuel cultivation in developing countries. Benefits are likely to accrue to developing country biofuel crop producers, including smallholder farmers by generating employment and increasing rural incomes (Peskett et al. 2007). However, major concerns are being raised about potential negative economic and environmental impacts from biofuel production (World Bank 2008a). Firstly, some biofuels are not economically viable at current oil prices in the absence of subsidies, which means costs to tax-payers. Second, the production of biofuels in developing countries could reduce food availability and affordability in local markets. Third, biofuel production may not provide savings in greenhouse gas reduction; for example, in Indonesia the clearance of peat swamp forests for oil palm production is estimated to have been a major contributor to making Indonesia the third largest emitter of GHGs in 2006 (PEACE, 2007).²⁸ And fourth, biofuel crop cultivation may have serious costs in terms of loss of natural habitats; for example, many species being promoted for biofuel production, including *Jatropha curcas*, have become invasive in countries where they have been introduced (World Bank, 2008, p. 44). But to what extent has Impact Evaluation assessed the environmental and poverty effects of biofuel production?

Rajagopal and Zilberman (2007) review a number of studies examining the environmental implications of biofuels. They suggest that the impacts of biofuel production need to be evaluated on a case-by-case basis. For example, the net impact on GHGs associated with biofuel production depends on a number of context-specific factors, including: emissions associated with feed-stock cultivation; the biofuel production process; transport of biofuels to markets; and, importantly, changes in land use.

Rajagopal and Zilberman (2007) also note that little is known about the poverty impacts of biofuel production in developing countries. Again, a wide number of factors effect need to be considered here, including whether the poor are producing or working on the crop, the feedstock and production system, transport and institutional structures, existing crop production and processing regimes, labour requirements, security of land tenure, and the stability of prices (see Peskett et al, 2007, for a summary). Naturally, the net effect on poverty will vary across crops and

²⁸ Moreover, Searchinger et al (2009) argue that biofuel production from maize in the United States in recent years has not reduced greenhouse gas emissions as land use change was not incorporated in the emissions calculations.

countries, and as such biofuel production offers is in need of rigorous Impact Evaluations.

One example of how could be used IE to assess biofuel production comes from Malawi (NASFAM, personal communication). NASFAM, the largest producer organisation in Malawi, is in the pilot phase of a project to promote smallholder *jatropha curcas* production amongst its smallholder farming clubs. *Jatropha curcas* thrives on poor and eroded soils and is now being increasingly used in reforestation programs in tropical countries. It also has good potential as a second generation biofuel. NASFAM is a farmer-directed business system based on the individual participation of close to 100,000 Malawian smallholders, most of them farming less than a hectare of land. Through its network of smallholder-owned business organisations, it develops the commercial capacity of its members and delivers programmes that enhance their productivity. NASFAM is considering using IE to compare 400 'grower' households in around 20 farming clubs, against a further 400 'non grower' households, acting as the control group. The primary purpose of the evaluation is to assess the extent to which *jatropha* production will increase and stabilise the incomes of smallholder farmers in Malawi. Of particular concern in this evaluation will be the food security impacts of *jatropha* adoption, and the relationship between *jatropha* production and hybrid maize production. The evaluation could help to determine the extent to which NASFAM supports *jatropha* production amongst its members.

Forest carbon

Climate change is leading to initiatives to preserve carbon held in tropical forests. High on the agenda and a key theme in current climate change negotiations is the proposal to integrate REDD+ into a global climate regime (for example, see Ebeling and Yasue, 2008; Karsenty, 2008; and Neeff and Ascui, 2009). It has been estimated that REDD initiatives could generate annual revenue flows of between US\$ 2.2 to 13.5 billion (Ebeling and Yasue, 2008). REDD promoters also suggest that it could offer 'co-benefits' for the poor.

While the details of designing forest carbon schemes that provide co-benefits for the poor are complex, three issues stand out (Luttrell *et al.*, 2007; Peskett *et al.*, 2007; Peskett and Harkin, 2007). First, the complexity of engaging in carbon markets means poor communities will often need to work through intermediaries, or brokers, such as NGOs, co-operatives and social movements. Second, the land, and therefore carbon rights of the poor need to be assured if they are not going to be dispossessed. And third, carbon market contracts need to be designed in a clear, transparent and equitable fashion. Experiences of contract farming – where a firm lends inputs such as credit, fertiliser, seed and extension to a farmer, in exchange for exclusive purchase rights over the contracted crop – are instructive. Here, it is essential that state or non-state actors offer accessible, transparent and legally-binding mechanisms for dispute resolution between firms and farmers, if such contracts are going to work for both parties (Prowse, 2007a).

In addition to the evaluations of PES interventions cited above, there are a number of planned and ongoing evaluations which provide examples of how rigorous evaluation designs can be applied to projects relevant to REDD+. For instance, Alix-Garcia *et al.* (2008) are studying the behavioural response of households and communities to the Payments for Hydrological Services program in Mexico. They assess environmental effectiveness by comparing the deforestation rates of the

properties enrolled in the program in 2004 with those rejected for administrative reasons and those that applied in the following years, using data from newly interpreted high-resolution satellite images. Additionally, the study also measures deforestation spillovers to nearby areas to determine if reduced deforestation on properties participating in the program have displaced the surrounding areas. While this ongoing study is currently focusing on properties that entered the scheme in 2004, the team is hoping to extend the analysis to include multiple years. This proposed project in Mexico offers an illustration of the potential to use an experimental IE design to evaluate REDD+ interventions.

While still in the project preparation phase, a further example comes from Uganda (GEF, 2008). While not strictly speaking a climate change intervention, the project – Developing an Experimental Methodology for testing the Effectiveness of Payments for Ecosystem Services to Enhance Conservation in Productive Landscapes in Uganda – aims to “test the effectiveness of PES as a viable means for financing and procuring biodiversity conservation outside protected areas using an experimental methodology” (p. 4). The project attempts to determine the effectiveness of different payment arrangements for ecosystem services. It will offer payments to individual landowners in one treatment group and payment at the community level or to local institutions in another. In doing so the project seeks to provide both social and environmental benefits. The project will include 12 randomly selected communities from a homogeneous region in Uganda identified as at risk of deforestation. The decision to use experimental design is motivated by the need for rigorous evidence of environmental interventions and the project document states that “a major aim of the project will be to successfully demonstrate this methodology to catalyze wider replication in the GEF portfolio” (p. 5).

Environmental labelling

Responses to climate change have implications for two fast-growing exports – non-traditional agricultural products and tourism. Concerns about ‘food miles’ are leading to carbon-related labelling schemes (see Macgregor and Vorley, 2006; Ellis and Warner, 2007). For example, in early 2007 leading UK supermarkets introduced labelling schemes which could discourage the purchase of fruit and vegetables from countries such as Kenya and Ethiopia. One scheme, from Marks and Spencer, aimed to reduce the amount of air-freighted produce, and to label such items in stores. Another, by Tesco, aimed at reducing the company’s carbon footprint by reducing air-freighted products by over sixty per cent, and labelling the remaining air-freighted goods (Garside *et al.*, 2007).

Here we can clearly see the potential development versus environment trade-off in some climate change interventions. Over one million people in rural Africa rely, directly and indirectly, on fresh fruit and vegetables exports to the UK, and it is estimated that not buying fresh produce air-freighted from Africa would reduce UK emissions by less than 0.1% (Ellis and Warner, 2007). Since late 2007 both supermarkets have become more cautious in their approach to reducing air-freighted goods and to implementing such labelling schemes. Interestingly, both have indicated that such labels have had no discernable impact on sales (Garside *et al.*, 2007). Similar concerns about developed country ‘carbon footprint’ could discourage holidaymakers from visiting countries such as South Africa, Namibia and The Gambia, from which the poor can accrue up to 15-35 per cent of total expenditure (see Mitchell *et al.*, 2007).

As labelling schemes may be creating non-tariff barriers for exports from developing countries and could reduce market demand, it is clear that a more sophisticated labelling scheme, that takes into account the overall environmental impact, not just the air transport component, and that also factors in the development impacts of consumption decisions, would be preferable (Ellis and Warner, 2007). But how could this be realised? And what metrics should be used?

Garside *et al.* (2007) and Chi *et al.* (2009) highlight that if environmental harm is to be compared against poverty reduction or broader development goals, then schemes need to consider developing countries' 'ecological space' for carbon emissions, quantify both the degree of harm from air-freighted produce or tourist flights, and the poverty impact on individuals and households. The extent to which rigorous IE methods could contribute is discussed in Box 3.

Box 3 - Impact evaluation and a 'Good for Development' label

It can be argued that IE techniques can assess both the demand for such labelling schemes, and the impact they have on well-being in developing countries, as well as carbon emissions.

First, by randomising which products within a range of goods in supermarket outlets carry the 'air-freighted' label, it would be very simple to assess the extent to which consumers react to such labels, and whether there is substantial demand for them. As noted above, initial indications suggest that they have little impact on sales.

Second, IE could be used to assess possible impact on producers. Air-freighted goods are often produced on estates or by outgrowers (as they offer increased reliability of supply quantity and quality compared to spot markets or smallholder producers). Depending on the number of estates engaged, or the number of outgrower farmers, it may be possible to randomise the units where air-freighted goods are being labelled.

If it is possible to randomize in this manner, then a 'before and after' double difference IE could be conducted to assess one or more of the following research questions: (i) the possible impact on the profitability of the estate/farm; (ii) possible impact on the well-being of workers or smallholders; (iii) and estimates of the reduction in carbon emission caused by the 'air-freighted' label.

If it is the case that such labels reduce the profitability of firms and the well-being of poor workers, having quantitative data would strengthen the case for some compensatory mechanism (possibly financed by a price premium paid by consumers).

5. Adaptation interventions

Adaptation interventions are undertaken at different scales, across sectors and through different strategies.²⁹ As with all fields, the type of intervention will have implications for how IEs are designed. This section provides a brief discussion of IE of adaptation interventions in agriculture and water sectors, and when adaptation involves some form of social protection. The final section discusses a populist approach to tackling the effects of climate change: community-based adaptation.

Agriculture

Current and predicted climate change means that adaptation in the agricultural sector is urgent (World Bank, 2007). Farmers are already altering their practices in response to changes in the climate (Deressa *et al.*, 2009), and poor people and countries will need outside assistance for adaptation (World Bank, 2007). Poor farmers' ability to cope with stresses induced by climate change will depend, *inter alia*, on access to knowledge, training, credit and technologies (Kranjac - Berisavljevic *et al.*, 2009). For example, the World Bank (2009d) outlines three strategic objectives for adaptation efforts in agriculture: monitor climate change impacts on crops, forests, livestock and fisheries; support farmers and lenders in managing the risks of climate change impacts; and improve management techniques and crop varieties/livestock breeds to prevent crop and livestock losses due to climate change and increased pest pressures (World Bank, 2009d). Poor farmers' ability to adapt will also depend on their health and food security status, their ability to access labour markets, and opportunities to derive a greater proportion of income from non-climate-affected farm and non-farm sources (for example, see Sabates-Wheeler *et al.*, 2008). Whether based on the application of improved technology, husbandry and capital markets, or interventions to support human capital and diversified livelihood portfolios, adaptation interventions in agriculture are likely to include elements that are similar to existing agricultural interventions. For example, many projects outlined in National Adaptation Plans (NAPAs) are reminiscent of conventional rural development projects.

The AADAPT initiative by the World Bank shows how rigorous impact evaluations of agricultural development and adaptation interventions can be structured (World Bank, 2009f). At a recent meeting in Addis Ababa a number of proposed evaluations were presented. Examples include an evaluation of the Rural Capacity Building Project (RCBP) in Ethiopia (Hiluf *et al.*, 2009), Ethiopia Nile Irrigation and Drainage Project (Tessema *et al.*, 2009), the Agricultural Development Program Support Project in Malawi (Musopole *et al.*, 2009), Market-led Smallholder Development in the Zambezi Valley in Mozambique (Banze *et al.*, 2009) and Impact of the Productive Safety Nets Project on Agricultural Productivity in Ghana (Dannson *et al.*, 2009). All of these research projects propose to use experimental or quasi-experimental methods to evaluate agricultural interventions of relevance to climate change adaptation. For instance Dannson *et al.* (2009) plan to randomly select districts for

²⁹ Hedger *et al.* (2008) and McGray *et al.* (2007) distinguish between three types of adaptation interventions: (1) Serendipitous adaptation - development activities that contribute to adaptation without being designed to do so; (2) Mainstreaming or climate proofing of development efforts - this includes changing the design of ongoing development activities or designing development interventions so that they are also successful in a changing climate (McGray *et al.*, 2007); (3) Discrete adaptation - activities specifically designed to address climate change and where adaptation is the primary objective, although common development strategies might still be applied.

participation in the Productive Safety Nets Project on Agricultural Productivity in Ghana, and then randomly select four proposals from each district for funding in the first year. They will then compare agricultural productivity and household consumption among beneficiary and pipeline communities in order to evaluate impact. Similarly, Musopole et al. (2009) will use an experimental design to evaluate three different methods of disseminating two different agricultural technologies of relevance to adaptation, namely conservation agriculture and fertiliser management. The evaluation of the RCBP in Ethiopia faces a common problem for evaluators in that the treatment has already been assigned to the intervention units (Hiluf *et al.*, 2009). However, the study utilises quasi-experimental methods to deal with this, using propensity score matching to construct the control group and difference-in-difference to estimate impact. As these evaluations are still in the early stages, there are not yet any results to report on. Nevertheless, they illustrate the feasibility of using IE methods to assess the impact of adaptation intervention in agriculture.

Water resource management

There is a wide spectrum of adaptation interventions to improve water management. These include increasing storage capacity by building reservoirs and dams, improving water supply, desalination and extraction of sea water, water recycling to improve water use efficiency, changes in agricultural practices to reduce the demand for irrigation, improving water conservation and watershed management, and protecting natural resources such as forests (Kundzewicz *et al.*, 2007; World Bank, 2009d).

As with all interventions, the choice of impact evaluation design depends on the intervention, but it is likely that both experimental and quasi-experimental approaches could be applicable to a range of adaptation interventions in this sector. Here we offer two examples: one regarding production (irrigation) and one on consumption (rural water supply). First, a recent study of two irrigation projects in Andhra Pradesh, India provides a useful example of an IE using quasi-experimental design to evaluate the impact of a large scale infrastructure program in the water sector (IEG, 2008b). While there was no baseline data and the project was closed when the evaluation was undertaken, as a number of farmers were yet to be connected to the system and were due to receive irrigated water in the 2005 and 2006 seasons the study team adopted the 'pipeline approach' and the final group to be treated was selected as the control group. Impact was estimated by applying difference-in-difference methodology to data from two survey rounds. While some of the predicted benefits failed to materialise and the projects suffered from delays and higher costs than was budgeted, the IE suggests access to irrigation leads to an increase in both yields and farm income. The study also assessed the effectiveness of participatory irrigation management, suggesting that while water user associations can contribute to water management, there is still need for government support, for instance to ensure equitable distribution and resolve disputes.

Turning to the supply of potable water, White (2006) briefly discusses the use of IE by the World Bank to assess three rural water supply projects in Paraguay through the 1980s and 1990s. Over US \$80 million was spent through the National Environmental Sanitation Service, which created over four hundred community-level institutions – termed *juntas de saneamiento* – to operate and maintain the water distribution and delivery systems. An Impact Evaluation compared the well-being outcomes of five villages which had received clean and safe water from the project, and five villages which had not. Single difference results (in other words, a static 'with vs. without' comparison) highlight that villages with water had seven times

fewer hospital visits than those without, and that morbidity, in particular diarrhoea and vomiting, was 3-4 times less frequent in villages with this improved water supply.

Importantly, the evaluation provided some figures on efficiency and equity. For example, the supply of clean water was often based on tariffs set below cost-recovery levels. Despite this subsidy, 10-15 percent of the rural villagers had still not been able to connect to the water system. While reducing the subsidy would have reduced poor households ability to access clean water, there was an important need for *juntas* to levy tariffs which enabled them to replace materials and infrastructure. Generating such figures are important if the costs and benefits of similar adaptation schemes are to be measured and incorporated into budgets and expenditure plans.

Social protection

Social protection is a broad concept which refers to public, private, formal and informal efforts to support communities, households and individuals in their efforts to prevent, manage and overcome vulnerability (CPRC, 2008). Within the formal, public domain, it encompasses a range of interventions, including grants and insurance schemes, which support individuals from falling beneath a socially acceptable minimum standard of living. Examples include food aid, public works programmes, conditional and unconditional cash transfers as well as social insurance schemes for unemployment, old age and illness. Social protection is increasingly seen by development agencies and some developing country governments as an effective way to increase access to basic services and improve the wellbeing of poor households. The spread of conditional cash transfer programs is testament to this.

One clear argument in favour of formal, public social protection is as follows. High levels of insecurity, whether based on environmental, market, socio-political or health risks, can have both immediate and longer term repercussions for people's income and wellbeing (see CPRC, 2008; de Javry *et al.*, 2006; Vakis, 2006). People respond to such shocks, or the expectation of such shocks, in a variety of ways, including through selling off productive assets, taking loans, reducing consumption and withdrawing children from school (Andersson *et al.*, 2009; de Javry *et al.*, 2006; UNDP, 2007; Vakis, 2006). Such short-term responses can lead to long-term detrimental impacts on poverty and human development. One of the central objectives of social protection programmes is to prevent such behaviour (UNDP, 2007). Impact evaluations have played an important role in demonstrating that such programmes help promote long-term human development objectives (for example Attanasio *et al.*, 2005; Gertler, 2000; Schultz, 2004).

Social protection and social assistance/transfers are also now being seen as an effective adaptation strategy (Anderson *et al.*, 2009; Commission on Climate Change and Development, 2009; Oswald, 2009; UNDP 2007). A range of different social protection instruments can promote adaptation and increase people's capacity to manage risk and cope with shocks. Examples include contributory insurance schemes designed to pool risks, cash transfers targeting vulnerable groups, social funds, service fee waivers, public works programmes and cash transfers for agricultural productive inputs in the aftermath of a shock (see UNDP, 2007; Vakis, 2006). While more evidence is needed on the impact of social protection interventions on adaptation, impact evaluations of existing schemes demonstrate both the potential effectiveness of such interventions and the possibilities of using experimental or quasi-experimental approaches to evaluate their impact (see Attanasio *et al.*, 2005;

Gertler, 2000; Schultz, 2004). Indeed, de Janvry *et al.* (2006) and Andersson *et al.* (2009) evaluate two different social protection programs and assess whether they protect the beneficiaries from shocks.³⁰ De Janvry *et al.* (2006) utilise experimental panel data from the evaluation of the *Progresa* conditional cash transfer program in Mexico to assess whether the program protected children from the impacts of shocks. The results indicate that the *Progresa* transfers largely or completely protected children from the effect of these shocks on school enrolment” (de Janvry *et al.*, 2006, p. 372). While the program was not sufficient to avoid an increase in child employment in response to shocks, the analysis suggests the conditional cash transfer prevented this employment from crowding out schooling. Andersson *et al.* (2009) use a quasi-experimental design to evaluate the impact of the Productive Safety Net Program (PSNP) in Ethiopia, a public works program targeting the food insecure. Employing household survey panel data analysis using matching techniques, they assess whether the program protects households’ livestock and tree holdings during a period of insecurity and uncertainty. While they found the program appeared to contribute to an increase in tree holdings, there was no evidence that it protected household’s livestock holdings. These and many other evaluations show how IE techniques are able to assess the efficacy of social protection interventions in shielding individuals and households from insecurity and risk – a vital part of adaptation to climate change.

Community-based adaptation

Community-level adaptation (CBA) is an autonomous, bottom-up approach to adaptation, based on the premise that, through participatory learning and action, communities are best able to identify, prioritise and implement climate change adaptation (see Ayers and Forsyth, 2009). CBA builds on the technical knowledge and coping strategies of individuals and communities (for example, see Bharara and Seeland, 1994; Chatterjee *et al.*, 2005; Mendelsohn and Dinar, 1999; Mortimore and Adams, 2001). CBA is often facilitated by a well-known local organisation, and can be implemented like a small-scale development project. A number of key principles have guided early CBA practice (Huq and Reid, 2007). First, that outside agencies must gain the trust of communities through immersed in the field and through using brokers and intermediaries (such as local NGOs or community groups). Second, that possible future adaptation initiatives must be embedded in communities’ existing knowledge of climate variability, and must be based on community members’ participation. Third, that community-based adaptation is a form of action research, and can only be learnt through practice. Fourth, that experiences from pilot activities should be shared and collated. Fifth, that the involvement of women is paramount. And sixth, that communicating the concept of climate change should be in the vernacular and use a wide range of communication channels including art, theatre of video. However, whilst popular amongst non-governmental organisation, CBA has been subject to growing critique. For example, Sabates-Wheeler *et al.* (2008) suggest that CBA needs to engage much more seriously with the literature on livelihood and income diversification.³¹

³⁰ An ongoing study by Marta Vicarelli is also using data from PROGRESA in Mexico, and combines this with data on local climatic conditions to assess the impact of local climatic variabilities on household consumption and the extent to which PROGRESA reduces vulnerability in the case of climatic shocks (see <http://www.hks.harvard.edu/centers/cid/programs/sustsci/people/research-fellows/current-fellows/marta-vicarelli>).

³¹ Sabates-Wheeler *et al.* (2008) outline three main ways in which the livelihoods literature could improve CBA practice. First, it appears that CBA commonly assumes that localised livelihood diversification is a useful risk-spreading strategy, thus contributing to adaptive capacity. But local diversification within local farm-based or non-farm activities may *increase* risk. For example, climatic threats may be so severe that

Moreover, framing folk wisdom, technical knowledge and coping strategies as community-based adaptation is relatively new, and therefore little attention has been paid to how it could be evaluated. At first glance, the bottom-up participatory emphasis of CBA suggests that it might not be well suited to IE techniques. For example, there appears to be some incongruence between the participatory action research approach of CBA and the positivist methodology utilised by experimental evaluation approaches (for example, see Prowse, 2007a). Despite this tension, there may be some scope for IE approaches within CBA activities.

For example, if CBA activities are conducted through pre-existing self-help groups or farming clubs, which are supported by local institution such as an NGO or co-operative, then during a pilot phase when CBA is rolled out across a district or region, clubs (or even villages) could be randomised, allowing for a simple 'with or without' comparison of the intervention.

Unusually, because the actual practices stemming from CBA will be different across groups/clubs/villages (for example, improved tilling methods might be a focus in one group, whilst reforestation might be the priority in another) such a 'with or without' comparison couldn't evaluate particular activities. Instead, IE could evaluate the principle of CBA as a whole. Hypothetically, such an IE could shed light on *whether* CBA improves asset holdings and resilience to shocks. However, to elucidate *how* and *why* CBA led to improved resilience the IE would need to incorporate qualitative and participatory methods.

Whilst not strictly a CBA initiative, Box 4 illustrates how an IE could be applied to CBA through the example of the Watershed Organisation Trust in Maharashtra, India.

Box 4 - Watershed Organisation Trust in Maharashtra

In Maharashtra, on the western coast of India, agriculture is particularly prone to variable patterns of monsoon rainfall. With most of the rural population dependent on arid or semi-arid land, making the most of the available precipitation is vital to lives and livelihoods.

From the early 1990s, the Watershed Organisation Trust (WOTR) was established to provide support to self-help groups and local NGOs in water management techniques. The aim has been to focus on micro-catchments with the creation of village self-help groups. These groups guided and implemented improvements to local watersheds. Many of the measures in the scheme have been conducted in a bottom-up, participatory manner, with examples including:

- planting trees and grasses to improve waterways and to provide fodder and fuel ;
- reducing tree felling and grazing to regenerate the local ecology;

all households and local livelihood strategies are affected. In this respect, the approach could pay more attention to non-local strategies, such as migration.

Second, Sabates-Wheeler et al (2008) suggest that the approach has tended to homogenise the poor, not recognise different groups of poor people (for example, the chronically poor vs. the transient poor), and not tailor adaptation strategies appropriately. And third, that the approach does not recognise that the ability to diversify into profitable non-farm activities is not wealth neutral.

- small-scale water barriers to reduce surface run-off, encourage the replenishment of aquifers, and reduce erosion.

The scheme also encouraged the uptake of new agricultural practices, and support to non-farm livelihood activities. Due to the centrality of women to agriculture and environmental management in Maharashtra, the success of these measures has been determined to a large extent by women's commitment and engagement. Moreover, the community-driven participatory approach which fostered a strong sense of ownership and control through the creation of village-level institutions.

In the last fifteen years, WOTR has boosted agricultural production and increased resilience to drought in over 150 watersheds encompassing over 160,000 hectares. WOTR now contributes to state- and national-level dialogues in community-based watershed management.

6. Conclusion

This paper gives an overview of the extent to which IE could be utilised in assessing the impact of climate change interventions in developing countries. It has highlighted an apparent lack of rigorous IEs of behaviour change to support climate change interventions. Apart from a few quasi-experimental evaluations in the related field of conservation, the application of IE to climate change interventions has been limited. Moreover, only two of these studies include estimates of both environmental and welfare outcomes (Sims, 2008; Uchida *et al.*, 2007). While in many cases evaluating climate change interventions are challenging, this is not a valid argument for not doing so. If calls for increasing financing of climate change mitigation and adaptation by hundreds of billions a year are to remain credible and gain support, evidence of the effectiveness of current spending is essential. Moreover, donors are likely to remain hesitant in providing additional funding unless it is clear that interventions are reaching their environmental and developmental objectives. As current funding falls far short of recent estimates of what will be required, evidence from IEs is essential to determine which adaptation and mitigation interventions are the most cost-effective.

As many climate interventions are at an early stage of implementation, this is an opportune time for planners and evaluators to integrate IE designs from the start (when appropriate and affordable). Importantly, new studies should evaluate the positive and negative impacts of climate change interventions on both environmental and welfare outcomes. While appropriate outcome indicators will differ between interventions, future evidence syntheses will be improved by work to develop a consensus on a set of common or comparable outcome indicators at an early stage.
