

Figure 26.7: Zenith-angle dependence of multi-GeV neutrino interactions from SuperKamiokande [68]. The shaded boxes show the expectation in the absence of any oscillations.

Muons that enter the detector from outside after production in charged-current interactions of neutrinos naturally reflect a higher energy portion of the neutrino spectrum than contained events because

Table 26.3: Measured fluxes ($10^{-9} \text{ m}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$) of neutrino-induced muons as a function of the effective minimum muon energy E_μ .

$E_\mu >$	1 GeV	1 GeV	1 GeV	2 GeV	3 GeV	3 GeV
Ref.	CWI [71]	Baksan [72]	MACRO [73]	IMB [74]	Kam [75]	SuperK [76]
F_μ	2.17 ± 0.21	2.77 ± 0.17	2.29 ± 0.15	2.26 ± 0.11	1.94 ± 0.12	1.74 ± 0.07

the muon range increases with energy as well as the cross section. The relevant energy range is $\sim 10 < E_\nu < 1000$ GeV, depending somewhat on angle. Neutrinos in this energy range show a $\sec\theta$ effect similar to muons (see Eq. (26.4)). This causes the flux of horizontal neutrino-induced muons to be approximately a factor two higher than the vertically upward flux. The upper and lower edges of the horizontal shaded region in Fig. 26.6 correspond to horizontal and vertical intensities of neutrino-induced muons. Table 26.3 gives the measured fluxes of upward-moving neutrino-induced muons averaged over the lower hemisphere. Generally the definition of minimum muon energy depends on where it passes through the detector. The tabulated effective minimum energy estimates the average over various accepted trajectories.

26.5. Air showers

So far we have discussed inclusive or uncorrelated fluxes of various components of the cosmic radiation. An air shower is caused by a single cosmic ray with energy high enough for its cascade to be detectable at the ground. The shower has a hadronic core, which acts as a collimated source of electromagnetic subshowers, generated mostly from $\pi^0 \rightarrow \gamma\gamma$ decays. The resulting electrons and positrons are the most numerous charged particles in the shower. The number of muons, produced by decays of charged mesons, is an order of magnitude lower. Air showers spread over a large area on the ground, and arrays of detectors operated for long times are useful for studying cosmic rays with primary energy $E_0 > 100$ TeV, where the low flux makes measurements with small detectors in balloons and satellites difficult.

Greisen [77] gives the following approximate expressions for the numbers and lateral distributions of particles in showers at ground level. The total number of muons N_μ with energies above 1 GeV is

$$N_\mu(> 1 \text{ GeV}) \approx 0.95 \times 10^5 \left(N_e / 10^6 \right)^{3/4}, \quad (26.8)$$

where N_e is the total number of charged particles in the shower (not just e^\pm). The number of muons per square meter, ρ_μ , as a function of the lateral distance r (in meters) from the center of the shower is

$$\rho_\mu = \frac{1.25 N_\mu}{2\pi \Gamma(1.25)} \left(\frac{1}{320} \right)^{1.25} r^{-0.75} \left(1 + \frac{r}{320} \right)^{-2.5}, \quad (26.9)$$

where Γ is the gamma function. The number density of charged particles is

$$\rho_e = C_1(s, d, C_2) x^{(s-2)} (1+x)^{(s-4.5)} (1+C_2 x^d). \quad (26.10)$$

Here s , d , and C_2 are parameters in terms of which the overall normalization constant $C_1(s, d, C_2)$ is given by

$$C_1(s, d, C_2) = \frac{N_e}{2\pi r_1^2} [B(s, 4.5 - 2s) + C_2 B(s + d, 4.5 - d - 2s)]^{-1}, \quad (26.11)$$

where $B(m, n)$ is the beta function. The values of the parameters depend on shower size (N_e), depth in the atmosphere, identity of the primary nucleus, etc. For showers with $N_e \approx 10^6$ at sea level, Greisen uses $s = 1.25$, $d = 1$, and $C_2 = 0.088$. Finally, x is r/r_1 , where r_1 is the Molière radius, which depends on the density of the atmosphere and hence on the altitude at which showers are detected. At sea level $r_1 \approx 78$ m. It increases with altitude as the air density decreases. (See

the section on electromagnetic cascades in the article on the passage of particles through matter in this *Review*).

The lateral spread of a shower is determined largely by Coulomb scattering of the many low-energy electrons and is characterized by the Molière radius. The lateral spread of the muons (ρ_μ) is larger and depends on the transverse momenta of the muons at production as well as multiple scattering.

There are large fluctuations in development from shower to shower, even for showers of the same energy and primary mass—especially for small showers, which are usually well past maximum development when observed at the ground. Thus the shower size N_e and primary energy E_0 are only related in an average sense, and even this relation depends on depth in the atmosphere. One estimate of the relation is [84]

$$E_0 \sim 3.9 \times 10^6 \text{ GeV} (N_e / 10^6)^{0.9} \quad (26.12)$$

for vertical showers with $10^{14} < E < 10^{17}$ eV at 920 g cm^{-2} (965 m above sea level). As E_0 increases the shower maximum (on average) moves down into the atmosphere and the relation between N_e and E_0 changes. Moreover, because of fluctuations, N_e as a function of E_0 is not correctly obtained by inverting Eq. (26.12). At the maximum of shower development, there are approximately 2/3 particles per GeV of primary energy.

There are three common types of air shower detectors: shower arrays that study the shower size N_e and the lateral distribution on the ground, Cherenkov detectors that detect the Cherenkov radiation emitted by the charged particles of the shower, and fluorescence detectors that study the nitrogen fluorescence excited by the charged particles in the shower. The fluorescence light is emitted isotropically so the showers can be observed from the side. Detailed simulations and cross-calibrations between different types of detectors are necessary to establish the primary energy spectrum from air-shower experiments.

Figure 26.8 shows the “all-particle” spectrum. The differential energy spectrum has been multiplied by $E^{2.6}$ in order to display the features of the steep spectrum that are otherwise difficult to discern. The steepening that occurs between 10^{15} and 10^{16} eV is known as the *knee* of the spectrum. The feature around $10^{18.5}$ eV is called the *ankle* of the spectrum.

Figure 26.8: The all-particle spectrum as a function of E (energy-per-nucleus) from air shower measurements [79–90,100–104].

Measurements of flux with small air shower experiments in the knee region differ by as much as a factor of two, indicative of systematic uncertainties in interpretation of the data. (For a review see Ref. 78.) In establishing the spectrum shown in Fig. 26.8, efforts have been made to minimize the dependence of the analysis on the primary composition. Ref. 87 uses an unfolding procedure to obtain the spectra of the individual components, giving a result for the all-particle spectrum between 10^{15} and 10^{17} eV that lies toward the upper range of the data shown in Fig. 26.8. In the energy range above 10^{17} eV, the fluorescence technique [89] is particularly useful because it can establish the primary energy in a model-independent way by observing most of the longitudinal development of each shower, from which E_0 is obtained by integrating the energy deposition in the atmosphere. The result, however, depends strongly on the light absorption in the atmosphere and the calculation of the detector's aperture.

Assuming the cosmic ray spectrum below 10^{18} eV is of galactic origin, the *knee* could reflect the fact that most cosmic accelerators in the galaxy have reached their maximum energy. Some types of expanding supernova remnants, for example, are estimated not to be able to accelerate protons above energies in the range of 10^{15} eV. Effects of propagation and confinement in the galaxy [91] also need to be considered. The KASCADE-Grande experiment [90] has reported observation of a second steepening of the spectrum near 8×10^{16} eV, with evidence that this structure is accompanied a transition to heavy primaries.

Concerning the ankle, one possibility is that it is the result of a higher energy population of particles overtaking a lower energy population, for example an extragalactic flux beginning to dominate over the galactic flux (e.g. Ref. 89). Another possibility is that the dip structure in the region of the ankle is due to $\gamma p \rightarrow e^+ + e^-$ energy losses of extragalactic protons on the 2.7 K cosmic microwave radiation (CMB) [93]. This dip structure has been cited as a robust signature of both the protonic and extragalactic nature of the highest energy cosmic rays [92]. If this interpretation is correct, then the galactic cosmic rays do not contribute significantly to the flux above 10^{18} eV, consistent with the maximum expected range of acceleration by supernova remnants.

Figure 26.9: Expanded view of the highest energy portion of the cosmic-ray spectrum from data of HiRes 1&2 [101], the Telescope Array [103], and the Auger Observatory [104]. The HiRes stereo spectrum [112] is consistent with the HiRes 1&2 monocular results. The differential cosmic ray flux is multiplied by $E^{2.6}$. The red arrow indicates the change in the plotted data for a systematic shift in the energy scale of 20%.

The energy-dependence of the composition from the knee through the ankle is useful in discriminating between these two viewpoints, since a heavy composition above 10^{18} eV is inconsistent with the formation of the ankle by pair production losses on the CMB.

Figure 26.10: Differential limits on the flux of cosmogenic neutrinos set by four neutrino experiments. The curves show the Waxman-Bahcall benchmark flux (WB, [111]) and a representative midrange model for the expected flux of cosmogenic neutrinos (ESS, [110]). The expected flux is uncertain by over an order of magnitude in either direction.

The HiRes and Auger experiments, however, present very different interpretations of data on the depth of shower maximum X_{max} , a quantity that correlates strongly with the interaction cross section of the primary particle. If these results are interpreted using standard extrapolations of measured proton and nuclear cross sections, then the HiRes data [94] is consistent with the ultrahigh-energy cosmic ray (UHECR) composition getting lighter and containing only protons and helium above 10^{19} eV, while Auger [95,96] sees a composition getting lighter up to 2×10^{18} eV and becoming heavier after that, intermediate between protons and iron at 3×10^{19} eV. This may mean that the extragalactic cosmic rays have a mixed composition at acceleration similar to the GeV galactic cosmic rays. It is important to note that the measurements of X_{max} may be interpreted with equal validity in terms of a changing proton-air cross-section and no change in composition.

If the cosmic ray flux at the highest energies is cosmological in origin, there should be a rapid steepening of the spectrum (called the GZK feature) around 5×10^{19} eV, resulting from the onset of inelastic interactions of UHE cosmic rays with the cosmic microwave background [97,98]. Photo-dissociation of heavy nuclei in the mixed composition model [99] would have a similar effect. UHECR experiments have detected events of energy above 10^{20} eV [89,100–102]. The AGASA experiment [100] did not observe the expected GZK feature. The HiRes fluorescence experiment [101,112] has detected evidence of the GZK suppression, and the Auger observatory [102–104] has presented spectra showing this suppression based on surface detector measurements calibrated against its fluorescence detector using events detected in hybrid mode, i.e. with both the surface and the fluorescence detectors. Recent observations by the Telescope Array [103] also exhibit this suppression.

Figure 26.9 gives an expanded view of the high energy end of the spectrum, showing only the more recent data. This figure shows the differential flux multiplied by $E^{2.6}$. The experiments are consistent in normalization if one takes quoted systematic errors in the energy scales into account. The continued power law type of flux beyond the GZK cutoff previously claimed by the AGASA experiment [100] is not supported by the HiRes, Telescope Array, and Auger data.

One half of the energy that UHECR protons lose in photoproduction interactions that cause the GZK effects ends up in neutrinos [105].

Measuring this *cosmogenic* neutrino flux above 10^{18} eV would help resolve the UHECR uncertainties mentioned above. The magnitude of this flux depends strongly on the cosmic ray spectrum at acceleration, the cosmic ray composition, and the cosmological evolution of the cosmic ray sources. In the case that UHECR have mixed composition only the proton fraction would produce cosmogenic neutrinos. Heavy nuclei propagation produces mostly $\bar{\nu}_e$ at lower energy from neutron decay.

The expected rate of cosmogenic neutrinos is lower than current limits obtained by IceCube [106], the Auger observatory [108], RICE [107], and ANITA-2 [109], which are shown in Figure 26.10 together with a model for cosmogenic neutrino production [110] and the Waxman-Bahcall benchmark flux of neutrinos produced in cosmic ray sources [111]. At production, the dominant component of neutrinos comes from π^\pm decays and has flavor content $\nu_e : \nu_\mu : \nu_\tau = 1 : 2 : 0$. After oscillations, the arriving cosmogenic neutrinos are expected to be an equal mixture of all three flavors. The sensitivity of each experiment depends on neutrino flavor. IceCube, RICE, and ANITA are sensitive to all three flavors, and the sensitivity to different flavors is energy dependent. The limit of Auger is only for ν_τ and $\bar{\nu}_\tau$ which should be about 1/3 of the total neutrino flux after oscillations, so this limit is plotted multiplied by a factor of three for comparison with the other limits and with the theoretical estimates.

27. ACCELERATOR PHYSICS OF COLLIDERS

Revised July 2011 by D.A. Edwards (DESY) and M.J. Syphers (MSU).

27.1. Luminosity

This article provides background for the High-Energy Collider Parameter Tables that follow. The number of events, N_{exp} , is the product of the cross section of interest, σ_{exp} , and the time integral over the instantaneous *luminosity*, \mathcal{L} :

$$N_{exp} = \sigma_{exp} \times \int \mathcal{L}(t) dt. \quad (27.1)$$

Today's colliders all employ bunched beams. If two bunches containing n_1 and n_2 particles collide head-on with frequency f , a basic expression for the luminosity is

$$\mathcal{L} = f \frac{n_1 n_2}{4\pi\sigma_x\sigma_y} \quad (27.2)$$

where σ_x and σ_y characterize the rms transverse beam sizes in the horizontal (bend) and vertical directions. In this form it is assumed that the bunches are identical in transverse profile, that the profiles are Gaussian and independent of position along the bunch, and the particle distributions are not altered during bunch crossing.

Whatever the distribution at the source, by the time the beam reaches high energy, the normal form is a useful approximation as suggested by the σ -notation. In the case of an electron storage ring, synchrotron radiation leads to a Gaussian distribution in equilibrium, but even in the absence of radiation the central limit theorem of probability and the diminished importance of space charge effects produces a similar result.

The luminosity may be obtained directly by measurement of the beam properties in Eq. (27.2), but the beam measurements are apt to interfere with data acquisition, so this method though valuable to establish collider performance is not suitable for continuous use. A similar expression to Eq. (27.1) with N_{ref} from a known reference cross section, σ_{ref} , may be used to determine σ_{exp} according to $\sigma_{exp} = (N_{exp}/N_{ref})\sigma_{ref}$.

In the Tables, luminosity is stated in units of $\text{cm}^{-2}\text{s}^{-1}$. Integrated luminosity, on the other hand is usually quoted as the inverse of the standard measures of cross section such as femtobarns and, recently, attobarns.

Subsequent sections in this report enlarge briefly on the dynamics behind collider design, comment on the realization of collider performance in a selection of today's facilities, and end with some remarks on future possibilities.

27.2. Beam Dynamics

The first concern of beam dynamics is stability. While a reference particle proceeds along the design, or reference, trajectory other particles in the bunch are to remain close by. Assume that the reference particle carries a right-handed Cartesian coordinate system, with the z -coordinate pointed in the direction of motion along the reference trajectory. The independent variable is the distance s of the reference particle along this trajectory rather than time, and for simplicity this path is taken to be planar. The transverse coordinates are x and y , where $\{x, z\}$ defines the plane of the reference trajectory.

Several time scales are involved, and the approximations used in writing the equations of motion reflect that circumstance. All of today's high energy colliders are alternating gradient synchrotrons [1,2], and the shortest time scale is that associated with transverse stability, the betatron oscillations, so called because of their analysis for the betatron accelerator species years ago. The linearized equations of motion of a particle displaced from the reference particle are

$$\begin{aligned} x'' + K_x x &= 0, & K_x &\equiv \frac{e}{p} \frac{\partial B}{\partial x} + \frac{1}{\rho^2} \\ y'' + K_y y &= 0, & K_y &\equiv -\frac{e}{p} \frac{\partial B}{\partial x} \\ z' &= -x/\rho \end{aligned} \quad (27.3)$$

where the magnetic field $B(s)$ is only in the y direction, contains only dipole and quadrupole terms, and is treated as static here. The radius of curvature due to the field on the reference orbit is ρ ; p and e are the particle's momentum and charge respectively. The prime denotes d/ds .

The equations for x and y are those of harmonic oscillators but with restoring force periodic in s , that is, they are instances of Hill's equation. The solution may be written in the form

$$\begin{aligned} x(s) &= A_x \sqrt{\beta_x} \cos \psi_x \\ x'(s) &= -\frac{A_x}{\sqrt{\beta_x}} [\alpha \cos \psi_x + \sin \psi_x] \end{aligned} \quad (27.4)$$

where A_x is a constant of integration, $\alpha \equiv -(1/2)d\beta_x(s)/ds$, and the envelope of the motion is modulated by the *amplitude function*, β_x . A solution of the same form describes the motion in y . The subscripts will be suppressed in the following discussion.

The amplitude function satisfies

$$2\beta\beta'' - \beta'^2 + 4\beta^2 K = 4, \quad (27.5)$$

and in a region free of magnetic field it should be noted that the solution of Eq. (27.5) is a parabola. Expressing A in terms of x , x' yields

$$\begin{aligned} A^2 &= \gamma x^2 + 2\alpha x x' + \beta x'^2 \\ &= \frac{1}{\beta} [x^2 + (\alpha x + \beta x')^2] \end{aligned} \quad (27.6)$$

with $\gamma \equiv (1 + \alpha^2)/\beta$. In a single pass system such as a linac, the *Courant-Snyder parameters* α , β , γ may be selected to match the $x x'$ distribution of the input beam; in a recursive system, the parameters are usually defined by the structure rather than by the beam.

The relationships between the parameters and the structure may be seen by treatment of a simple *lattice* consisting of equally spaced thin lens quadrupoles equal in magnetic field gradient magnitude but alternating in sign. For this discussion, the weak focusing effects of the bending magnets may be neglected. The propagation of $X \equiv \{x, x'\}$ through a repetition period may be written $X_2 = M X_1$, with the matrix $M = FODO$ composed of the matrices

$$F = \begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix}, \quad D = \begin{pmatrix} 1 & 0 \\ 1/f & 1 \end{pmatrix}, \quad O = \begin{pmatrix} 1 & L \\ 0 & 1 \end{pmatrix},$$

where f is the magnitude of the focal length and L the lens spacing. Then

$$M = \begin{pmatrix} 1 + \frac{L}{f} & 2L + \frac{L^2}{f} \\ -\frac{L}{f^2} & 1 - \frac{L}{f} - \frac{L^2}{f^2} \end{pmatrix}. \quad (27.7)$$

The matrix for y is identical in form differing only by a change in sign of terms linear in f . An eigenvector-eigenvalue analysis of the matrix M shows that the motion is stable provided $f > L/2$. While that criterion is easily met, in practice instability may be caused by many other factors, including the beam-beam interaction itself.

Standard focus-drift-defocus-drift, or *FODO*, cells such as characterized in simple form by Eq. (27.7) occupy most of the layout of a large collider ring and may be used to set the scale of the amplitude function and related phase advance. Conversion of Eq. (27.4) to a matrix form equivalent to Eq. (27.7) gives

$$M = \begin{pmatrix} c + \alpha s & \beta s \\ -\gamma s & c - \alpha s \end{pmatrix} \quad (27.8)$$

where $c \equiv \cos \Delta\psi$, $s \equiv \sin \Delta\psi$, and the relation between structure and amplitude function is specified by setting the values of the latter to be the same at both ends of the cell. By comparison of Eq. (27.7) and Eq. (27.8) one finds $c = 1 - L^2/(2f^2)$, so the choice $f = L/\sqrt{2}$ would give a phase advance $\Delta\psi$ of 90 degrees for the standard cell. The amplitude function – a maximum at the focusing quadrupole – would then be $2.7L$, illustrating the relationship of alternating gradient focusing amplitudes to relatively local aspects of the design. Other functions such as injection, extraction, and HEP experiments

are included by lattice sections matched to the β , α standard cell parameters at the insertion points.

The phase advances according to $d\psi/ds = 1/\beta$; that is, β also plays the role of a local $\lambda/2\pi$, and the *tune*, ν , is the number of such oscillations per turn about the closed path. In the neighborhood of an interaction point (IP), the beam optics of the ring is configured so as to produce a near focus; the value of the amplitude function at this point is designated β^* .

The motion as it develops with s describes an ellipse in $\{x, x' \equiv dx/ds\}$ phase space the area of which is πA^2 , where A is the constant in Eq. (27.4). If the interior of that ellipse is populated by an ensemble of non-interacting particles, that area, given the name *emittance* and denoted by ε , would change only with energy. For a beam with a Gaussian distribution in x, x' , the area containing one standard deviation σ_x is the definition of emittance in the Tables:

$$\varepsilon_x \equiv \pi \frac{\sigma_x^2}{\beta_x}, \quad (27.9)$$

with a corresponding expression in the other transverse direction, y . This definition includes 39% of the beam. For most of the entries in the Tables the standard deviation is used as the beam radius.

To complete the coordinates used to describe the motion, we take as the variable conjugate to z the fractional momentum deviation $\delta p/p$ from that of the reference particle. Radiofrequency electric fields in the s direction provide a means for longitudinal oscillations, and the frequency determines the bunch length. The frequency of this system appears in the Tables as does the rms value of $\delta p/p$ characterized as “energy spread” of the beam.

For HEP bunch length is a significant quantity for a variety of reasons, but in the present context if the bunch length becomes larger than β^* the luminosity is adversely affected. This is because β grows parabolically as one proceeds away from the interaction point and so the beam size increases thus lowering the contribution to the luminosity from such locations. This is often called the “hourglass” effect.

The other major external electromagnetic field interaction in the single particle context is the production of synchrotron radiation due to centripetal acceleration, given by the Larmor formula multiplied by a relativistic magnification factor of γ^4 [3]. In the case of electron rings this process determines the equilibrium emittance through a balance between radiation damping and excitation of oscillations, and further serves as the barrier to future higher energy versions in this variety of collider.

27.3. Impediments to High Luminosity

Eq. (27.2) can be recast in terms of emittances and amplitude functions as

$$\mathcal{L} = f \frac{n_1 n_2}{4\sqrt{\varepsilon_x \beta_x^* \varepsilon_y \beta_y^*}}. \quad (27.10)$$

So to achieve high luminosity, all one has to do is make high population bunches of low emittance collide at high frequency at locations where the beam optics provides as low values of the amplitude functions as possible.

Such expressions as Eq. (27.10) of the luminosity are special cases of the more general forms available elsewhere [4]. But while there are no fundamental limits to the process, there are certainly challenges. Here we have space to mention only a few of these. The beam-beam tune shift appears in the Tables. A bunch in beam 1 presents a (nonlinear) lens to a particle in beam 2 resulting in changes to the particle’s transverse tune with a range characterized by the parameter [4]

$$\xi_{y,2} = \frac{r_e n_1 \beta_{y,2}^*}{2\pi \gamma_2 \sigma_{y,1} (\beta_{x,1} + \sigma_{y,1})} \quad (27.11)$$

where $r_e = e^2/(4\pi\epsilon_0 mc^2)$ is the classical radius of the electron. The transverse oscillations are susceptible to resonant perturbations from a variety of sources such as imperfections in the magnetic guide field, so certain values of the tune must be avoided. Accordingly, the tune spread arising from ξ is limited, but limited to a value difficult to

predict. But a glance at the Tables shows that electrons are more forgiving than protons thanks to the damping effects of synchrotron radiation; the ξ -values for the former are about an order of magnitude larger than those for protons.

A subject of present intense interest is the *electron-cloud effect* [5,6]; actually a variety of related processes come under this heading. They typically involve a buildup of electron density in the vacuum chamber due to emission from the chamber walls stimulated by electrons or photons originating from the beam itself. For instance, there is a process closely resembling the multipacting effects familiar from radiofrequency system commissioning. Low energy electrons are ejected from the walls by photons from positron or proton beam-produced synchrotron radiation. These electrons are accelerated toward a beam bunch, but by the time they reach the center of the vacuum chamber the bunch has gone and so the now-energetic electrons strike the opposite wall to produce more secondaries. These secondaries are now accelerated by a subsequent bunch, and so on. Among the disturbances that this electron accumulation can produce is enhancement of the tune spread within the bunch; the near-cancellation of bunch-induced electric and magnetic fields is no longer in effect.

The benefits of low emittance are clear in Eq. (27.10). For electron synchrotrons, radiation damping provides an automatic route. For hadrons, particularly antiprotons, two inventions have played a prominent role. Stochastic cooling [7] was employed first in the *SppS* and subsequently in the Tevatron. Electron cooling [8] was also used in the Tevatron complex to great advantage. Further innovations are underway due to the needs of potential future projects; these are noted in the final section.

27.4. Comments on Present Facilities

Collider accelerator physics of course goes far beyond the elements of the preceding sections. In this section elaboration is made on various issues associated with some of the recently operating colliders, particularly factors which impact integrated luminosity. The various colliders utilizing hadrons have important unique differences and hence are broken out separately. As space is limited, general references are provided where much further information can be obtained.

27.4.1. LHC: [9] The superconducting Large Hadron Collider is the world’s highest energy collider. Operation for HEP is currently conducted with 3.5 TeV protons in each beam. Progress is rapid and current status is best checked at the Web site referenced in the heading of this subsection. To meet its luminosity goals the LHC will have to contend with a high beam current of 0.5 A, leading to stored energies of several hundred MJ per beam. Component protection, beam collimation, and controlled energy deposition will be given very high priorities. Additionally, at energies of 5-7 TeV per particle, synchrotron radiation will move from being a curiosity to a challenge in a hadron accelerator for the first time. At design beam current the system must remove roughly 7 kW at 1.8 K due to synchrotron radiation. As the photons are emitted their interactions with the vacuum chamber wall can generate free electrons, with consequent “electron cloud” development. Much care was taken to design a special liner for the chamber to mitigate this issue.

The two proton beams are contained in separate pipes throughout most of the circumference, but naturally must be brought together into a single pipe at the interaction points. The large number of bunches, and subsequent short bunch spacing, would lead to approximately 30 head-on collisions through 120 m of common beam pipe at each IP. Thus, a small crossing angle is employed, which reduces the luminosity by about 15%. Still, the bunches moving in one direction will have long-range encounters with the counter-rotating bunches and the resulting perturbations of the particle motion constitute a continued course of study. Initial luminosity measurements were made by the “van der Meer scan” as was done long ago on the ISR [10]. The detectors will have measurements based on a reference cross section; for an example see the discussion in the ATLAS design report [11]. The Tables also show the performance anticipated for Pb-Pb collisions. The ALICE [12] experiment is designed to concentrate on these high energy-density phenomena.

In the coming years, an ambitious upgrade program, Super LHC [13], has as its target an order-of-magnitude increase in luminosity.

27.4.2. Tevatron : [14] The first superconducting synchrotron in history, the Tevatron was the highest energy collider for 25 years. Operation was terminated in September 2011. The route to high integrated luminosity in the Tevatron was governed by the antiproton production rate, the turn-around time to produce another store, and the resulting optimization of store time. The overall reliability of the accelerator complex plays a crucial role, as it can take many hours to produce an adequate number of antiprotons for collisions.

Unlike the LHC, the beams in the Tevatron circulated in a single vacuum pipe and thus were placed on separated orbits which wrap around each other in a helical pattern outside of the interaction regions. Hence, long-range encounters played an important role here as well, though the effects could be different from the LHC where the encounters are more or less “in phase” with each other through a single interaction region. In the Tevatron, the 70 long-range encounters were distributed about the synchrotron and their mitigation was limited by the available aperture.

In recent years the antiproton bunch intensities approached those of the proton bunches, and their emittances were greatly reduced using improved beam cooling, so much so that detrimental effects on the proton beam became apparent. The antiproton beam emittance was adjusted prior to collision conditions to optimize the proton bunch lifetime during the store [15]. The Tevatron ultimately achieved luminosities a factor of 400 over the original design specification.

27.4.3. e^+e^- Rings : As should be expected, synchrotron radiation plays a major role in the design and optimization of e^+e^- colliders. While vacuum stability and electron clouds can be of concern in the positron rings, synchrotron radiation along with the restoration of longitudinal momentum by the RF system have the positive effect of generating very small transverse beam sizes and small momentum spread. Further reduction of beam size at the interaction points using standard beam optics techniques and successfully contending with high beam currents has led to record luminosities in these rings, far exceeding those of hadron colliders. To maximize integrated luminosity the beam can be “topped off” by injecting new particles without removing existing ones – a feature difficult to imitate in hadron colliders.

Asymmetric energies of the two beams have allowed for the enhancement of B -physics research and for interesting interaction region designs. As the bunch spacing can be quite short, the lepton beams sometimes pass through each other at an angle and hence have reduced luminosity. Recently, however, the invention of high frequency “crab crossing” schemes have produced full restoration of the luminous region. KEK-B has attained over 1 fb^{-1} of integrated luminosity in a single day, and its upgrade plans are aiming for initial luminosities of $8 \times 10^{35} \text{ cm}^{-2}\text{s}^{-1}$ [16].

27.4.4. HERA : [17] Now decommissioned, HERA was the first facility to employ both applications of superconductivity: magnets and accelerating structures. Its next-generation cold-iron superconducting magnets for the proton beam were the culmination of lessons learned from the Tevatron experience and extensive development of the technology since then. The HERA team felt comfortable with a larger dynamic range of the magnet system, enabling the use of the existing DESY complex for injection. Though the HERA magnets could reach fields consistent with energies above 1 TeV, other accelerator systems precluded operation above 920 GeV.

The lepton beams (positrons or electrons) were provided by the existing complex, and were accelerated to 27.5 GeV using conventional magnets. The interaction region where the beams had common vacuum chambers had the interesting feature that the lepton beam could be manipulated without detrimental effects on the proton beam due to the large difference in magnetic rigidity. A 4-times higher frequency RF system was used at collision to generate shorter bunches, thus helping alleviate the hour glass effect at the collision points. As in any high energy lepton storage ring, the lepton beam naturally would become transversely polarized (within about 40 minutes, for

HERA). “Spin rotators” were implemented on either side of an IP to produce longitudinal polarization at the experiment.

27.4.5. RHIC : [18] The Relativistic Heavy Ion Collider employs superconducting magnets, and collides combinations of fully-stripped ions such as H-H (p-p), Au-Au, Cu-Cu, and d-Au.

The high charge per particle (+79 for gold, for instance) makes intra-beam scattering of particles within the bunch of special concern, even for seemingly modest bunch intensities. Another special feature of accelerating heavy ions in RHIC is that the beams experience a “transition energy” during acceleration – a point where the derivative with respect to momentum of the revolution period is zero. This is more typical of low-energy accelerators, where the necessary phase jump required of the RF system is implemented rapidly and little time is spent near this condition. In the case of RHIC with heavy ions, the superconducting magnets do not ramp very quickly and the period of time spent crossing transition is long and must be dealt with carefully. For p-p operation the beams are always above their transition energy and so this condition is completely avoided.

RHIC is also distinctive in its ability to accelerate and collide polarized proton beams. As proton beam polarization must be maintained from its low-energy source, successful acceleration through the myriad of depolarizing resonance conditions in high energy circular accelerators has taken years to accomplish. An energy of 250 GeV per proton with $\sim 48\%$ final polarization per beam has been realized.

27.5. Future Prospects

Present design activity emphasizes a lepton collider as the next major HEP project contingent upon the initial results from the LHC. Synchrotron radiation precludes a higher energy successor to LEP. Four alternatives are noted in this section: two approaches to an electron-positron linear collider, a muon ring collider, and potential use of plasma acceleration.

27.5.1. Electron-Positron Linear Colliders : A major problem confronting a high energy, high luminosity single pass collider design is the power requirement, so measures must be taken to keep the demand within bounds as illustrated in a transformed Eq. (27.2) as developed in the *TESLA Design Report* [19]:

$$\mathcal{L} = \frac{1}{4\pi r_e^{3/2}} \frac{P_b}{E_{cm}} \left(\frac{\pi \delta_E}{\gamma \varepsilon_y} \right)^{1/2} H_D. \quad (27.12)$$

Here, P_b is the total power of both beams and E_{cm} their cms energy. Management of P_b leads to an upward push on the product of collision frequency and bunch population with an attendant rise in the energy radiated due to the electromagnetic field of one bunch acting on the particles of the other. The fractional spread in the collision energy that results from this radiation is represented by δ_E and keeping a significant fraction of the luminosity within a percent or so of the nominal energy represents a design goal. A consequence is the use of flat beams, where δ_E is managed by the beam width, and luminosity adjusted by the beam height, thus the explicit appearance of the vertical emittance ε_y . The final factor in Eq. (27.12), H_D , represents the enhancement of luminosity due to the pinch effect during bunch crossing.

The approach designated by the International Linear Collider (ILC) is presented in the Tables, and the contrast with the collision-point parameters of the circular colliders is striking, though reminiscent in direction of those of the SLAC Linear Collider that are no longer shown. The ILC *Reference Design Report* [20] has a baseline cms energy of 500 GeV with upgrade provision for 1 TeV, and luminosity comparable to the LHC. The ILC is based on superconducting accelerating structures of the 1.3 GHz TESLA variety.

At CERN, a design effort is underway on the Compact Linear Collider (CLIC), each linac of which is itself a two-beam accelerator, in that a high energy, low current beam is fed by a low energy, high current driver [21]. The CLIC design employs normal conducting 12 GHz accelerating structures at a gradient of 100 MeV/m, some three times the current capability of the superconducting ILC cavities. The design cms energy is 3 TeV.

27.5.2. Muon Collider: The muon to electron mass ratio of 210 implies less concern about synchrotron radiation by a factor of about 2×10^9 and its $1.6 \mu\text{s}$ lifetime means that it will last for some $150B$ turns in a ring about half of which is occupied by bend magnets with average field B (tesla). Design effort became serious in the mid 1990s and a collider outline emerged quickly [22].

Removal of the synchrotron radiation barrier reduces collider facility scale to a level compatible with on-site placement at some locations. If a Higgs particle is detected the $(m_\mu/m_e)^2$ cross section advantage in s-channel production would be valuable. And a neutrino factory could potentially be realized in the course of construction [23].

The challenges to luminosity achievement were clear and very attractive for R&D: targetting, collection, and emittance reduction are three that come immediately to mind. The proton source needs to deliver a beam power of several MW, collection would be aided by magnetic fields common on neutron stars (though scaled back for application on earth), and the emittance requirements have inspired fascinating investigations into phase space manipulation that are finding application in other facilities. A summary of the status may be found in a presentation to the HEPAP P5 Panel [24].

27.5.3. Plasma Acceleration: At the 1956 CERN Symposium, a paper by Veksler in which he suggested acceleration of protons to the TeV scale using a bunch of electrons anticipated current interest in plasma acceleration [25]. A half-century later this is more than a suggestion, with the demonstration, as a striking example, of energy enhancement of 28.5 GeV at SLAC [26].

How plasma acceleration will find application in an HEP facility is not yet clear, given the necessity of coordinating multiple plasma chambers. Active R&D is underway; for recent discussion of parameters for a laser-plasma based electron positron collider, see, for example, relevant papers in an Advanced Accelerator Concepts Workshop [27].

HIGH-ENERGY COLLIDER PARAMETERS: e^+e^- Colliders (I)

Updated in early 2012 with numbers received from representatives of the colliders (contact J. Beringer, LBNL). The table shows parameter values as achieved by January 1, 2012. Quantities are, where appropriate, r.m.s.; unless noted otherwise, energies refer to beam energy; H and V indicate horizontal and vertical directions; s.c. stands for superconducting. Parameters for the defunct SPEAR, DORIS, PETRA, PEP, SLC, TRISTAN, and VEPP-2M colliders may be found in our 1996 edition (Phys. Rev. D54, 1 July 1996, Part I).

	VEPP-2000 (Novosibirsk)	VEPP-4M (Novosibirsk)	BEPC (China)	BEPC-II (China)	DAΦNE (Frascati)

HIGH-ENERGY COLLIDER PARAMETERS: e^+e^- Colliders (II)

Updated in early 2012 with numbers received from representatives of the colliders (contact J. Beringer, LBNL). For existing colliders, the table shows parameter values as achieved by January 1, 2012. For future colliders, design values are quoted. Quantities are, where appropriate, r.m.s.; unless noted otherwise, energies refer to beam energy; H and V indicate horizontal and vertical directions; s.c. stands for superconducting.

29. NEUTRINO BEAM LINES AT HIGH-ENERGY PROTON SYNCHROTRONS

Created in May 2012 with numbers verified by representatives of the synchrotrons (contact C.-J. Lin, LBNL). For existing (future) neutrino beam lines the latest achieved (design) values are given.

The main source of neutrinos at proton synchrotrons is from the decay of pions and kaons produced by protons striking a nuclear target. There are different schemes to focus the secondary particles to enhance neutrino flux and/or tune the neutrino energy profile. In wide-band beams (WBB), the neutrino parent mesons are focused over a wide momentum range to obtain maximum neutrino intensity. In narrow-band beams (NBB), the secondary particles are first momentum-selected to produce a monochromatic parent beam. Another approach to generate a narrow-band neutrino spectrum is to select neutrinos that decay off-axis relative to the momentum of the parent mesons. For a comprehensive review of the topic, including other historical neutrino beam lines, see the article by S. E. Kopp, "Accelerator-based neutrino beams," Phys. Rept. **439**, 101 (2007).

30.1. Notation

Table 30.1: Summary of variables used in this section. The kinematic variables β and γ have their usual meanings.

Symbol	Definition	Units or Value
α	Fine structure constant ($e^2/4\pi\epsilon_0\hbar c$)	1/137.035 999 11(46)
M	Incident particle mass	MeV/ c^2
E	Incident part. energy γMc^2	MeV
T	Kinetic energy	MeV
$m_e c^2$	Electron mass $\times c^2$	0.510 998 918(44) MeV
r_e	Classical electron radius $e^2/4\pi\epsilon_0 m_e c^2$	2.817 940 325(28) fm
N_A	Avogadro's number	$6.022 1415(10) \times 10^{23}$ mol $^{-1}$
ze	Charge of incident particle	
Z	Atomic number of absorber	
A	Atomic mass of absorber	g mol $^{-1}$
K/A	$4\pi N_A r_e^2 m_e c^2 / A$	0.307 075 MeV g $^{-1}$ cm 2 for $A = 1$ g mol $^{-1}$
I	Mean excitation energy	eV (<i>Nota bene!</i>)
$\delta(\beta\gamma)$	Density effect correction to ionization energy loss	
$\hbar\omega_p$	Plasma energy ($\sqrt{4\pi N_e r_e^3} m_e c^2 / \alpha$)	$\sqrt{\rho(Z/A)} \times 28.816$ eV (ρ in g cm $^{-3}$)
N_e	Electron density	(units of r_e) $^{-3}$
w_j	Weight fraction of the j th element in a compound or mixture	
n_j	α number of j th kind of atoms in a compound or mixture	
—	$4\alpha r_e^2 N_A / A$	(716.408 g cm $^{-2}$) $^{-1}$ for $A = 1$ g mol $^{-1}$
X_0	Radiation length	g cm $^{-2}$
E_c	Critical energy for electrons	MeV
$E_{\mu c}$	Critical energy for muons	GeV
E_s	Scale energy $\sqrt{4\pi/\alpha} m_e c^2$	21.2052 MeV
R_M	Molière radius	g cm $^{-2}$

30.2. Electronic energy loss by heavy particles [1–34]

30.2.1. Moments and cross sections :

The electronic interactions of fast charged particles with speed $v = \beta c$ occur in *single collisions with energy losses* E [1], leading to ionization, atomic, or collective excitation. Most frequently the energy losses are small (for 90% of all collisions the energy losses are less than 100 eV). In thin absorbers few collisions will take place and the total energy loss will show a large variance [1]; also see Sec. 30.2.7 below. For particles with charge ze more massive than electrons (“heavy” particles), scattering from free electrons is adequately described by the Rutherford differential cross section [2], * †

$$\frac{d\sigma_R(E; \beta)}{dE} = \frac{2\pi r_e^2 m_e c^2 z^2 (1 - \beta^2 E/T_{\max})}{\beta^2 E^2}, \quad (30.1)$$

where T_{\max} is the maximum energy transfer possible in a single collision. But in matter electrons are not free. E must be finite and depends on atomic and bulk structure. For electrons bound

* For spin 0 particles. The β dependence in the parentheses is different for spin 1/2 and spin 1 particles, but it is not important except at energies far above atomic binding energies.

† In high-energy physics E normally means total energy, $T + mc^2$. In stopping power discussions, E means kinetic energy, and we follow that convention (with some inconsistency).

in atoms Bethe [3] used “Born Theorie” to obtain the differential cross section

$$\frac{d\sigma_B(E; \beta)}{dE} = \frac{d\sigma_R(E, \beta)}{dE} B(E). \quad (30.2)$$

Examples of $B(E)$ and $d\sigma_B/dE$ can be seen in Figs. 5 and 6 of Ref. 1.

of a few %. With the symbol definitions and values given in Table 30.1, the units are $\text{MeV g}^{-1}\text{cm}^2$. At the lower limit the projectile velocity becomes comparable to atomic electron “velocities” (Sec. 30.2.3), and at the upper limit radiative effects begin to be important (Sec. 30.6). Both limits are Z dependent.

Fig. 30.1: Stopping power ($= -dE/dx$) for positive muons in copper as a function of $\beta\gamma = p/Mc$ over nine orders of magnitude in momentum (12 orders of magnitude in kinetic energy). Solid curves indicate the total stopping power. Data below the break at $\beta\gamma \approx 0.1$ are taken from ICRU 49 [4], and data at higher energies are from Ref. 5. Vertical bands indicate boundaries between different approximations discussed in the text. The short dotted lines labeled “ μ^- ” illustrate the “Barkas effect,” the dependence of stopping power on projectile charge at very low energies [6].

Bethe’s theory extends only to some energy above which atomic effects were not important. The free-electron cross section (Eq. (30.1)) can be used to extend the cross section to T_{\max} . At high energies σ_B is further modified by polarization of the medium, and this “density effect,” discussed in Sec. 30.2.4, must also be included. Less important corrections are discussed below.

The mean number of collisions with energy loss between E and $E + dE$ occurring in a distance δx is $N_e \delta x (d\sigma/dE) dE$, where $d\sigma(E; \beta)/dE$ contains all contributions. It is convenient to define the moments

$$M_j(\beta) = N_e \delta x \int E^j \frac{d\sigma(E; \beta)}{dE} dE, \quad (30.3)$$

so that M_0 is the mean number of collisions in δx , M_1 is the mean energy loss in δx , $M_2 - M_1^2$ is the variance, *etc.* The number of collisions is Poisson-distributed with mean M_0 . N_e is either measured in electrons/g ($N_e = N_A Z/A$) or electrons/cm³ ($N_e = N_A \rho Z/A$). The former is used throughout this chapter, since quantities of interest (dE/dx , X_0 , *etc.*) vary smoothly with composition when there is no density dependence.

30.2.2. Stopping power at intermediate energies :

The mean rate of energy loss by moderately relativistic charged heavy particles, $M_1/\delta x$, is well-described by the “Bethe” equation,

$$-\left\langle \frac{dE}{dx} \right\rangle = K z^2 \frac{Z}{A} \frac{1}{\beta^2} \left[\frac{1}{2} \ln \frac{2m_e c^2 \beta^2 \gamma^2 T_{\max}}{I^2} - \beta^2 - \frac{\delta(\beta\gamma)}{2} \right]. \quad (30.4)$$

It describes the mean rate of energy loss in the region $0.1 \lesssim \beta\gamma \lesssim 1000$ for intermediate- Z materials with an accuracy

Here T_{\max} is the maximum kinetic energy which can be imparted to a free electron in a single collision, and the other variables are defined in Table 30.1. A minor dependence on M at the highest energies is introduced through T_{\max} , but for all practical purposes $\langle dE/dx \rangle$ in a given material is a function of β alone.

For heavy projectiles, like ions, additional terms are required to account for higher-order photon coupling to the target, and to account for the finite size of the target radius. These can change dE/dx by a factor of two or more for the heaviest nuclei in certain kinematic regimes [7].

Few concepts in high-energy physics are as misused as $\langle dE/dx \rangle$. The main problem is that the mean is weighted by very rare events with large single-collision energy deposits. Even with samples of hundreds of events a dependable value for the mean energy loss cannot be obtained. Far better and more easily measured is the most probable energy loss, discussed in Sec. 30.2.7. The most probable energy loss in a detector is considerably below the mean given by the Bethe equation.

In a TPC (Sec. 31.6.5), the mean of 50%–70% of the samples with the smallest signals is often used as an estimator.

Although it must be used with cautions and caveats, $\langle dE/dx \rangle$ as described in Eq. (30.4) still forms the basis of much of our understanding of energy loss by charged particles. Extensive tables are available [5,4, pdg.lbl.gov/AtomicNuclearProperties/].

The function as computed for muons on copper is shown as the “Bethe” region of Fig. 30.1. Mean energy loss behavior below this region is discussed in Sec. 30.2.3, and the radiative effects at high energy are discussed in Sec. 30.6. Only in the Bethe region is it a function of β alone; the mass dependence

Figure 30.2: Mean energy loss rate in liquid (bubble chamber) hydrogen, gaseous helium, carbon, aluminum, iron, tin, and lead. Radiative effects, relevant for muons and pions, are not included. These become significant for muons in iron for $\beta\gamma \gtrsim 1000$, and at lower momenta for muons in higher- Z absorbers. See Fig. 30.23.

Figure 30.3: Stopping power at minimum ionization for the chemical elements. The straight line is fitted for $Z > 6$. A simple functional dependence on Z is not to be expected, since $\langle -dE/dx \rangle$ also depends on other variables.

is more complicated elsewhere. The stopping power in several other materials is shown in Fig. 30.2. Except in hydrogen, particles with the same velocity have similar rates of energy loss in different materials, although there is a slow decrease in the rate of energy loss with increasing Z . The qualitative behavior difference at high energies between a gas (He in the figure) and the other materials shown in the figure is due to the density-effect correction, $\delta(\beta\gamma)$, discussed in Sec. 30.2.4. The stopping power functions are characterized by broad minima whose position drops from $\beta\gamma = 3.5$ to 3.0 as Z goes from 7 to 100 . The values of minimum ionization as a function of atomic number are shown in Fig. 30.3.

In practical cases, most relativistic particles (*e.g.*, cosmic-ray muons) have mean energy loss rates close to the minimum; they are “minimum-ionizing particles,” or mip’s.

Eq. (30.4) may be integrated to find the total (or partial) “continuous slowing-down approximation” (CSDA) range R for

Figure 30.4: Range of heavy charged particles in liquid (bubble chamber) hydrogen, helium gas, carbon, iron, and lead. For example: For a K^+ whose momentum is $700 \text{ MeV}/c$, $\beta\gamma = 1.42$. For lead we read $R/M \approx 396$, and so the range is 195 g cm^{-2} .

a particle which loses energy only through ionization and atomic excitation. Since dE/dx depends only on β , R/M is a function of E/M or pc/M . In practice, range is a useful concept only for low-energy hadrons ($R \lesssim \lambda_I$, where λ_I is the nuclear interaction length), and for muons below a few hundred GeV (above which radiative effects dominate). R/M as a function of $\beta\gamma = p/Mc$ is shown for a variety of materials in Fig. 30.4.

The mass scaling of dE/dx and range is valid for the electronic losses described by the Bethe equation, but not for radiative losses, relevant only for muons and pions.

For a particle with mass M and momentum $M\beta\gamma c$, T_{\max} is given by

$$T_{\max} = \frac{2m_e c^2 \beta^2 \gamma^2}{1 + 2\gamma m_e/M + (m_e/M)^2}. \quad (30.5)$$

In older references [2,8] the “low-energy” approximation $T_{\max} = 2m_e c^2 \beta^2 \gamma^2$, valid for $2\gamma m_e/M \ll 1$, is often implicit. For a pion in copper, the error thus introduced into dE/dx is greater than 6% at 100 GeV .

At energies of order 100 GeV , the maximum 4-momentum transfer to the electron can exceed $1 \text{ GeV}/c$, where hadronic structure effects significantly modify the cross sections. This problem has been investigated by J.D. Jackson [9], who concluded that for hadrons (but not for large nuclei) corrections to dE/dx are negligible below energies where radiative effects dominate. While the cross section for rare hard collisions is modified, the average stopping power, dominated by many softer collisions, is almost unchanged.

“The determination of the mean excitation energy is the principal non-trivial task in the evaluation of the Bethe stopping-power formula” [10]. Recommended values have varied substantially with time. Estimates based on experimental stopping-power measurements for protons, deuterons, and alpha particles and on oscillator-strength distributions and dielectric-response functions were given in ICRU 49 [4]. See also ICRU

Figure 30.5: Mean excitation energies (divided by Z) as adopted by the ICRU [11]. Those based on experimental measurements are shown by symbols with error flags; the interpolated values are simply joined. The grey point is for liquid H_2 ; the black point at 19.2 eV is for H_2 gas. The open circles show more recent determinations by Bichsel [13]. The dotted curve is from the approximate formula of Barkas [14] used in early editions of this *Review*.

37 [11]. These values, shown in Fig. 30.5, have since been widely used. Machine-readable versions can also be found [12]. These values are widely used.

30.2.3. Energy loss at low energies : Shell corrections C/Z must be included in the square brackets of Eq. (30.4) [4,11,13,14] to correct for atomic binding having been neglected in calculating some of the contributions to Eq. (30.4). The Barkas form [14] was used in generating Fig. 30.1. For copper it contributes about 1% at $\beta\gamma = 0.3$ (kinetic energy 6 MeV for a pion), and the correction decreases very rapidly with increasing energy.

Equation 30.2, and therefore Eq. (30.4), are based on a first-order Born approximation. Higher-order corrections, again important only at lower energies, are normally included by adding the “Bloch correction” $z^2 L_2(\beta)$ inside the square brackets (Eq.(2.5) in [4]).

An additional “Barkas correction” $zL_1(\beta)$ reduces the stopping power for a negative particle below that for a positive particle with the same mass and velocity. In a 1956 paper, Barkas *et al.* noted that negative pions had a longer range than positive pions [6]. The effect has been measured for a number of negative/positive particle pairs, including a detailed study with antiprotons [15].

A detailed discussion of low-energy corrections to the Bethe formula is given in ICRU Report 49 [4]. When the corrections are properly included, the Bethe treatment is accurate to about 1% down to $\beta \approx 0.05$, or about 1 MeV for protons.

For $0.01 < \beta < 0.05$, there is no satisfactory theory. For protons, one usually relies on the phenomenological fitting formulae developed by Andersen and Ziegler [4,16]. As shown in ICRU 49 [4] (using data taken from Ref. 16), the nuclear plus electronic proton stopping power in copper is $113 \text{ MeV cm}^2 \text{ g}^{-1}$ at $T = 10 \text{ keV}$, rises to a maximum of $210 \text{ MeV cm}^2 \text{ g}^{-1}$ at 100–150 keV, then falls to $120 \text{ MeV cm}^2 \text{ g}^{-1}$ at 1 MeV.

For particles moving more slowly than $\approx 0.01c$ (more or less the velocity of the outer atomic electrons), Lindhard has been quite successful in describing electronic stopping power, which is proportional to β [17]. Finally, we note that at even lower energies, *e.g.*, for protons of less than several hundred eV, non-ionizing nuclear recoil energy loss dominates the total energy loss [4,17,18].

30.2.4. Density effect : As the particle energy increases, its electric field flattens and extends, so that the distant-collision contribution to Eq. (30.4) increases as $\ln \beta\gamma$. However, real media become polarized, limiting the field extension and effectively truncating this part of the logarithmic rise [2–8,19–21]. At very high energies,

$$\delta/2 \rightarrow \ln(\hbar\omega_p/I) + \ln \beta\gamma - 1/2, \quad (30.6)$$

where $\delta(\beta\gamma)/2$ is the density effect correction introduced in Eq. (30.4) and $\hbar\omega_p$ is the plasma energy defined in Table 30.1. A comparison with Eq. (30.4) shows that $|dE/dx|$ then grows as $\ln \beta\gamma$ rather than $\ln \beta^2\gamma^2$, and that the mean excitation energy I is replaced by the plasma energy $\hbar\omega_p$. The ionization stopping power as calculated with and without the density effect correction is shown in Fig. 30.1. Since the plasma frequency scales as the square root of the electron density, the correction is much larger for a liquid or solid than for a gas, as is illustrated by the examples in Fig. 30.2.

The density effect correction is usually computed using Sternheimer’s parameterization [19]:

$$\delta(\beta\gamma) = \begin{cases} 2(\ln 10)x - \bar{C} & \text{if } x \geq x_1; \\ 2(\ln 10)x - \bar{C} + a(x_1 - x)^k & \text{if } x_0 \leq x < x_1; \\ 0 & \text{if } x < x_0 \text{ (nonconductors);} \\ \delta_0 10^{2(x-x_0)} & \text{if } x < x_0 \text{ (conductors)} \end{cases} \quad (30.7)$$

Here $x = \log_{10} \eta = \log_{10}(p/Mc)$. \bar{C} (the negative of the C used in Ref. 19) is obtained by equating the high-energy case of Eq. (30.7) with the limit given in Eq. (30.6). The other parameters are adjusted to give a best fit to the results of detailed calculations for momenta below $Mc \exp(x_1)$. Parameters for elements and nearly 200 compounds and mixtures of interest are published in a variety of places, notably in Ref. 21. A recipe for finding the coefficients for nontabulated materials is given by Sternheimer and Peierls [22], and is summarized in Ref. 5.

The remaining relativistic rise comes from the $\beta^2\gamma^2$ growth of T_{\max} , which in turn is due to (rare) large energy transfers to a few electrons. When these events are excluded, the energy deposit in an absorbing layer approaches a constant value, the Fermi plateau (see Sec. 30.2.6 below). At extreme energies (*e.g.*, $> 332 \text{ GeV}$ for muons in iron, and at a considerably higher energy for protons in iron), radiative effects are more important than ionization losses. These are especially relevant for high-energy muons, as discussed in Sec. 30.6.

30.2.5. Energetic knock-on electrons (δ rays) : The distribution of secondary electrons with kinetic energies $T \gg I$ is [2]

$$\frac{d^2 N}{dT dx} = \frac{1}{2} K z^2 \frac{Z}{A} \frac{1}{\beta^2} \frac{F(T)}{T^2} \quad (30.8)$$

for $I \ll T \leq T_{\max}$, where T_{\max} is given by Eq. (30.5). Here β is the velocity of the primary particle. The factor F is spin-dependent, but is about unity for $T \ll T_{\max}$. For spin-0 particles $F(T) = (1 - \beta^2 T/T_{\max})$; forms for spins 1/2 and 1 are also given by Rossi [2] (Sec. 2.3, Eqns. 7 and 8). For incident electrons, the indistinguishability of projectile and target means that the range of T extends only to half the kinetic energy of the incident particle. Additional formulae are given in Ref. 23. Equation (30.8) is inaccurate for T close to I [24].

δ rays of even modest energy are rare. For a $\beta \approx 1$ particle, for example, on average only one collision with $T_e > 10 \text{ keV}$ will occur along a path length of 90 cm of Ar gas [1].

A δ ray with kinetic energy T_e and corresponding momentum p_e is produced at an angle θ given by

$$\cos \theta = (T_e/p_e)(p_{\max}/T_{\max}), \quad (30.9)$$

where p_{\max} is the momentum of an electron with the maximum possible energy transfer T_{\max} .

Figure 30.6: Bethe dE/dx , two examples of restricted energy loss, and the Landau most probable energy per unit thickness in silicon. The change of Δ_p/x with thickness x illustrates its $a \ln x + b$ dependence. Minimum ionization ($dE/dx|_{\min}$) is $1.664 \text{ MeV g}^{-1} \text{ cm}^2$. Radiative losses are excluded. The incident particles are muons.

30.2.6. Restricted energy loss rates for relativistic ionizing particles: Further insight can be obtained by examining the mean energy deposit by an ionizing particle when energy transfers are restricted to $T \leq T_{\text{cut}} \leq T_{\text{max}}$. The restricted energy loss rate is

$$-\frac{dE}{dx} \Big|_{T < T_{\text{cut}}} = Kz^2 \frac{Z}{A} \frac{1}{\beta^2} \left[\frac{1}{2} \ln \frac{2m_e c^2 \beta^2 \gamma^2 T_{\text{cut}}}{I^2} - \frac{\beta^2}{2} \left(1 + \frac{T_{\text{cut}}}{T_{\text{max}}} \right) - \frac{\delta}{2} \right]. \quad (30.10)$$

This form approaches the normal Bethe function (Eq. (30.4)) as $T_{\text{cut}} \rightarrow T_{\text{max}}$. It can be verified that the difference between Eq. (30.4) and Eq. (30.10) is equal to $\int_{T_{\text{cut}}}^{T_{\text{max}}} T(d^2N/dTdx)dT$, where $d^2N/dTdx$ is given by Eq. (30.8).

Since T_{cut} replaces T_{max} in the argument of the logarithmic term of Eq. (30.4), the $\beta\gamma$ term producing the relativistic rise in the close-collision part of dE/dx is replaced by a constant, and $|dE/dx|_{T < T_{\text{cut}}}$ approaches the constant “Fermi plateau.” (The density effect correction δ eliminates the explicit $\beta\gamma$ dependence produced by the distant-collision contribution.) This behavior is illustrated in Fig. 30.6, where restricted loss rates for two examples of T_{cut} are shown in comparison with the full Bethe dE/dx and the Landau-Vavilov most probable energy loss (to be discussed in Sec. 30.2.7 below).

30.2.7. Fluctuations in energy loss: For detectors of moderate thickness x (e.g. scintillators or LAr cells),* the energy loss probability distribution $f(\Delta; \beta\gamma, x)$ is adequately described by the highly-skewed Landau (or Landau-Vavilov) distribution [25,26]. The most probable energy loss is [27]

$$\Delta_p = \xi \left[\ln \frac{2m_e c^2 \beta^2 \gamma^2}{I} + \ln \frac{\xi}{I} + j - \beta^2 - \delta(\beta\gamma) \right], \quad (30.11)$$

where $\xi = (K/2) \langle Z/A \rangle (x/\beta^2) \text{ MeV}$ for a detector with a thickness x in g cm^{-2} , and $j = 0.200$ [27]. † While dE/dx is independent of thickness, Δ_p/x scales as $a \ln x + b$. The density correction $\delta(\beta\gamma)$ was not included in Landau’s or Vavilov’s work, but it was later included by Bichsel [27]. The high-energy

behavior of $\delta(\beta\gamma)$ (Eq. (30.6)) is such that

$$\Delta_p \xrightarrow{\beta\gamma \gtrsim 100} \xi \left[\ln \frac{2m_e c^2 \xi}{(\hbar\omega_p)^2} + j \right]. \quad (30.12)$$

Thus the Landau-Vavilov most probable energy loss, like the restricted energy loss, reaches a Fermi plateau. The Bethe dE/dx and Landau-Vavilov-Bichsel Δ_p/x in silicon are shown as a function of muon energy in Fig. 30.6. The energy deposit in the $1600 \mu\text{m}$ case is roughly the same as in a 3 mm thick plastic scintillator.

Figure 30.7: Electronic energy deposit distribution for a 10 GeV muon traversing 1.7 mm of silicon, the stopping power equivalent of about 0.3 cm of PVC scintillator [1,13,29]. The Landau-Vavilov function (dot-dashed) uses a Rutherford cross section without atomic binding corrections but with a kinetic energy transfer limit of T_{max} . The solid curve was calculated using Bethe-Fano theory. $M_0(\Delta)$ and $M_1(\Delta)$ are the cumulative 0th moment (mean number of collisions) and 1st moment (mean energy loss) in crossing the silicon. (See Sec. 30.2.1. The fwhm of the Landau-Vavilov function is about 4ξ for detectors of moderate thickness. Δ_p is the most probable energy loss, and $\langle\Delta\rangle$ divided by the thickness is the Bethe $\langle dE/dx \rangle$.)

The distribution function for the energy deposit by a 10 GeV muon going through a detector of about this thickness is shown in Fig. 30.7. In this case the most probable energy loss is 62% of the mean ($M_1(\langle\Delta\rangle)/M_1(\infty)$). Folding in experimental resolution displaces the peak of the distribution, usually toward a higher value. 90% of the collisions ($M_1(\langle\Delta\rangle)/M_1(\infty)$) contribute to energy deposits below the mean. It is the very rare high-energy-transfer collisions, extending to T_{max} at several GeV, that drives the mean into the tail of the distribution. *The mean of the energy loss given by the Bethe equation, Eq. (30.4), is thus ill-defined experimentally and is not useful for describing energy loss by single particles.** It rises as $\ln \beta\gamma$ because T_{max} increases as $\beta^2 \gamma^2$. The large single-collision energy transfers that increasingly extend the long tail are rare, making the mean of an experimental distribution consisting of a few hundred events subject to large fluctuations and sensitive to cuts. *The most probable energy loss should be used.†*

The Landau distribution fails to describe energy loss in thin absorbers such as gas TPC cells [1] and Si detectors [27], as shown clearly in Fig. 1 of Ref. 1 for an argon-filled TPC cell. Also

* It does find application in dosimetry, where only bulk deposit is relevant.

† An alternative approach is taken in TPC analysis, where some fraction of the highest energy deposit signals along a track, e.g. 20%, are discarded before taking the average.

* $G \lesssim 0.05\text{--}0.1$, where G is given by Rossi [Ref. 2, Eq. 2.7.10]. It is Vavilov’s κ [26].

† Rossi [2], Talman [28], and others give somewhat different values for j . The most probable loss is not sensitive to its value.

Figure 30.8: Straggling functions in silicon for 500 MeV pions, normalized to unity at the most probable value δ_p/x . The width w is the full width at half maximum.

see Talman [28]. While Δ_p/x may be calculated adequately with Eq. (30.11), the distributions are significantly wider than the Landau width $w = 4\xi$ [Ref. 27, Fig. 15]. Examples for 500 MeV pions incident on thin silicon detectors are shown in Fig. 30.8. For very thick absorbers the distribution is less skewed but never approaches a Gaussian.

The most probable energy loss, scaled to the mean loss at minimum ionization, is shown in Fig. 30.9 for several silicon detector thicknesses.

Figure 30.9: Most probable energy loss in silicon, scaled to the mean loss of a minimum ionizing particle, $388 \text{ eV}/\mu\text{m}$ ($1.66 \text{ MeV g}^{-1} \text{ cm}^2$).

30.2.8. Energy loss in mixtures and compounds : A mixture or compound can be thought of as made up of thin layers of pure elements in the right proportion (Bragg additivity). In this case,

$$\frac{dE}{dx} = \sum w_j \left. \frac{dE}{dx} \right|_j, \quad (30.13)$$

where $dE/dx|_j$ is the mean rate of energy loss (in MeV g cm^{-2}) in the j th element. Eq. (30.4) can be inserted into Eq. (30.13) to find expressions for $\langle Z/A \rangle$, $\langle I \rangle$, and $\langle \delta \rangle$; for example, $\langle Z/A \rangle = \sum w_j Z_j/A_j = \sum n_j Z_j / \sum n_j A_j$. However, $\langle I \rangle$ as defined this way is an underestimate, because in a compound electrons are more tightly bound than in the free elements, and $\langle \delta \rangle$ as calculated this way has little relevance, because it is the electron density that matters. If possible, one uses the tables given in Refs. 21 and 30, which include effective excitation energies and interpolation coefficients for calculating the density effect correction for the chemical elements and nearly 200 mixtures and com-

pounds. If a compound or mixture is not found, then one uses the recipe for δ given in Ref. 22 (repeated in Ref. 5), and calculates $\langle I \rangle$ according to the discussion in Ref. 10. (Note the “13%” rule!)

30.2.9. Ionization yields : Physicists frequently relate total energy loss to the number of ion pairs produced near the particle’s track. This relation becomes complicated for relativistic particles due to the wandering of energetic knock-on electrons whose ranges exceed the dimensions of the fiducial volume. For a qualitative appraisal of the nonlocality of energy deposition in various media by such modestly energetic knock-on electrons, see Ref. 31. The mean local energy dissipation per local ion pair produced, W , while essentially constant for relativistic particles, increases at slow particle speeds [32]. For gases, W can be surprisingly sensitive to trace amounts of various contaminants [32]. Furthermore, ionization yields in practical cases may be greatly influenced by such factors as subsequent recombination [33].

30.3. Multiple scattering through small angles

A charged particle traversing a medium is deflected by many small-angle scatters. Most of this deflection is due to Coulomb scattering from nuclei, and hence the effect is called multiple Coulomb scattering. (However, for hadronic projectiles, the strong interactions also contribute to multiple scattering.) The Coulomb scattering distribution is well represented by the theory of Molière [35]. It is roughly Gaussian for small deflection angles, but at larger angles (greater than a few θ_0 , defined below) it behaves like Rutherford scattering, with larger tails than does a Gaussian distribution.

If we define

$$\theta_0 = \theta_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{2}} \theta_{\text{space}}^{\text{rms}}. \quad (30.14)$$

then it is sufficient for many applications to use a Gaussian approximation for the central 98% of the projected angular distribution, with a width given by [36,37]

$$\theta_0 = \frac{13.6 \text{ MeV}}{\beta c p} z \sqrt{x/X_0} \left[1 + 0.038 \ln(x/X_0) \right]. \quad (30.15)$$

Here p , βc , and z are the momentum, velocity, and charge number of the incident particle, and x/X_0 is the thickness of the scattering medium in radiation lengths (defined below). This value of θ_0 is from a fit to Molière distribution for singly charged particles with $\beta = 1$ for all Z , and is accurate to 11% or better for $10^{-3} < x/X_0 < 100$.

Eq. (30.15) describes scattering from a single material, while the usual problem involves the multiple scattering of a particle traversing many different layers and mixtures. Since it is from a fit to a Molière distribution, it is incorrect to add the individual θ_0 contributions in quadrature; the result is systematically too small. It is much more accurate to apply Eq. (30.15) once, after finding x and X_0 for the combined scatterer.

Figure 30.10: Quantities used to describe multiple Coulomb scattering. The particle is incident in the plane of the figure.

Figure 30.11: Fractional energy loss per radiation length in lead as a function of electron or positron energy. Electron (positron) scattering is considered as ionization when the energy loss per collision is below 0.255 MeV, and as Møller (Bhabha) scattering when it is above. Adapted from Fig. 3.2 from Messel and Crawford, *Electron-Photon Shower Distribution Function Tables for Lead, Copper, and Air Absorbers*, Pergamon Press, 1970. Messel and Crawford use $X_0(\text{Pb}) = 5.82 \text{ g/cm}^2$, but we have modified the figures to reflect the value given in the Table of Atomic and Nuclear Properties of Materials ($X_0(\text{Pb}) = 6.37 \text{ g/cm}^2$).

The nonprojected (space) and projected (plane) angular distributions are given approximately by [35]

$$\frac{1}{2\pi\theta_0^2} \exp\left[-\frac{\theta_{\text{space}}^2}{2\theta_0^2}\right] d\Omega, \quad (30.16)$$

$$\frac{1}{\sqrt{2\pi}\theta_0} \exp\left[-\frac{\theta_{\text{plane}}^2}{2\theta_0^2}\right] d\theta_{\text{plane}}, \quad (30.17)$$

where θ is the deflection angle. In this approximation, $\theta_{\text{space}}^2 \approx (\theta_{\text{plane},x}^2 + \theta_{\text{plane},y}^2)$, where the x and y axes are orthogonal to the direction of motion, and $d\Omega \approx d\theta_{\text{plane},x} d\theta_{\text{plane},y}$. Deflections into $\theta_{\text{plane},x}$ and $\theta_{\text{plane},y}$ are independent and identically distributed.

Fig. 30.10 shows these and other quantities sometimes used to describe multiple Coulomb scattering. They are

$$\psi_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{3}} \theta_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{3}} \theta_0, \quad (30.18)$$

$$y_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{3}} x \theta_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{3}} x \theta_0, \quad (30.19)$$

$$s_{\text{plane}}^{\text{rms}} = \frac{1}{4\sqrt{3}} x \theta_{\text{plane}}^{\text{rms}} = \frac{1}{4\sqrt{3}} x \theta_0. \quad (30.20)$$

All the quantitative estimates in this section apply only in the limit of small $\theta_{\text{plane}}^{\text{rms}}$ and in the absence of large-angle scatters. The random variables s , ψ , y , and θ in a given plane are correlated. Obviously, $y \approx x\psi$. In addition, y and θ have the correlation coefficient $\rho_{y\theta} = \sqrt{3}/2 \approx 0.87$. For Monte Carlo generation of a joint ($y_{\text{plane}}, \theta_{\text{plane}}$) distribution, or for other calculations, it may be most convenient to work with independent Gaussian random variables (z_1, z_2) with mean zero and variance one, and then set

$$y_{\text{plane}} = z_1 x \theta_0 (1 - \rho_{y\theta}^2)^{1/2} / \sqrt{3} + z_2 \rho_{y\theta} x \theta_0 / \sqrt{3} \quad (30.21)$$

$$= z_1 x \theta_0 / \sqrt{12} + z_2 x \theta_0 / 2; \quad (30.22)$$

$$\theta_{\text{plane}} = z_2 \theta_0. \quad (30.23)$$

Note that the second term for y_{plane} equals $x \theta_{\text{plane}}/2$ and represents the displacement that would have occurred had the deflection θ_{plane} all occurred at the single point $x/2$.

For heavy ions the multiple Coulomb scattering has been measured and compared with various theoretical distributions [38].

30.4. Photon and electron interactions in matter

30.4.1. Radiation length: High-energy electrons predominantly lose energy in matter by bremsstrahlung, and high-energy photons by e^+e^- pair production. The characteristic amount of matter traversed for these related interactions is called the radiation length X_0 , usually measured in g cm^{-2} . It is both (a) the mean distance over which a high-energy electron loses all but $1/e$ of its energy by bremsstrahlung, and (b) $\frac{7}{9}$ of the mean free path for pair production by a high-energy photon [39]. It is also the appropriate scale length for describing high-energy electromagnetic cascades. X_0 has been calculated and tabulated by Y.S. Tsai [40]:

$$\frac{1}{X_0} = 4\alpha r_e^2 \frac{N_A}{A} \left\{ Z^2 [L_{\text{rad}} - f(Z)] + Z L'_{\text{rad}} \right\}. \quad (30.24)$$

For $A = 1 \text{ g mol}^{-1}$, $4\alpha r_e^2 N_A/A = (716.408 \text{ g cm}^{-2})^{-1}$. L_{rad} and L'_{rad} are given in Table 30.2. The function $f(Z)$ is an infinite sum, but for elements up to uranium can be represented to 4-place accuracy by

$$f(Z) = a^2 \left[(1 + a^2)^{-1} + 0.20206 - 0.0369 a^2 + 0.0083 a^4 - 0.002 a^6 \right], \quad (30.25)$$

where $a = \alpha Z$ [41].

Table 30.2: Tsai's L_{rad} and L'_{rad} , for use in calculating the radiation length in an element using Eq. (30.24).

Element	Z	L_{rad}	L'_{rad}
H	1	5.31	6.144
He	2	4.79	5.621
Li	3	4.74	5.805
Be	4	4.71	5.924
Others	> 4	$\ln(184.15 Z^{-1/3})$	$\ln(1194 Z^{-2/3})$

Figure 30.12: The normalized bremsstrahlung cross section $k d\sigma_{\text{LPM}}/dk$ in lead versus the fractional photon energy $y = k/E$. The vertical axis has units of photons per radiation length.

The radiation length in a mixture or compound may be approximated by

$$1/X_0 = \sum w_j / X_j, \quad (30.26)$$

where w_j and X_j are the fraction by weight and the radiation length for the j th element.

Figure 30.13: Two definitions of the critical energy E_c .

Figure 30.14: Electron critical energy for the chemical elements, using Rossi's definition [2]. The fits shown are for solids and liquids (solid line) and gases (dashed line). The rms deviation is 2.2% for the solids and 4.0% for the gases. (Computed with code supplied by A. Fassó.)

30.4.2. Energy loss by electrons: At low energies electrons and positrons primarily lose energy by ionization, although other processes (Møller scattering, Bhabha scattering, e^+ annihilation) contribute, as shown in Fig. 30.11. While ionization loss rates rise logarithmically with energy, bremsstrahlung losses rise nearly linearly (fractional loss is nearly independent of energy), and dominates above a few tens of MeV in most materials (See Sec. 30.4.3 below.)

Ionization loss by electrons and positrons differ somewhat, and both differ from loss by heavy particles because of the kinematics, spin, and the identity of the incident electron with the electrons which it ionizes. Complete discussions and tables can be found in Refs. 10, 11, and 30.

At very high energies and except at the high-energy tip of the bremsstrahlung spectrum, the cross section can be approximated in the “complete screening case” as [40]

$$\frac{d\sigma}{dk} = (1/k)4\alpha r_e^2 \left\{ \left(\frac{4}{3} - \frac{4}{3}y + y^2 \right) [Z^2(L_{\text{rad}} - f(Z)) + Z L'_{\text{rad}}] + \frac{1}{9}(1-y)(Z^2 + Z) \right\}, \quad (30.27)$$

where $y = k/E$ is the fraction of the electron's energy transferred to the radiated photon. At small y (the “infrared limit”) the term on the second line ranges from 1.7% (low Z) to 2.5% (high Z) of the total. If it is ignored and the first line simplified with the definition of X_0 given in Eq. (30.24), we have

$$\frac{d\sigma}{dk} = \frac{A}{X_0 N_A k} \left(\frac{4}{3} - \frac{4}{3}y + y^2 \right). \quad (30.28)$$

This cross section (times k) is shown by the top curve in Fig. 30.12.

This formula is accurate except in near $y = 1$, where

Figure 30.15: Photon total cross sections as a function of energy in carbon and lead, showing the contributions of different processes [48]:

- $\sigma_{\text{p.e.}}$ = Atomic photoelectric effect (electron ejection, photon absorption)
- σ_{Rayleigh} = Rayleigh (coherent) scattering—atom neither ionized nor excited
- σ_{Compton} = Incoherent scattering (Compton scattering off an electron)
- κ_{nuc} = Pair production, nuclear field
- κ_e = Pair production, electron field
- $\sigma_{\text{g.d.r.}}$ = Photonuclear interactions, most notably the Giant Dipole Resonance [49]. In these interactions, the target nucleus is broken up.

Original figures through the courtesy of John H. Hubbell (NIST).

screening may become incomplete, and near $y = 0$, where the infrared divergence is removed by the interference of bremsstrahlung amplitudes from nearby scattering centers (the LPM effect) [42,43] and dielectric suppression [44,45]. These and other suppression effects in bulk media are discussed in Sec. 30.4.5.

With decreasing energy ($E \lesssim 10$ GeV) the high- y cross section drops and the curves become rounded as $y \rightarrow 1$. Curves of this

Fig. 30.16: The photon mass attenuation length (or mean free path) $\lambda = 1/(\mu/\rho)$ for various elemental absorbers as a function of photon energy. The mass attenuation coefficient is μ/ρ , where ρ is the density. The intensity I remaining after traversal of thickness t (in mass/unit area) is given by $I = I_0 \exp(-t/\lambda)$. The accuracy is a few percent. For a chemical compound or mixture, $1/\lambda_{\text{eff}} \approx \sum_{\text{elements}} w_Z/\lambda_Z$, where w_Z is the proportion by weight of the element with atomic number Z . The processes responsible for attenuation are given in Fig. 30.11. Since coherent processes are included, not all these processes result in energy deposition. The data for $30 \text{ eV} < E < 1 \text{ keV}$ are obtained from http://www-cxro.lbl.gov/optical_constants (courtesy of Eric M. Gullikson, LBNL). The data for $1 \text{ keV} < E < 100 \text{ GeV}$ are from <http://physics.nist.gov/PhysRefData>, through the courtesy of John H. Hubbell (NIST).

familiar shape can be seen in Rossi [2] (Figs. 2.11.2,3); see also the review by Koch & Motz [46].

Except at these extremes, and still in the complete-screening approximation, the number of photons with energies between k_{min} and k_{max} emitted by an electron travelling a distance $d \ll X_0$ is

$$N_\gamma = \frac{d}{X_0} \left[\frac{4}{3} \ln \left(\frac{k_{\text{max}}}{k_{\text{min}}} \right) - \frac{4(k_{\text{max}} - k_{\text{min}})}{3E} + \frac{k_{\text{max}}^2 - k_{\text{min}}^2}{2E^2} \right]. \quad (30.29)$$

30.4.3. Critical energy: An electron loses energy by bremsstrahlung at a rate nearly proportional to its energy, while the ionization loss rate varies only logarithmically with the electron energy. The *critical energy* E_c is sometimes defined as the energy at which the two loss rates are equal [47]. Among alternate definitions is that of Rossi [2], who defines the critical energy as the energy at which the ionization loss per radiation length is equal to the electron energy. Equivalently, it is the same as the first definition with the approximation $|dE/dx|_{\text{brems}} \approx E/X_0$. This form has been found to describe transverse electromagnetic shower development more accurately (see below). These definitions are illustrated in the case of copper in Fig. 30.13.

The accuracy of approximate forms for E_c has been limited by the failure to distinguish between gases and solid or liquids, where there is a substantial difference in ionization at the relevant energy because of the density effect. We distinguish these two cases in Fig. 30.14. Fits were also made with functions of the form $a/(Z+b)^\alpha$, but α was found to be essentially unity. Since E_c also depends on A , I , and other factors, such forms are at best approximate.

Values of E_c for both electrons and positrons in more than 300 materials can be found at pdg.lbl.gov/AtomicNuclearProperties.

Figure 30.17: Probability P that a photon interaction will result in conversion to an e^+e^- pair. Except for a few-percent contribution from photonuclear absorption around 10 or 20 MeV, essentially all other interactions in this energy range result in Compton scattering off an atomic electron. For a photon attenuation length λ (Fig. 30.16), the probability that a given photon will produce an electron pair (without first Compton scattering) in thickness t of absorber is $P[1 - \exp(-t/\lambda)]$.

30.4.4. Energy loss by photons : Contributions to the photon cross section in a light element (carbon) and a heavy element (lead) are shown in Fig. 30.15. At low energies it is seen that the photoelectric effect dominates, although Compton scattering, Rayleigh scattering, and photonuclear absorption also contribute. The photoelectric cross section is characterized by discontinuities (absorption edges) as thresholds for photoionization of various atomic levels are reached. Photon attenuation lengths for a variety of elements are shown in Fig. 30.16, and data for $30 \text{ eV} < k < 100 \text{ GeV}$ for all elements is available from the web pages given in the caption. Here k is the photon energy.

Figure 30.18: The normalized pair production cross section $d\sigma_{LPM}/dy$, versus fractional electron energy $x = E/k$.

The increasing domination of pair production as the energy increases is shown in Fig. 30.17. Using approximations similar to those used to obtain Eq. (30.28), Tsai's formula for the differential cross section [40] reduces to

$$\frac{d\sigma}{dx} = \frac{A}{X_0 N_A} \left[1 - \frac{4}{3}x(1-x) \right] \quad (30.30)$$

in the complete-screening limit valid at high energies. Here $x = E/k$ is the fractional energy transfer to the pair-produced electron (or positron), and k is the incident photon energy. The cross section is very closely related to that for bremsstrahlung, since the Feynman diagrams are variants of one another. The cross section is of necessity symmetric between x and $1-x$, as can be seen by the solid curve in Fig. 30.18. See the review by Motz, Olsen, & Koch for a more detailed treatment [50].

Eq. (30.30) may be integrated to find the high-energy limit for the total e^+e^- pair-production cross section:

$$\sigma = \frac{7}{9} (A/X_0 N_A) . \quad (30.31)$$

Equation Eq. (30.31) is accurate to within a few percent down to energies as low as 1 GeV, particularly for high- Z materials.

30.4.5. Bremsstrahlung and pair production at very high energies : At ultrahigh energies, Eqns. 30.27–30.31 will fail because of quantum mechanical interference between amplitudes from different scattering centers. Since the longitudinal momentum transfer to a given center is small ($\propto k/E(E-k)$, in the case of bremsstrahlung), the interaction is spread over a comparatively long distance called the formation length ($\propto E(E-k)/k$) via the uncertainty principle. In alternate language, the formation length is the distance over which the highly relativistic electron and the photon “split apart.” The interference is usually destructive. Calculations of the “Landau-Pomeranchuk-Migdal” (LPM) effect may be made semi-classically based on the average multiple scattering, or more rigorously using a quantum transport approach [42,43].

In amorphous media, bremsstrahlung is suppressed if the photon energy k is less than $E^2/(E + E_{LPM})$ [43], where*

$$E_{LPM} = \frac{(m_e c^2)^2 \alpha X_0}{4\pi \hbar c \rho} = (7.7 \text{ TeV/cm}) \times \frac{X_0}{\rho} . \quad (30.32)$$

Since physical distances are involved, X_0/ρ , in cm, appears. The energy-weighted bremsstrahlung spectrum for lead, $k d\sigma_{LPM}/dk$, is shown in Fig. 30.12. With appropriate scaling by X_0/ρ , other materials behave similarly.

For photons, pair production is reduced for $E(k-E) > k E_{LPM}$. The pair-production cross sections for different photon energies are shown in Fig. 30.18.

If $k \ll E$, several additional mechanisms can also produce suppression. When the formation length is long, even weak factors can perturb the interaction. For example, the emitted photon can coherently forward scatter off of the electrons in the media. Because of this, for $k < \omega_p E/m_e \sim 10^{-4}$, bremsstrahlung is suppressed by a factor $(km_e/\omega_p E)^2$ [45]. Magnetic fields can also suppress bremsstrahlung.

In crystalline media, the situation is more complicated, with coherent enhancement or suppression possible. The cross section depends on the electron and photon energies and the angles between the particle direction and the crystalline axes [52].

30.4.6. Photonuclear and electronuclear interactions at still higher energies : At still higher photon and electron energies, where the bremsstrahlung and pair production cross-sections are heavily suppressed by the LPM effect, photonuclear and electronuclear interactions predominate over electromagnetic interactions.

At photon energies above about 10^{20} eV, for example, photons usually interact hadronically. The exact cross-over energy depends on the model used for the photonuclear interactions. At still higher energies ($\gtrsim 10^{23}$ eV), photonuclear interactions can become coherent, with the photon interaction spread over multiple nuclei. Essentially, the photon coherently converts to a ρ^0 , in a process that is somewhat similar to kaon regeneration [53]. These processes are illustrated in Fig. 30.19.

Figure 30.19: Interaction length for a photon in ice as a function of photon energy for the Bethe-Heitler (BH), LPM (Mig) and photonuclear (γA) cross sections [53]. The Bethe-Heitler interaction length is $9X_0/7$, and X_0 is 0.393 m in ice.

Similar processes occur for electrons. As electron energies increase and the LPM effect suppresses bremsstrahlung,

* This definition differs from that of Ref. 51 by a factor of two. E_{LPM} scales as the 4th power of the mass of the incident particle, so that $E_{LPM} = (1.4 \times 10^{10} \text{ TeV/cm}) \times X_0/\rho$ for a muon.

electronuclear interactions become more important. At energies above 10^{21} eV, these electronuclear interactions dominate electron energy loss [53].

30.5. Electromagnetic cascades

When a high-energy electron or photon is incident on a thick absorber, it initiates an electromagnetic cascade as pair production and bremsstrahlung generate more electrons and photons with lower energy. The longitudinal development is governed by the high-energy part of the cascade, and therefore scales as the radiation length in the material. Electron energies eventually fall below the critical energy, and then dissipate their energy by ionization and excitation rather than by the generation of more shower particles. In describing shower behavior, it is therefore convenient to introduce the scale variables

$$t = x/X_0, \quad y = E/E_c, \quad (30.33)$$

so that distance is measured in units of radiation length and energy in units of critical energy.

Figure 30.20: An EGS4 simulation of a 30 GeV electron-induced cascade in iron. The histogram shows fractional energy deposition per radiation length, and the curve is a gamma-function fit to the distribution. Circles indicate the number of electrons with total energy greater than 1.5 MeV crossing planes at $X_0/2$ intervals (scale on right) and the squares the number of photons with $E \geq 1.5$ MeV crossing the planes (scaled down to have same area as the electron distribution).

Longitudinal profiles from an EGS4 [54] simulation of a 30 GeV electron-induced cascade in iron are shown in Fig. 30.20. The number of particles crossing a plane (very close to Rossi's Π function [2]) is sensitive to the cutoff energy, here chosen as a total energy of 1.5 MeV for both electrons and photons. The electron number falls off more quickly than energy deposition. This is because, with increasing depth, a larger fraction of the cascade energy is carried by photons. Exactly what a calorimeter measures depends on the device, but it is not likely to be exactly any of the profiles shown. In gas counters it may be very close to the electron number, but in glass Cherenkov detectors and other devices with “thick” sensitive regions it is closer to the energy deposition (total track length). In such detectors the signal is proportional to the “detectable” track length T_d , which is in general less than the total track length T . Practical devices are sensitive to electrons with energy above some detection threshold E_d , and $T_d = T F(E_d/E_c)$. An analytic form for $F(E_d/E_c)$ obtained by Rossi [2] is given by Fabjan [55]; see also Amaldi [56].

The mean longitudinal profile of the energy deposition in an electromagnetic cascade is reasonably well described by a gamma

distribution [57]:

$$\frac{dE}{dt} = E_0 b \frac{(bt)^{a-1} e^{-bt}}{\Gamma(a)} \quad (30.34)$$

The maximum t_{\max} occurs at $(a-1)/b$. We have made fits to shower profiles in elements ranging from carbon to uranium, at energies from 1 GeV to 100 GeV. The energy deposition profiles are well described by Eq. (30.34) with

$$t_{\max} = (a-1)/b = 1.0 \times (\ln y + C_j), \quad j = e, \gamma, \quad (30.35)$$

where $C_e = -0.5$ for electron-induced cascades and $C_\gamma = +0.5$ for photon-induced cascades. To use Eq. (30.34), one finds $(a-1)/b$ from Eq. (30.35) and Eq. (30.33), then finds a either by assuming $b \approx 0.5$ or by finding a more accurate value from Fig. 30.21. The results are very similar for the electron number profiles, but there is some dependence on the atomic number of the medium. A similar form for the electron number maximum was obtained by Rossi in the context of his “Approximation B,” [2] (see Fabjan’s review in Ref. 55), but with $C_e = -1.0$ and $C_\gamma = -0.5$; we regard this as superseded by the EGS4 result.

Figure 30.21: Fitted values of the scale factor b for energy deposition profiles obtained with EGS4 for a variety of elements for incident electrons with $1 \leq E_0 \leq 100$ GeV. Values obtained for incident photons are essentially the same.

The “shower length” $X_s = X_0/b$ is less conveniently parameterized, since b depends upon both Z and incident energy, as shown in Fig. 30.21. As a corollary of this Z dependence, the number of electrons crossing a plane near shower maximum is underestimated using Rossi’s approximation for carbon and seriously overestimated for uranium. Essentially the same b values are obtained for incident electrons and photons. For many purposes it is sufficient to take $b \approx 0.5$.

The length of showers initiated by ultra-high energy photons and electrons is somewhat greater than at lower energies since the first or first few interaction lengths are increased via the mechanisms discussed above.

The gamma function distribution is very flat near the origin, while the EGS4 cascade (or a real cascade) increases more rapidly. As a result Eq. (30.34) fails badly for about the first two radiation lengths; it was necessary to exclude this region in making fits.

Because fluctuations are important, Eq. (30.34) should be used only in applications where average behavior is adequate. Grindhammer *et al.* have developed fast simulation algorithms in which the variance and correlation of a and b are obtained by fitting Eq. (30.34) to individually simulated cascades, then generating profiles for cascades using a and b chosen from the correlated distributions [58].

The transverse development of electromagnetic showers in different materials scales fairly accurately with the *Molière radius* R_M , given by [59,60]

$$R_M = X_0 E_s / E_c, \quad (30.36)$$

where $E_s \approx 21$ MeV (Table 30.1), and the Rossi definition of E_c is used.

In a material containing a weight fraction w_j of the element with critical energy E_{cj} and radiation length X_j , the Molière radius is given by

$$\frac{1}{R_M} = \frac{1}{E_s} \sum \frac{w_j E_{cj}}{X_j}. \quad (30.37)$$

Measurements of the lateral distribution in electromagnetic cascades are shown in Refs. 59 and 60. On the average, only 10% of the energy lies outside the cylinder with radius R_M . About 99% is contained inside of $3.5R_M$, but at this radius and beyond composition effects become important and the scaling with R_M fails. The distributions are characterized by a narrow core, and broaden as the shower develops. They are often represented as the sum of two Gaussians, and Grindhammer [58] describes them with the function

$$f(r) = \frac{2r R^2}{(r^2 + R^2)^2}, \quad (30.38)$$

where R is a phenomenological function of x/X_0 and $\ln E$.

At high enough energies, the LPM effect (Sec. 30.4.5) reduces the cross sections for bremsstrahlung and pair production, and hence can cause significant elongation of electromagnetic cascades [43].

30.6. Muon energy loss at high energy

At sufficiently high energies, radiative processes become more important than ionization for all charged particles. For muons and pions in materials such as iron, this “critical energy” occurs at several hundred GeV. (There is no simple scaling with particle mass, but for protons the “critical energy” is much, much higher.) Radiative effects dominate the energy loss of energetic muons found in cosmic rays or produced at the newest accelerators. These processes are characterized by small cross sections, hard spectra, large energy fluctuations, and the associated generation of electromagnetic and (in the case of photonuclear interactions) hadronic showers [61–69]. As a consequence, at these energies the treatment of energy loss as a uniform and continuous process is for many purposes inadequate.

It is convenient to write the average rate of muon energy loss as [70]

$$-dE/dx = a(E) + b(E) E. \quad (30.39)$$

Here $a(E)$ is the ionization energy loss given by Eq. (30.4), and $b(E)$ is the sum of e^+e^- pair production, bremsstrahlung, and photonuclear contributions. To the approximation that these slowly-varying functions are constant, the mean range x_0 of a muon with initial energy E_0 is given by

$$x_0 \approx (1/b) \ln(1 + E_0/E_{\mu c}), \quad (30.40)$$

where $E_{\mu c} = a/b$. Fig. 30.22 shows contributions to $b(E)$ for iron. Since $a(E) \approx 0.002$ GeV $g^{-1} cm^2$, $b(E)E$ dominates the energy loss above several hundred GeV, where $b(E)$ is nearly constant. The rates of energy loss for muons in hydrogen, uranium, and iron are shown in Fig. 30.23 [5].

The “muon critical energy” $E_{\mu c}$ can be defined more exactly as the energy at which radiative and ionization losses are equal, and can be found by solving $E_{\mu c} = a(E_{\mu c})/b(E_{\mu c})$. This definition corresponds to the solid-line intersection in Fig. 30.13, and is different from the Rossi definition we used for electrons. It serves the same function: below $E_{\mu c}$ ionization losses dominate, and above $E_{\mu c}$ radiative effects dominate. The dependence of $E_{\mu c}$ on atomic number Z is shown in Fig. 30.24.

Figure 30.22: Contributions to the fractional energy loss by muons in iron due to e^+e^- pair production, bremsstrahlung, and photonuclear interactions, as obtained from Groom *et al.* [5] except for post-Born corrections to the cross section for direct pair production from atomic electrons.

Figure 30.23: The average energy loss of a muon in hydrogen, iron, and uranium as a function of muon energy. Contributions to dE/dx in iron from ionization and the processes shown in Fig. 30.22 are also shown.

Figure 30.24: Muon critical energy for the chemical elements, defined as the energy at which radiative and ionization energy loss rates are equal [5]. The equality comes at a higher energy for gases than for solids or liquids with the same atomic number because of a smaller density effect reduction of the ionization losses. The fits shown in the figure exclude hydrogen. Alkali metals fall 3–4% above the fitted function, while most other solids are within 2% of the function. Among the gases the worst fit is for radon (2.7% high).

The radiative cross sections are expressed as functions of the fractional energy loss ν . The bremsstrahlung cross section goes roughly as $1/\nu$ over most of the range, while for the pair production case the distribution goes as ν^{-3} to ν^{-2} [71]. “Hard” losses are therefore more probable in bremsstrahlung, and in fact energy losses due to pair production may very nearly be treated as continuous. The simulated [69] momentum distribution of an incident 1 TeV/c muon beam after it crosses 3 m of iron is shown in Fig. 30.25. The most probable loss is 8 GeV, or $3.4 \text{ MeV g}^{-1}\text{cm}^2$. The full width at half maximum is 9 GeV/c, or 0.9%. The radiative tail is almost entirely due to bremsstrahlung, although most of the events in which more than 10% of the incident energy lost experienced relatively hard photonuclear interactions. The latter can exceed detector resolution [72], necessitating the reconstruction of lost energy. Tables [5] list the stopping power as $9.82 \text{ MeV g}^{-1}\text{cm}^2$ for a 1 TeV muon, so that the mean loss should be 23 GeV ($\approx 23 \text{ GeV}/c$), for a final momentum of 977 GeV/c, far below the peak. This agrees with the indicated mean calculated from the simulation. Electromagnetic and hadronic cascades in detector materials can obscure muon tracks in detector planes and reduce tracking efficiency [73].

Figure 30.25: The momentum distribution of 1 TeV/c muons after traversing 3 m of iron as calculated with the MARS15 Monte Carlo code [69] by S.I. Striganov [5].

30.7. Cherenkov and transition radiation [74,75,34]

A charged particle radiates if its velocity is greater than the local phase velocity of light (Cherenkov radiation) or if it crosses suddenly from one medium to another with different optical properties (transition radiation). Neither process is important for energy loss, but both are used in high-energy and cosmic-ray physics detectors.

Figure 30.26: Cherenkov light emission and wavefront angles. In a dispersive medium, $\theta_c + \eta \neq 90^\circ$.

30.7.1. Optical Cherenkov radiation : The angle θ_c of Cherenkov radiation, relative to the particle’s direction, for a particle with velocity βc in a medium with index of refraction n is

$$\begin{aligned} \cos \theta_c &= (1/n\beta) \\ \text{or } \tan \theta_c &= \sqrt{\beta^2 n^2 - 1} \\ &\approx \sqrt{2(1 - 1/n\beta)} \quad \text{for small } \theta_c, \text{ e.g. in gas} \end{aligned} \quad (30.41)$$

The threshold velocity β_t is $1/n$, and $\gamma_t = 1/(1 - \beta_t^2)^{1/2}$. Therefore, $\beta_t \gamma_t = 1/(2\delta + \delta^2)^{1/2}$, where $\delta = n - 1$. Values of δ for various commonly used gases are given as a function of pressure and wavelength in Ref. 76. For values at atmospheric pressure, see Table 6.1. Data for other commonly used materials are given in Ref. 77.

Practical Cherenkov radiator materials are dispersive. Let ω be the photon’s frequency, and let $k = 2\pi/\lambda$ be its wavenumber. The photons propagate at the group velocity $v_g = d\omega/dk = c/[n(\omega) + \omega(dn/d\omega)]$. In a non-dispersive medium, this simplifies to $v_g = c/n$.

In his classical paper, Tamm [78] showed that for dispersive media the radiation is concentrated in a thin conical shell whose vertex is at the moving charge, and whose opening half-angle η is given by

$$\begin{aligned} \cot \eta &= \left[\frac{d}{d\omega} (\omega \tan \theta_c) \right]_{\omega_0} \\ &= \left[\tan \theta_c + \beta^2 \omega n(\omega) \frac{dn}{d\omega} \cot \theta_c \right]_{\omega_0}, \end{aligned} \quad (30.42)$$

where ω_0 is the central value of the small frequency range under consideration. (See Fig. 30.26.) This cone has a opening half-angle η , and, unless the medium is non-dispersive ($dn/d\omega = 0$), $\theta_c + \eta \neq 90^\circ$. The Cherenkov wavefront ‘sideslips’ along with the particle [79]. This effect may have timing implications for ring imaging Cherenkov counters [80], but it is probably unimportant for most applications.

The number of photons produced per unit path length of a particle with charge ze and per unit energy interval of the photons is

$$\begin{aligned} \frac{d^2 N}{dE dx} &= \frac{\alpha z^2}{hc} \sin^2 \theta_c = \frac{\alpha^2 z^2}{r_e m_e c^2} \left(1 - \frac{1}{\beta^2 n^2(E)} \right) \\ &\approx 370 \sin^2 \theta_c(E) \text{ eV}^{-1} \text{ cm}^{-1} \quad (z = 1), \end{aligned} \quad (30.43)$$

or, equivalently,

$$\frac{d^2 N}{dx d\lambda} = \frac{2\pi \alpha z^2}{\lambda^2} \left(1 - \frac{1}{\beta^2 n^2(\lambda)} \right). \quad (30.44)$$

The index of refraction n is a function of photon energy $E = \hbar\omega$, as is the sensitivity of the transducer used to detect the light. For practical use, Eq. (30.43) must be multiplied by the the transducer response function and integrated over the region for which $\beta n(\omega) > 1$. Further details are given in the discussion of Cherenkov detectors in the Particle Detectors section (Sec. 31 of this Review).

When two particles are close together (lateral separation $\lesssim 1$ wavelength), the electromagnetic fields from the particles may add coherently, affecting the Cherenkov radiation. Because of their opposite charges, the radiation from an e^+e^- pair at close separation is suppressed compared to two independent leptons [81].

30.7.2. Coherent radio Cherenkov radiation :

Coherent Cherenkov radiation is produced by many charged particles with a non-zero net charge moving through matter on an approximately common “wavefront”—for example, the electrons and positrons in a high-energy electromagnetic cascade. The signals can be visible above backgrounds for shower energies as low as 10^{17} eV; see Sec. 32.3.2 for more details. The

phenomenon is called the Askaryan effect [82]. Near the end of a shower, when typical particle energies are below E_c (but still relativistic), a charge imbalance develops. The photons can Compton-scatter atomic electrons, and positrons can annihilate with atomic electrons to contribute even more photons which can in turn Compton scatter. These processes result in a roughly 20% excess of electrons over positrons in a shower. The net negative charge leads to coherent radio Cherenkov emission. The radiation includes a component from the decelerating charges (as in bremsstrahlung). Because the emission is coherent, the electric field strength is proportional to the shower energy and the signal power increases as its square. The electric field strength also increases linearly with frequency, up to a maximum frequency determined by the lateral spread of the shower. This cutoff occurs at about 1 GHz in ice, and scales inversely with the Moliere radius. At low frequencies, the radiation is roughly isotropic, but, as the frequency rises toward the cutoff frequency, the radiation becomes increasingly peaked around the Cherenkov angle. The radiation is linearly polarized in the plane containing the shower axis and the photon direction. A measurement of the signal polarization can be used to help determine the shower direction. The characteristics of this radiation have been nicely demonstrated in a series of experiments at SLAC [83]. A detailed discussion of the radiation can be found in Ref. 84.

30.7.3. Transition radiation: The energy radiated when a particle with charge ze crosses the boundary between vacuum and a medium with plasma frequency ω_p is

$$I = \alpha z^2 \gamma \hbar \omega_p / 3, \quad (30.45)$$

where

$$\hbar \omega_p = \sqrt{4\pi N_e r_e^3} m_e c^2 / \alpha = \sqrt{\rho \text{ (in g/cm}^3\text{)} \langle Z/A \rangle} \times 28.81 \text{ eV}. \quad (30.46)$$

For styrene and similar materials, $\hbar \omega_p \approx 20$ eV; for air it is 0.7 eV.

The number spectrum $dN_\gamma/d(\hbar\omega)$ diverges logarithmically at low energies and decreases rapidly for $\hbar\omega/\gamma\hbar\omega_p > 1$. About half the energy is emitted in the range $0.1 \leq \hbar\omega/\gamma\hbar\omega_p \leq 1$. Inevitable absorption in a practical detector removes the divergence. For a particle with $\gamma = 10^3$, the radiated photons are in the soft x-ray range 2 to 40 keV. The γ dependence of the emitted energy thus comes from the hardening of the spectrum rather than from an increased quantum yield.

The number of photons with energy $\hbar\omega > \hbar\omega_0$ is given by the answer to problem 13.15 in Ref. 34,

$$N_\gamma(\hbar\omega > \hbar\omega_0) = \frac{\alpha z^2}{\pi} \left[\left(\ln \frac{\gamma \hbar \omega_p}{\hbar \omega_0} - 1 \right)^2 + \frac{\pi^2}{12} \right], \quad (30.47)$$

within corrections of order $(\hbar\omega_0/\gamma\hbar\omega_p)^2$. The number of photons above a fixed energy $\hbar\omega_0 \ll \gamma\hbar\omega_p$ thus grows as $(\ln \gamma)^2$, but the number above a fixed fraction of $\gamma\hbar\omega_p$ (as in the example above) is constant. For example, for $\hbar\omega > \gamma\hbar\omega_p/10$, $N_\gamma = 2.519 \alpha z^2 / \pi = 0.59\% \times z^2$.

The particle stays “in phase” with the x ray over a distance called the formation length, $d(\omega)$. Most of the radiation is produced in a distance $d(\omega) = (2c/\omega)(1/\gamma^2 + \theta^2 + \omega_p^2/\omega^2)^{-1}$. Here θ is the x-ray emission angle, characteristically $1/\gamma$. For $\theta = 1/\gamma$ the formation length has a maximum at $d(\gamma\omega_p/\sqrt{2}) = \gamma c/\sqrt{2}\omega_p$. In practical situations it is tens of μm .

Since the useful x-ray yield from a single interface is low, in practical detectors it is enhanced by using a stack of N foil radiators—foils L thick, where L is typically several formation lengths—separated by gas-filled gaps. The amplitudes at successive interfaces interfere to cause oscillations about the single-interface spectrum. At increasing frequencies above the position of the last interference maximum ($L/d(\omega) = \pi/2$), the formation zones, which have opposite phase, overlap more and

Figure 30.27: X-ray photon energy spectra for a radiator consisting of 200 25 μm thick foils of Mylar with 1.5 mm spacing in air (solid lines) and for a single surface (dashed line). Curves are shown with and without absorption. Adapted from Ref. 85.

more and the spectrum saturates, $dI/d\omega$ approaching zero as $L/d(\omega) \rightarrow 0$. This is illustrated in Fig. 30.27 for a realistic detector configuration.

For regular spacing of the layers fairly complicated analytic solutions for the intensity have been obtained [85]. (See also Ref. 86 and references therein.) Although one might expect the intensity of coherent radiation from the stack of foils to be proportional to N^2 , the angular dependence of the formation length conspires to make the intensity $\propto N$.

31.1. Introduction

This review summarizes the detector technologies employed at accelerator particle physics experiments. Several of these detectors are also used in a non-accelerator context and examples of such applications will be provided. The detector techniques which are specific to non-accelerator particle physics experiments are the subject of Chap. 32. More detailed discussions of detectors and their underlying physics can be found in books by Ferbel [1], Kleinknecht [2], Knoll [3], Green [4], Leroy & Rancoita [5], and Grupen [6].

In Table 31.1 are given typical resolutions and deadtimes of common charged particle detectors. The quoted numbers are usually based on typical devices, and should be regarded only as rough approximations for new designs. The spatial resolution refers to the intrinsic detector resolution, i.e. without multiple scattering. We note that analog detector readout can provide better spatial resolution than digital readout by measuring the deposited charge in neighboring channels. Quoted ranges attempt to be representative of both possibilities. The time resolution is defined by how accurately the time at which a particle crossed the detector can be determined. The deadtime is the minimum separation in time between two resolved hits on the same channel. Typical performance of calorimetry and particle identification are provided in the relevant sections below.

Table 31.1: Typical resolutions and deadtimes of common charged particle detectors. Revised November 2011.

Detector Type	Intrinsic Spatial Resolution (rms)	Time Resolution	Dead Time
Resistive plate chamber	$\lesssim 10$ mm	1–2 ns	—
Streamer chamber	$300 \mu\text{m}^a$	$2 \mu\text{s}$	100 ms
Liquid argon drift [7]	$\sim 175\text{--}450 \mu\text{m}$	~ 200 ns	$\sim 2 \mu\text{s}$
Scintillation tracker	$\sim 100 \mu\text{m}$	$100 \text{ps}/n^b$	10 ns
Bubble chamber	$10\text{--}150 \mu\text{m}$	1 ms	50ms^c
Proportional chamber	$50\text{--}100 \mu\text{m}^d$	2 ns	20–200 ns
Drift chamber	$50\text{--}100 \mu\text{m}$	2ns^e	20–100 ns
Micro-pattern gas detectors	$30\text{--}40 \mu\text{m}$	< 10 ns	10–100 ns
Silicon strip	$\text{pitch}/(3 \text{ to } 7)^f$	few ns ^g	$\lesssim 50 \text{ns}^g$
Silicon pixel	$\lesssim 10 \mu\text{m}$	few ns ^g	$\lesssim 50 \text{ns}^g$
Emulsion	$1 \mu\text{m}$	—	—

^a $300 \mu\text{m}$ is for 1 mm pitch (wirespacing/ $\sqrt{12}$).

^b n = index of refraction.

^c Multiple pulsing time.

^d Delay line cathode readout can give $\pm 150 \mu\text{m}$ parallel to anode wire.

^e For two chambers.

^f The highest resolution (“7”) is obtained for small-pitch detectors ($\lesssim 25 \mu\text{m}$) with pulse-height-weighted center finding.

^g Limited by the readout electronics [8].

31.2. Photon detectors

Updated August 2011 by D. Chakraborty (Northern Illinois U) and T. Sumiyoshi (Tokyo Metro U).

Most detectors in high-energy, nuclear, and astrophysics rely on the detection of photons in or near the visible range, $100 \text{nm} \lesssim \lambda \lesssim 1000 \text{nm}$, or $E \approx$ a few eV. This range covers scintillation and Cherenkov radiation as well as the light detected in many astronomical observations.

Generally, photodetection involves generating a detectable electrical signal proportional to the (usually very small) number of incident photons. The process involves three distinct steps:

1. Generation of a primary photoelectron or electron-hole ($e-h$) pair by an incident photon by the photoelectric or photoconductive effect,
2. Amplification of the p.e. signal to detectable levels by one or more multiplicative bombardment steps and/or an avalanche process (usually), and,

3. Collection of the secondary electrons to form the electrical signal. The important characteristics of a photodetector include the following in statistical averages:

1. Quantum efficiency (QE or ϵ_Q): the number of primary photoelectrons generated per incident photon ($0 \leq \epsilon_Q \leq 1$; in silicon more than one e - h pair per incident photon can be generated for $\lambda \lesssim 165$ nm),
2. Collection efficiency (CE or ϵ_C): the overall acceptance factor other than the generation of photoelectrons ($0 \leq \epsilon_C \leq 1$),
3. Gain (G): the number of electrons collected for each photoelectron generated,
4. Dark current or dark noise: the electrical signal when there is no photon,
5. Energy resolution: electronic noise (ENC or N_e) and statistical fluctuations in the amplification process compound the Poisson distribution of n_γ photons from a given source:

$$\frac{\sigma(E)}{\langle E \rangle} = \sqrt{\frac{f_N}{n_\gamma \epsilon_Q \epsilon_C} + \left(\frac{N_e}{G n_\gamma \epsilon_Q \epsilon_C} \right)^2}, \quad (31.1)$$

where f_N , or the excess noise factor (ENF), is the contribution to the energy distribution variance due to amplification statistics [9],

6. Dynamic range: the maximum signal available from the detector (this is usually expressed in units of the response to noise-equivalent power, or NEP, which is the optical input power that produces a signal-to-noise ratio of 1),
7. Time dependence of the response: this includes the transit time, which is the time between the arrival of the photon and the electrical pulse, and the transit time spread, which contributes to the pulse rise time and width, and
8. Rate capability: inversely proportional to the time needed, after the arrival of one photon, to get ready to receive the next.

requirements, power consumption, calibration needs, aging, cost, and so on. Several technologies employing different phenomena for the three steps described above, and many variants within each, offer a wide range of solutions to choose from. The salient features of the main technologies and the common variants are described below. Some key characteristics are summarized in Table 31.2.

31.2.1. Vacuum photodetectors: Vacuum photodetectors can be broadly subdivided into three types: photomultiplier tubes, microchannel plates, and hybrid photodetectors.

31.2.1.1. Photomultiplier tubes: A versatile class of photon detectors, vacuum photomultiplier tubes (PMT) has been employed by a vast majority of all particle physics experiments to date [9]. Both “transmission-” and “reflection-type” PMT’s are widely used. In the former, the photocathode material is deposited on the inside of a transparent window through which the photons enter, while in the latter, the photocathode material rests on a separate surface that the incident photons strike. The cathode material has a low work function, chosen for the wavelength band of interest. When a photon hits the cathode and liberates an electron (the photoelectric effect), the latter is accelerated and guided by electric fields to impinge on a secondary-emission electrode, or dynode, which then emits a few (~ 5) secondary electrons. The multiplication process is repeated typically 10 times in series to generate a sufficient number of electrons, which are collected at the anode for delivery to the external circuit. The total gain of a PMT depends on the applied high voltage V as $G = AV^{kn}$, where $k \approx 0.7$ – 0.8 (depending on the dynode material), n is the number of dynodes in the chain, and A a constant (which also depends on n). Typically, G is in the range of 10^5 – 10^6 . Pulse risetimes are usually in the few nanosecond range. With *e.g.* two-level discrimination the effective time resolution can be much better.

Table 31.2: Representative characteristics of some photodetectors commonly used in particle physics. The time resolution of the devices listed here vary in the 10–2000 ps range.

Type	λ (nm)	$\epsilon_Q \epsilon_C$	Gain	Risetime (ns)	Area (mm ²)	1-p.e noise (Hz)	HV (V)	Price (USD)
PMT*	115–1700	0.15–0.25	10^3 – 10^7	0.7–10	10^2 – 10^5	10 – 10^4	500–3000	100–5000
MCP*	100–650	0.01–0.10	10^3 – 10^7	0.15–0.3	10^2 – 10^4	0.1–200	500–3500	10–6000
HPD*	115–850	0.1–0.3	10^3 – 10^4	7	10^2 – 10^5	10 – 10^3	$\sim 2 \times 10^4$	~ 600
GPM*	115–500	0.15–0.3	10^3 – 10^6	$O(0.1)$	$O(10)$	10 – 10^3	300–2000	$O(10)$
APD	300–1700	~ 0.7	10 – 10^8	$O(1)$	10 – 10^3	1 – 10^3	400–1400	$O(100)$
PPD	320–900	0.15–0.3	10^5 – 10^6	~ 1	1–10	$O(10^6)$	30–60	$O(100)$
VLPC	500–600	~ 0.9	$\sim 5 \times 10^4$	~ 10	1	$O(10^4)$	~ 7	~ 1

*These devices often come in multi-anode configurations. In such cases, area, noise, and price are to be considered on a “per readout-channel” basis.

The QE is a strong function of the photon wavelength (λ), and is usually quoted at maximum, together with a range of λ where the QE is comparable to its maximum. Spatial uniformity and linearity with respect to the number of photons are highly desirable in a photodetector’s response.

Optimization of these factors involves many trade-offs and vary widely between applications. For example, while a large gain is desirable, attempts to increase the gain for a given device also increases the ENF and after-pulsing (“echos” of the main pulse). In solid-state devices, a higher QE often requires a compromise in the timing properties. In other types, coverage of large areas by focusing increases the transit time spread.

Other important considerations also are highly application-specific. These include the photon flux and wavelength range, the total area to be covered and the efficiency required, the volume available to accommodate the detectors, characteristics of the environment such as chemical composition, temperature, magnetic field, ambient background, as well as ambient radiation of different types and, mode of operation (continuous or triggered), bias (high-voltage)

A large variety of PMT’s, including many just recently developed, covers a wide span of wavelength ranges from infrared (IR) to extreme ultraviolet (XUV) [10]. They are categorized by the window materials, photocathode materials, dynode structures, anode configurations, *etc.* Common window materials are borosilicate glass for IR to near-UV, fused quartz and sapphire (Al_2O_3) for UV, and MgF_2 or LiF for XUV. The choice of photocathode materials include a variety of mostly Cs- and/or Sb-based compounds such as CsI, CsTe, bi-alkali (SbRbCs, SbKCs), multi-alkali (SbNa_2KCs), GaAs(Cs), GaAsP, *etc.* Sensitive wavelengths and peak quantum efficiencies for these materials are summarized in Table 31.3. Typical dynode structures used in PMT’s are circular cage, line focusing, box and grid, venetian blind, and fine mesh. In some cases, limited spatial resolution can be obtained by using a mosaic of multiple anodes. Fast PMT’s with very large windows—measuring up to 508 mm across—have been developed in recent years for detection of Cherenkov radiation in neutrino experiments such as Super-Kamiokande and KamLAND among many others. Specially prepared low-radioactivity glass is used to make these PMT’s, and they are also able to withstand the high pressure of

the surrounding liquid.

PMT's are vulnerable to magnetic fields—sometimes even the geomagnetic field causes large orientation-dependent gain changes. A high-permeability metal shield is often necessary. However, proximity-focused PMT's, *e.g.* the fine-mesh types, can be used even in a high magnetic field (≥ 1 T) if the electron drift direction is parallel to the field. CMS uses custom-made vacuum phototriodes (VPT) mounted on the back face of projective lead tungstate crystals to detect scintillation light in the endcap sections of its electromagnetic calorimeters, which are inside a 3.8 T superconducting solenoid. A VPT employs a single dynode (thus, $G \approx 10$) placed close to the photocathode, and a mesh anode plane between the two, to help it cope with the strong magnetic field, which is not too unfavorably oriented with respect to the photodetector axis in the endcaps (within 25°), but where the radiation level is too high for Avalanche Photodiodes (APD's) like those used in the barrel section.

31.2.1.2. Microchannel plates: A typical Microchannel plate (MCP) photodetector consists of one or more ~ 2 mm thick glass plates with densely packed $O(10 \mu\text{m})$ -diameter cylindrical holes, or “channels”, sitting between the transmission-type photocathode and anode planes, separated by $O(1 \text{ mm})$ gaps. Instead of discrete dynodes, the inner surface of each cylindrical tube serves as a continuous dynode for the entire cascade of multiplicative bombardments initiated by a photoelectron. Gain fluctuations can be minimized by operating in a saturation mode, whence each channel is only capable of a binary output, but the sum of all channel outputs remains proportional to the number of photons received so long as the photon flux is low enough to ensure that the probability of a single channel receiving more than one photon during a single time gate is negligible. MCP's are thin, offer good spatial resolution, have excellent time resolution (~ 20 ps), and can tolerate random magnetic fields up to 0.1 T and axial fields up to ~ 1 T. However, they suffer from relatively long recovery time per channel and short lifetime. MCP's are widely employed as image-intensifiers, although not so much in HEP or astrophysics.

31.2.1.3. Hybrid photon detectors: Hybrid photon detectors (HPD) combine the sensitivity of a vacuum PMT with the excellent spatial and energy resolutions of a Si sensor [11]. A single photoelectron ejected from the photocathode is accelerated through a potential difference of ~ 20 kV before it impinges on the silicon sensor/anode. The gain nearly equals the maximum number of e - h pairs that could be created from the entire kinetic energy of the accelerated electron: $G \approx eV/w$, where e is the electronic charge, V is the applied potential difference, and $w \approx 3.7$ eV is the mean energy required to create an e - h pair in Si at room temperature. Since the gain is achieved in a single step, one might expect to have the excellent resolution of a simple Poisson statistic with large mean, but in fact it is even better, thanks to the Fano effect discussed in Sec. 31.7.

Low-noise electronics must be used to read out HPD's if one intends to take advantage of the low fluctuations in gain, *e.g.* when counting small numbers of photons. HPD's can have the same $\epsilon_Q \epsilon_C$ and window geometries as PMT's and can be segmented down to $\sim 50 \mu\text{m}$. However, they require rather high biases and will not function in a magnetic field. The exception is proximity-focused devices (\Rightarrow no (de)magnification) in an axial field. With time resolutions of ~ 10 ps and superior rate capability, proximity-focused HPD's can be an alternative to MCP's. Current applications of HPD's include the CMS hadronic calorimeter and the RICH detector in LHCb. Large-size HPD's with sophisticated focusing may be suitable for future water Cherenkov experiments.

Hybrid APD's (HAPD's) add an avalanche multiplication step following the electron bombardment to boost the gain by a factor of ~ 50 . This affords a higher gain and/or lower electrical bias, but also degrades the signal definition.

Table 31.3: Properties of photocathode and window materials commonly used in vacuum photodetectors [10].

Photocathode material	λ (nm)	Window material	Peak ϵ_Q (λ/nm)
CsI	115–200	MgF ₂	0.11 (140)
CsTe	115–320	MgF ₂	0.14 (240)
Bi-alkali	300–650	Borosilicate	0.27 (390)
	160–650	Synthetic Silica	0.27 (390)
“Ultra Bi-alkali”	300–650	Borosilicate	0.43 (350)
	160–650	Synthetic Silica	0.43 (350)
Multi-alkali	300–850	Borosilicate	0.20 (360)
	160–850	Synthetic Silica	0.20 (360)
GaAs(Cs)*	160–930	Synthetic Silica	0.23 (280)
GaAsP(Cs)	300–750	Borosilicate	0.50 (500)
InP/InGaAsP [†]	350–1700	Borosilicate	0.01 (1100)

*Reflection type photocathode is used. [†]Requires cooling to $\sim -80^\circ\text{C}$.

31.2.2. Gaseous photon detectors: In gaseous photomultipliers (GPM) a photoelectron in a suitable gas mixture initiates an avalanche in a high-field region, producing a large number of secondary impact-ionization electrons. In principle the charge multiplication and collection processes are identical to those employed in gaseous tracking detectors such as multiwire proportional chambers, micromesh gaseous detectors (Micromegas), or gas electron multipliers (GEM). These are discussed in Sec. 31.6.4.

The devices can be divided into two types depending on the photocathode material. One type uses solid photocathode materials much in the same way as PMT's. Since it is resistant to gas mixtures typically used in tracking chambers, CsI is a common choice. In the other type, photoionization occurs on suitable molecules vaporized and mixed in the drift volume. Most gases have photoionization work functions in excess of 10 eV, which would limit their sensitivity to wavelengths far too short. However, vapors of TMAE (tetrakis dimethyl-amine ethylene) or TEA (tri-ethyl-amine), which have smaller work functions (5.3 eV for TMAE and 7.5 eV for TEA), are suited for XUV photon detection [12]. Since devices like GEM's offer sub-mm spatial resolution, GPM's are often used as position-sensitive photon detectors. They can be made into flat panels to cover large areas ($O(1 \text{ m}^2)$), can operate in high magnetic fields, and are relatively inexpensive. Many of the ring imaging Cherenkov (RICH) detectors to date have used GPM's for the detection of Cherenkov light [13]. Special care must be taken to suppress the photon-feedback process in GPM's. It is also important to maintain high purity of the gas as minute traces of O₂ can significantly degrade the detection efficiency.

31.2.3. Solid-state photon detectors: In a phase of rapid development, solid-state photodetectors are competing with vacuum- or gas-based devices for many existing applications and making way for a multitude of new ones. Compared to traditional vacuum- and gaseous photodetectors, solid-state devices are more compact, lightweight, rugged, tolerant to magnetic fields, and often cheaper. They also allow fine pixelization, are easy to integrate into large systems, and can operate at low electric potentials, while matching or exceeding most performance criteria. They are particularly well suited for detection of γ - and X-rays. Except for applications where coverage of very large areas or dynamic range is required, solid-state detectors are proving to be the better choice. Some hybrid devices attempt to combine the best features of different technologies while applications of nanotechnology are opening up exciting new possibilities.

Silicon photodiodes (PD) are widely used in high-energy physics as particle detectors and in a great number of applications (including solar cells!) as light detectors. The structure is discussed in some detail in Sec. 31.7. In its simplest form, the PD is a reverse-biased p - n junction. Photons with energies above the indirect bandgap energy (wavelengths shorter than about 1050 nm, depending on the temperature) can create e - h pairs (the photoconductive effect), which are collected on the p and n sides, respectively. Often, as in the PD's

used for crystal scintillator readout in CLEO, L3, Belle, BaBar, and GLAST, intrinsic silicon is doped to create a *p-i-n* structure. The reverse bias increases the thickness of the depleted region; in the case of these particular detectors, to full depletion at a depth of about 100 μm . Increasing the depletion depth decreases the capacitance (and hence electronic noise) and extends the red response. Quantum efficiency can exceed 90%, but falls toward the red because of the increasing absorption length of light in silicon. The absorption length reaches 100 μm at 985 nm. However, since $G = 1$, amplification is necessary. Optimal low-noise amplifiers are slow, but, even so, noise limits the minimum detectable signal in room-temperature devices to several hundred photons.

Very large arrays containing $O(10^7)$ of $O(10 \mu\text{m}^2)$ -sized photodiodes pixelizing a plane are widely used to photograph all sorts of things from everyday subjects at visible wavelengths to crystal structures with X-rays and astronomical objects from infrared to UV. To limit the number of readout channels, these are made into charge-coupled devices (CCD), where pixel-to-pixel signal transfer takes place over thousands of synchronous cycles with sequential output through shift registers [14]. Thus, high spatial resolution is achieved at the expense of speed and timing precision. Custom-made CCD's have virtually replaced photographic plates and other imagers for astronomy and in spacecraft. Typical QE's exceed 90% over much of the visible spectrum, and "thick" CCD's have useful QE up to $\lambda = 1 \mu\text{m}$. Active Pixel Sensor (APS) arrays with a preamplifier on each pixel and CMOS processing afford higher speeds, but are challenged at longer wavelengths. Much R&D is underway to overcome the limitations of both CCD and CMOS imagers.

In APD's, an exponential cascade of impact ionizations initiated by the original photogenerated *e-h* pair under a large reverse-bias voltage leads to an avalanche breakdown [15]. As a result, detectable electrical response can be obtained from low-intensity optical signals down to single photons. Excellent junction uniformity is critical, and a guard ring is generally used as a protection against edge breakdown. Well-designed APD's, such as those used in CMS' crystal-based electromagnetic calorimeter, have achieved $\epsilon_Q \epsilon_C \approx 0.7$ with sub-ns response time. The sensitive wavelength window and gain depend on the semiconductor used. The gain is typically 10–200 in linear and up to 10^8 in Geiger mode of operation. Stability and close monitoring of the operating temperature are important for linear-mode operation, and substantial cooling is often necessary. Position-sensitive APD's use time information at multiple anodes to calculate the hit position.

One of the most promising recent developments in the field is that of devices consisting of large arrays ($O(10^3)$) of tiny APD's packed over a small area ($O(1 \text{ mm}^2)$) and operated in a limited Geiger mode [16]. Among different names used for this class of photodetectors, "PPD" (for "Pixelized Photon Detector") is most widely accepted (formerly "SiPM"). Although each cell only offers a binary output, linearity with respect to the number of photons is achieved by summing the cell outputs in the same way as with a MCP in saturation mode (see above). PPD's are being adopted as the preferred solution for various purposes including medical imaging, *e.g.* positron emission tomography (PET). These compact, rugged, and economical devices allow auto-calibration through decent separation of photoelectron peaks and offer gains of $O(10^6)$ at a moderate bias voltage ($\sim 50 \text{ V}$). However, the single-photoelectron noise of a PPD, being the logical "or" of $O(10^3)$ Geiger APD's, is rather large: $O(1 \text{ MHz/mm}^2)$ at room temperature. PPD's are particularly well-suited for applications where triggered pulses of several photons are expected over a small area, *e.g.* fiber-guided scintillation light. Intense R&D is expected to lower the noise level and improve radiation hardness, resulting in coverage of larger areas and wider applications. Attempts are being made to combine the fabrication of the sensors and the front-end electronics (ASIC) in the same process with the goal of making PPD's and other finely pixelized solid-state photodetectors extremely easy to use.

Of late, much R&D has been directed to *p-i-n* diode arrays based on thin polycrystalline diamond films formed by chemical vapor deposition (CVD) on a hot substrate ($\sim 1000 \text{ K}$) from a hydrocarbon-containing gas mixture under low pressure ($\sim 100 \text{ mbar}$). These devices have maximum sensitivity in the extreme- to moderate-UV

region [17]. Many desirable characteristics, including high tolerance to radiation and temperature fluctuations, low dark noise, blindness to most of the solar radiation spectrum, and relatively low cost make them ideal for space-based UV/XUV astronomy, measurement of synchrotron radiation, and luminosity monitoring at (future) lepton collider(s).

Visible-light photon counters (VLPC) utilize the formation of an impurity band only 50 meV below the conduction band in As-doped Si to generate strong ($G \approx 5 \times 10^4$) yet sharp response to single photons with $\epsilon_Q \approx 0.9$ [18]. The smallness of the band gap considerably reduces the gain dispersion. Only a very small bias ($\sim 7 \text{ V}$) is needed, but high sensitivity to infrared photons requires cooling below 10 K. The dark noise increases sharply and exponentially with both temperature and bias. The Run 2 DØ detector used 86000 VLPC's to read the optical signal from its scintillating-fiber tracker and scintillator-strip preshower detectors.

31.3. Organic scintillators

Revised August 2011 by Kurtis F. Johnson (FSU).

Organic scintillators are broadly classed into three types, crystalline, liquid, and plastic, all of which utilize the ionization produced by charged particles (see Sec. 30.2 of this *Review*) to generate optical photons, usually in the blue to green wavelength regions [19]. Plastic scintillators are by far the most widely used, liquid organic scintillator is finding increased use, and crystal organic scintillators are practically unused in high-energy physics. Plastic scintillator densities range from 1.03 to 1.20 g cm^{-3} . Typical photon yields are about 1 photon per 100 eV of energy deposit [20]. A one-cm-thick scintillator traversed by a minimum-ionizing particle will therefore yield $\approx 2 \times 10^4$ photons. The resulting photoelectron signal will depend on the collection and transport efficiency of the optical package and the quantum efficiency of the photodetector.

Organic scintillator does not respond linearly to the ionization density. Very dense ionization columns emit less light than expected on the basis of dE/dx for minimum-ionizing particles. A widely used semi-empirical model by Birks posits that recombination and quenching effects between the excited molecules reduce the light yield [21]. These effects are more pronounced the greater the density of the excited molecules. Birks' formula is

$$\frac{d\mathcal{L}}{dx} = \mathcal{L}_0 \frac{dE/dx}{1 + k_B dE/dx}, \quad (31.2)$$

where \mathcal{L} is the luminescence, \mathcal{L}_0 is the luminescence at low specific ionization density, and k_B is Birks' constant, which must be determined for each scintillator by measurement. Decay times are in the ns range; rise times are much faster. The high light yield and fast response time allow the possibility of sub-ns timing resolution [22]. The fraction of light emitted during the decay "tail" can depend on the exciting particle. This allows pulse shape discrimination as a technique to carry out particle identification. Because of the hydrogen content (carbon to hydrogen ratio ≈ 1) plastic scintillator is sensitive to proton recoils from neutrons. Ease of fabrication into desired shapes and low cost has made plastic scintillator a common detector element. In the form of scintillating fiber it has found widespread use in tracking and calorimetry [23].

Demand for large volume detectors has lead to increased use of liquid organic scintillator, which has the same scintillation mechanism as plastic scintillator, due to its cost advantage. The containment vessel defines the detector shape; photodetectors or waveshifters may be immersed in the liquid.

31.3.1. Scintillation mechanism :

A charged particle traversing matter leaves behind it a wake of excited molecules. Certain types of molecules, however, will release a small fraction ($\approx 3\%$) of this energy as optical photons. This process, scintillation, is especially marked in those organic substances which contain aromatic rings, such as polystyrene (PS) and polyvinyltoluene (PVT). Liquids which scintillate include toluene, xylene and pseudocumene.

In fluorescence, the initial excitation takes place via the absorption of a photon, and de-excitation by emission of a longer wavelength photon. Fluors are used as “wavelength shifters” to shift scintillation light to a more convenient wavelength. Occurring in complex molecules, the absorption and emission are spread out over a wide band of photon energies, and have some overlap, that is, there is some fraction of the emitted light which can be re-absorbed [24]. This “self-absorption” is undesirable for detector applications because it causes a shortened attenuation length. The wavelength difference between the major absorption and emission peaks is called the Stokes shift. It is usually the case that the greater the Stokes shift, the smaller the self-absorption thus, a large Stokes shift is a desirable property for a fluor.

Figure 31.1: Cartoon of scintillation “ladder” depicting the operating mechanism of organic scintillator. Approximate fluor concentrations and energy transfer distances for the separate sub-processes are shown.

The plastic scintillators used in high-energy physics are binary or ternary solutions of selected fluors in a plastic base containing aromatic rings. (See the appendix in Ref. 25 for a comprehensive list of components.) Virtually all plastic scintillators contain as a base either PVT or PS. PVT-based scintillator can be up to 50% brighter.

Ionization in the plastic base produces UV photons with short attenuation length (several mm). Longer attenuation lengths are obtained by dissolving a “primary” fluor in high concentration (1% by weight) into the base, which is selected to efficiently re-radiate absorbed energy at wavelengths where the base is more transparent (see Fig. 31.1).

The primary fluor has a second important function. The decay time of the scintillator base material can be quite long – in pure polystyrene it is 16 ns, for example. The addition of the primary fluor in high concentration can shorten the decay time by an order of magnitude and increase the total light yield. At the concentrations used (1% and greater), the average distance between a fluor molecule and an excited base unit is around 100 Å, much less than a wavelength of light. At these distances the predominant mode of energy transfer from base to fluor is not the radiation of a photon, but a resonant dipole-dipole interaction, first described by Foerster, which strongly couples the base and fluor [26]. The strong coupling sharply increases the speed and the light yield of the plastic scintillators.

Unfortunately, a fluor which fulfills other requirements is usually not completely adequate with respect to emission wavelength or attenuation length, so it is necessary to add yet another wavelength shifter (the “secondary” fluor), at fractional percent levels, and occasionally a third (not shown in Fig. 31.1).

External wavelength shifters are widely used to aid light collection in complex geometries. Scintillation light is captured by a lightpipe

comprising a wave-shifting fluor dissolved in a nonscintillating base. The wavelength shifter must be insensitive to ionizing radiation and Cherenkov light. A typical wavelength shifter uses an acrylic base because of its good optical qualities, a single fluor to shift the light emerging from the plastic scintillator to the blue-green, and contains ultra-violet absorbing additives to deaden response to Cherenkov light.

31.3.2. Caveats and cautions :

Plastic scintillators are reliable, robust, and convenient. However, they possess quirks to which the experimenter must be alert. Exposure to solvent vapors, high temperatures, mechanical flexing, irradiation, or rough handling will aggravate the process. A particularly fragile region is the surface which can “craze” develop microcracks which degrade its transmission of light by total internal reflection. Crazing is particularly likely where oils, solvents, or *fingerprints* have contacted the surface.

They have a long-lived luminescence which does not follow a simple exponential decay. Intensities at the 10^{-4} level of the initial fluorescence can persist for hundreds of ns [19,27].

They will decrease their light yield with increasing partial pressure of oxygen. This can be a 10% effect in an artificial atmosphere [28]. It is not excluded that other gases may have similar quenching effects.

Their light yield may be changed by a magnetic field. The effect is very nonlinear and apparently not all types of plastic scintillators are so affected. Increases of $\approx 3\%$ at 0.45 T have been reported [29]. Data are sketchy and mechanisms are not understood.

Irradiation of plastic scintillators creates color centers which absorb light more strongly in the UV and blue than at longer wavelengths. This poorly understood effect appears as a reduction both of light yield and attenuation length. Radiation damage depends not only on the integrated dose, but on the dose rate, atmosphere, and temperature, before, during and after irradiation, as well as the materials properties of the base such as glass transition temperature, polymer chain length, *etc.* Annealing also occurs, accelerated by the diffusion of atmospheric oxygen and elevated temperatures. The phenomena are complex, unpredictable, and not well understood [30]. Since color centers are less disruptive at longer wavelengths, the most reliable method of mitigating radiation damage is to shift emissions at every step to the longest practical wavelengths, *e.g.*, utilize fluors with large Stokes shifts (aka the “Better red than dead” strategy).

31.3.3. Scintillating and wavelength-shifting fibers :

The clad optical fiber comprising scintillator and wavelength shifter (WLS) is particularly useful [31]. Since the initial demonstration of the scintillating fiber (SCIFI) calorimeter [32], SCIFI techniques have become mainstream [33]. SCIFI calorimeters are fast, dense, radiation hard, and can have leadglass-like resolution. SCIFI trackers can handle high rates and are radiation tolerant, but the low photon yield at the end of a long fiber (see below) forces the use of sensitive photodetectors. WLS scintillator readout of a calorimeter allows a very high level of hermeticity since the solid angle blocked by the fiber on its way to the photodetector is very small. The sensitive region of scintillating fibers can be controlled by splicing them onto clear (non-scintillating/non-WLS) fibers.

A typical configuration would be fibers with a core of polystyrene-based scintillator or WLS (index of refraction $n = 1.59$), surrounded by a cladding of PMMA ($n = 1.49$) a few microns thick, or, for added light capture, with another cladding of fluorinated PMMA with $n = 1.42$, for an overall diameter of 0.5 to 1 mm. The fiber is drawn from a boule and great care is taken during production to ensure that the intersurface between the core and the cladding has the highest possible uniformity and quality, so that the signal transmission via total internal reflection has a low loss. The fraction of generated light which is transported down the optical pipe is denoted the capture fraction and is about 6% for the single-clad fiber and 10% for the double-clad fiber. The number of photons from the fiber available at the photodetector is always smaller than desired, and increasing the light yield has proven difficult. A minimum-ionizing particle traversing a high-quality 1 mm diameter fiber perpendicular to its axis will produce fewer than 2000 photons, of which about 200 are captured. Attenuation may eliminate 95% of these photons in a large collider tracker.

A scintillating or WLS fiber is often characterized by its attenuation

length, over which the signal is attenuated to $1/e$ of its original value. Many factors determine the attenuation length, including the importance of re-absorption of emitted photons by the polymer base or dissolved fluors, the level of crystallinity of the base polymer, and the quality of the total internal reflection boundary [34]. Attenuation lengths of several meters are obtained by high quality fibers. However, it should be understood that the attenuation length is not the sole measure of fiber quality. Among other things, it is not constant with distance from the excitation source and it is wavelength dependent.

31.4. Inorganic scintillators:

Revised September 2009 by R.-Y. Zhu (California Institute of Technology) and C.L. Woody (BNL).

Inorganic crystals form a class of scintillating materials with much higher densities than organic plastic scintillators (typically $\sim 4\text{--}8\text{ g/cm}^3$) with a variety of different properties for use as scintillation detectors. Due to their high density and high effective atomic number, they can be used in applications where high stopping power or a high conversion efficiency for electrons or photons is required. These include total absorption electromagnetic calorimeters (see Sec. 31.9.1), which consist of a totally active absorber (as opposed to a sampling calorimeter), as well as serving as gamma ray detectors over a wide range of energies. Many of these crystals also have very high light output, and can therefore provide excellent energy resolution down to very low energies (\sim few hundred keV).

Some crystals are intrinsic scintillators in which the luminescence is produced by a part of the crystal lattice itself. However, other crystals require the addition of a dopant, typically fluorescent ions such as thallium (Tl) or cerium (Ce) which is responsible for producing the scintillation light. However, in both cases, the scintillation mechanism is the same. Energy is deposited in the crystal by ionization, either directly by charged particles, or by the conversion of photons into electrons or positrons which subsequently produce ionization. This energy is transferred to the luminescent centers which then radiate scintillation photons. The efficiency η for the conversion of energy deposit in the crystal to scintillation light can be expressed by the relation [35]

$$\eta = \beta \cdot S \cdot Q \quad (31.3)$$

where β is the efficiency of the energy conversion process, S is the efficiency of energy transfer to the luminescent center, and Q is the quantum efficiency of the luminescent center. The value of η ranges between 0.1 and ~ 1 depending on the crystal, and is the main factor in determining the intrinsic light output of the scintillator. In addition, the scintillation decay time is primarily determined by the energy transfer and emission process. The decay time of the scintillator is mainly dominated by the decay time of the luminescent center. For example, in the case of thallium doped sodium iodide (NaI(Tl)), the value of η is ~ 0.5 , which results in a light output $\sim 40,000$ photons per MeV of energy deposit. This high light output is largely due to the high quantum efficiency of the thallium ion ($Q \sim 1$), but the decay time is rather slow ($\tau \sim 250$ ns).

Table 31.4 lists the basic properties of some commonly used inorganic crystal scintillators. NaI(Tl) is one of the most common and widely used scintillators, with an emission that is well matched to a bi-alkali photomultiplier tube, but it is highly hygroscopic and difficult to work with, and has a rather low density. CsI(Tl) has high light yield, an emission that is well matched to solid state photodiodes, and is mechanically robust (high plasticity and resistance to cracking). However, it needs careful surface treatment and is slightly hygroscopic. Compared with CsI(Tl), pure CsI has identical mechanical properties, but faster emission at shorter wavelengths and light output approximately an order of magnitude lower. BaF₂ has a fast component with a sub-nanosecond decay time, and is the fastest known scintillator. However, it also has a slow component with a much longer decay time (~ 630 ns). Bismuth germanate (Bi₄Ge₃O₁₂ or BGO) has a high density, and consequently a short radiation length X_0 and Molière radius R_M . BGO's emission is well-matched to the spectral sensitivity of photodiodes, and it is easy to handle and not hygroscopic. Lead tungstate (PbWO₄ or PWO) has a very high density, with a very short X_0 and R_M , but its intrinsic light yield is rather low.

Cerium doped lutetium oxyorthosilicate (Lu₂SiO₅:Ce, or LSO:Ce) [36] and cerium doped lutetium-yttrium oxyorthosilicate (Lu_{2(1-x)}Y_{2x}SiO₅, LYSO:Ce) [37] are dense crystal scintillators which have a high light yield and a fast decay time. Only properties of LSO:Ce is listed in Table 31.4 since the properties of LYSO:Ce are similar to that of LSO:Ce except a little lower density than LSO:Ce depending on the yttrium fraction in LYSO:Ce. This material is also featured with excellent radiation hardness [38], so is expected to be used where extraordinary radiation hardness is required.

Table 31.4 also includes cerium doped lanthanum tri-halides, such as LaBr₃ [39], which is brighter and faster than LSO:Ce, but it is highly hygroscopic and has a lower density. The FWHM energy resolution measured for this material coupled to a PMT with bi-alkali photocathode for 0.662 MeV γ -rays from a ¹³⁷Cs source is about 3%, which is the best among all inorganic crystal scintillators. For this reason, LaBr₃ is expected to be widely used in applications where a good energy resolution for low energy photons are required, such as homeland security.

Beside the crystals listed in Table 31.4, a number of new crystals are being developed that may have potential applications in high energy or nuclear physics. Of particular interest is the family of yttrium and lutetium perovskites, which include YAP (YAlO₃:Ce) and LuAP (LuAlO₃:Ce) and their mixed compositions. These have been shown to be linear over a large energy range [40], and have the potential for providing extremely good intrinsic energy resolution. In addition, other fluoride crystals such as CeF₃ have been shown to provide excellent energy resolution in calorimeter applications.

Aiming at the best jet-mass resolution inorganic scintillators are being investigated for HEP calorimeters with dual readout for both Cherenkov and scintillation light to be used at future linear colliders. These materials may be used for an electromagnetic calorimeter [41] or a homogeneous hadronic calorimetry (HHCAL) detector concept, including both electromagnetic and hadronic parts [42]. Because of the unprecedented volume (70 to 100 m³) foreseen for the HHCAL detector concept the materials must be (1) dense (to minimize the leakage) and (2) cost-effective. It should also be UV transparent (for effective collection of the Cherenkov light) and allow for a clear discrimination between the Cherenkov and scintillation light. The preferred scintillation light is thus at a longer wavelength, and not necessarily bright or fast. Dense crystals, scintillating glasses and ceramics offer a very attractive implementation for this detector concept. Inorganic crystals being investigated are lead fluoride (PbF₂), lead chloride fluoride (PbFCl) and BSO [43].

Table 31.4 gives the light output of other crystals relative to NaI(Tl) and their dependence to the temperature variations measured for crystal samples of 1.5 X_0 cube with a Tyvek paper wrapping and a full end face coupled to a photodetector [44]. The quantum efficiencies of the photodetector is taken out to facilitate a direct comparison of crystal's light output. However, the useful signal produced by a scintillator is usually quoted in terms of the number of photoelectrons per MeV produced by a given photodetector. The relationship between the number of photons/MeV produced and photoelectrons/MeV detected involves the factors for the light collection efficiency L and the quantum efficiency QE of the photodetector:

$$N_{p.e.}/\text{MeV} = L \cdot QE \cdot N_{\gamma}/\text{MeV} \quad (31.4)$$

L includes the transmission of scintillation light within the crystal (*i.e.*, the bulk attenuation length of the material), reflections and scattering from the surfaces, and the size and shape of the crystal. These factors can vary considerably depending on the sample, but can be in the range of $\sim 10\text{--}60\%$. The internal light transmission depends on the intrinsic properties of the material, *e.g.* the density and type of the scattering centers and defects that can produce internal absorption within the crystal, and can be highly affected by factors such as radiation damage, as discussed below.

The quantum efficiency depends on the type of photodetector used to detect the scintillation light, which is typically $\sim 15\text{--}20\%$ for photomultiplier tubes and $\sim 70\%$ for silicon photodiodes for visible wavelengths. The quantum efficiency of the detector is usually highly wavelength dependent and should be matched to the particular crystal of interest to give the highest quantum yield at the wavelength

corresponding to the peak of the scintillation emission. Fig. 31.2 shows the quantum efficiencies of two photodetectors, a Hamamatsu R2059 PMT with bi-alkali cathode and quartz window and a Hamamatsu S8664 avalanche photodiode (APD) as a function of wavelength. Also shown in the figure are emission spectra of three crystal scintillators, BGO, LSO:Ce/LYSO:Ce and CsI(Tl), and the numerical values of the emission weighted quantum efficiency. The area under each emission spectrum is proportional to crystal's light yield, as shown in Table 31.4, where the quantum efficiencies of the photodetector has been taken out. Results with different photodetectors can be significantly different. For example, the response of CsI(Tl) relative to NaI(Tl) with a standard photomultiplier tube with a bi-alkali photo-cathode, e.g. Hamamatsu R2059, would be 45 rather than 165 because of the photomultiplier's low quantum efficiency at longer wavelengths. For scintillators which emit in the UV, a detector with a quartz window should be used.

For very low energy applications (typically below 1 MeV), non-proportionality of the scintillation light yield may be important. It has been known for a long time that the conversion factor between the energy deposited in a crystal scintillator and the number of photons produced is not constant. It is also known that the energy resolution measured by all crystal scintillators for low energy γ -rays is significantly worse than the contribution from photo-electron statistics alone, indicating an intrinsic contribution from the scintillator itself. Precision measurement using low energy electron beam shows that this non-proportionality is crystal dependent [45]. Recent study on this issue also shows that this effect is also sample dependent even for the same crystal [46]. Further work is therefore needed to fully understand this subject.

One important issue related to the application of a crystal scintillator is its radiation hardness. Stability of its light output, or the ability to track and monitor the variation of its light output in a radiation environment, is required for high resolution and precision calibration [47]. All known crystal scintillators suffer from radiation damage. A common damage phenomenon is the appearance of radiation induced absorption caused by the formation of color centers originated from the impurities or point defects in the crystal. This radiation induced absorption reduces the light attenuation length in the crystal, and hence its light output. For crystals with high defect density, a severe reduction of light attenuation length may cause a distortion of the light response uniformity, leading to a degradation of the energy resolution. Additional radiation damage effects may include a reduced intrinsic scintillation light yield (damage to the luminescent centers) and an increased phosphorescence (afterglow). For crystals to be used in the construction a high precision calorimeter in a radiation environment, its scintillation mechanism must not be damaged and its light attenuation length in the expected radiation environment must be long enough so that its light response uniformity, and thus its energy resolution, does not change [48].

Most of the crystals listed in Table 31.4 have been used in high energy or nuclear physics experiments when the ultimate energy resolution for electrons and photons is desired. Examples are the Crystal Ball NaI(Tl) calorimeter at SPEAR, the L3 BGO calorimeter at LEP, the CLEO CsI(Tl) calorimeter at CESR, the KTeV CsI calorimeter at the Tevatron, the BaBar, BELLE and BES II CsI(Tl) calorimeters at PEP-II, KEK and BEPC III. Because of its high density and relative low cost, PWO calorimeters are widely used by CMS and ALICE at LHC, by CLAS and PrimEx at CEBAF, and by PANDA at GSI. Recently, investigations have been made aiming at using LSO:Ce or LYSO:Ce crystals for future high energy or nuclear physics experiments [38].

31.5. Cherenkov detectors

Revised September 2009 by B.N. Ratcliff (SLAC).

Although devices using Cherenkov radiation are often thought of as only particle identification (PID) detectors, in practice they are used over a broader range of applications including; (1) fast particle counters; (2) hadronic PID; and (3) tracking detectors performing complete event reconstruction. Examples of applications from each category include; (1) the BaBar luminosity detector [49]; (2) the hadronic PID detectors at the B factory detectors—DIRC in BaBar [50] and the aerogel threshold Cherenkov in Belle [51]; and (3) large water Cherenkov counters such as Super-Kamiokande [53]. Cherenkov counters contain two main elements; (1) a radiator through which the charged particle passes, and (2) a photodetector. As Cherenkov radiation is a weak source of photons, light collection and detection must be as efficient as possible. The refractive index n and the particle's path length through the radiator L appear in the Cherenkov relations allowing the tuning of these quantities for particular applications.

Cherenkov detectors utilize one or more of the properties of Cherenkov radiation discussed in the Passages of Particles through Matter section (Sec. 30 of this *Review*): the prompt emission of a light pulse; the existence of a velocity threshold for radiation; and the dependence of the Cherenkov cone half-angle θ_c and the number of emitted photons on the velocity of the particle and the refractive index of the medium.

The number of photoelectrons ($N_{p.e.}$) detected in a given device is

$$N_{p.e.} = L \frac{\alpha^2 z^2}{r_e m_e c^2} \int \epsilon(E) \sin^2 \theta_c(E) dE, \quad (31.5)$$

where $\epsilon(E)$ is the efficiency for collecting the Cherenkov light and transducing it into photoelectrons, and $\alpha^2/(r_e m_e c^2) = 370 \text{ cm}^{-1} \text{ eV}^{-1}$.

The quantities ϵ and θ_c are functions of the photon energy E . As the typical energy dependent variation of the index of refraction is modest, a quantity called the *Cherenkov detector quality factor* N_0 can be defined as

$$N_0 = \frac{\alpha^2 z^2}{r_e m_e c^2} \int \epsilon dE, \quad (31.6)$$

so that, taking $z = 1$ (the usual case in high-energy physics),

$$N_{p.e.} \approx L N_0 (\sin^2 \theta_c). \quad (31.7)$$

This definition of the quality factor N_0 is not universal, nor, indeed, very useful for those common situations where ϵ factorizes as $\epsilon = \epsilon_{\text{coll}} \epsilon_{\text{det}}$ with the geometrical photon collection efficiency (ϵ_{coll}) varying substantially for different tracks while the photon detector efficiency (ϵ_{det}) remains nearly track independent. In this case, it can be useful to explicitly remove (ϵ_{coll}) from the definition of N_0 . A typical value of N_0 for a photomultiplier (PMT) detection system working in the visible and near UV, and collecting most of the Cherenkov light, is about 100 cm^{-1} . Practical counters, utilizing a variety of different photodetectors, have values ranging between about 30 and 180 cm^{-1} . Radiators can be chosen from a variety of transparent materials (Sec. 30 of this *Review* and Table 6.1). In addition to refractive index, the choice requires consideration of factors such as material density, radiation length and radiation hardness, transmission bandwidth, absorption length, chromatic dispersion, optical workability (for solids), availability, and cost. When the momenta of particles to be identified is high, the refractive index must be set close to one, so that the photon yield per unit length is low and a long particle path in the radiator is required. Recently, the gap in refractive index that has traditionally existed between gases and liquid or solid materials has been partially closed with transparent *silica aerogels* with indices that range between about 1.007 and 1.13.

Cherenkov counters may be classified as either *imaging* or *threshold* types, depending on whether they do or do not make use of Cherenkov angle (θ_c) information. Imaging counters may be used to track particles as well as identify them. The recent development of very fast photodetectors such as micro-channel plate PMTs (MCP PMT) (see Sec. 31.2 of this *Review*) also potentially allows very fast Cherenkov based time of flight (TOF) detectors of either class [57].

Threshold Cherenkov detectors [54], in their simplest form, make a yes/no decision based on whether the particle is above or below the Cherenkov threshold velocity $\beta_t = 1/n$. A straightforward enhancement of such detectors uses the number of observed photoelectrons (or a calibrated pulse height) to discriminate between species or to set probabilities for each particle species [55]. This strategy can increase the momentum range of particle separation by a modest amount (to a momentum some 20% above the threshold momentum of the heavier particle in a typical case).

Careful designs give $\langle \epsilon_{\text{coll}} \rangle \gtrsim 90\%$. For a photomultiplier with a typical bi-alkali cathode, $\int \epsilon_{\text{det}} dE \approx 0.27 \text{ eV}$, so that

$$N_{p.e.}/L \approx 90 \text{ cm}^{-1} (\sin^2 \theta_c) \quad (\text{i.e., } N_0 = 90 \text{ cm}^{-1}). \quad (31.8)$$

Suppose, for example, that n is chosen so that the threshold for species a is p_t ; that is, at this momentum species a has velocity $\beta_a = 1/n$. A second, lighter, species b with the same momentum has velocity β_b , so $\cos \theta_c = \beta_a/\beta_b$, and

$$N_{p.e.}/L \approx 90 \text{ cm}^{-1} \frac{m_a^2 - m_b^2}{p_t^2 + m_a^2}. \quad (31.9)$$

For K/π separation at $p = p_t = 1(5) \text{ GeV}/c$, $N_{p.e.}/L \approx 16(0.8) \text{ cm}^{-1}$ for π 's and (by design) 0 for K 's.

For limited path lengths $N_{p.e.}$ will usually be small. The overall efficiency of the device is controlled by Poisson fluctuations, which can be especially critical for separation of species where one particle type is dominant. Moreover, the effective number of photoelectrons is often less than the average number calculated above due to additional equivalent noise from the photodetector (see the discussion of the excess noise factor in Sec. 31.2 of this *Review*). It is common to design for at least 10 photoelectrons for the high velocity particle in order to obtain a robust counter. As rejection of the particle that is below threshold depends on *not* seeing a signal, electronic and other background noise can be important. Physics sources of light production for the below threshold particle, such as decay to an above threshold particle or the production of delta rays in the radiator, often limit the separation attainable, and need to be carefully considered. Well designed, modern multi-channel counters, such as the ACC at Belle [51], can attain adequate particle separation performance over a substantial momentum range for essentially the full solid angle of the spectrometer.

Imaging counters make the most powerful use of the information available by measuring the ring-correlated angles of emission of the individual Cherenkov photons. Since low-energy photon detectors can measure only the position (and, perhaps, a precise detection time) of the individual Cherenkov photons (not the angles directly), the photons must be “imaged” onto a detector so that their angles can be derived [56]. Typically the optics map the Cherenkov cone onto (a portion of) a distorted “circle” at the photodetector. Though the imaging process is directly analogous to familiar imaging techniques used in telescopes and other optical instruments, there is a somewhat bewildering variety of methods used in a wide variety of counter types with different names. Some of the imaging methods used include (1) focusing by a lens; (2) proximity focusing (i.e., focusing by limiting the emission region of the radiation); and (3) focusing through an aperture (a pinhole). In addition, the prompt Cherenkov emission coupled with the speed of modern photon detectors allows the use of (4) time imaging, a method which is little used in conventional imaging technology. Finally, (5) correlated tracking (and event reconstruction) can be performed in large water counters by combining the individual space position and time of each photon together with the constraint that Cherenkov photons are emitted from each track at the same polar angle (Sec. 32.3.1 of this *Review*).

In a simple model of an imaging PID counter, the fractional error on the particle velocity (δ_β) is given by

$$\delta_\beta \approx \frac{\sigma_\beta}{\beta} = \tan \theta_c \sigma(\theta_c) \quad , \quad (31.10)$$

where

$$\sigma(\theta_c) = \frac{\langle \sigma(\theta_i) \rangle}{\sqrt{N_{p.e.}}} \oplus C \quad , \quad (31.11)$$

and $\langle \sigma(\theta_i) \rangle$ is the average single photoelectron resolution, as defined by the optics, detector resolution and the intrinsic chromaticity spread of the radiator index of refraction averaged over the photon detection bandwidth. C combines a number of other contributions to resolution including, (1) correlated terms such as tracking, alignment, and multiple scattering, (2) hit ambiguities, (3) background hits from random sources, and (4) hits coming from other tracks. The actual separation performance is also limited by physics effects such as decays in flight and particle interactions in the material of the detector. In many practical cases, the performance is limited by these effects.

For a $\beta \approx 1$ particle of momentum (p) well above threshold entering a radiator with index of refraction (n), the number of σ separation (N_σ) between particles of mass m_1 and m_2 is approximately

$$N_\sigma \approx \frac{|m_1^2 - m_2^2|}{2p^2 \sigma(\theta_c) \sqrt{n^2 - 1}} \quad . \quad (31.12)$$

In practical counters, the angular resolution term $\sigma(\theta_c)$ varies between about 0.1 and 5 mrad depending on the size, radiator, and photodetector type of the particular counter. The range of momenta over which a particular counter can separate particle species extends from the point at which the number of photons emitted becomes sufficient for the counter to operate efficiently as a threshold device ($\sim 20\%$ above the threshold for the lighter species) to the value in the imaging region given by the equation above. For example, for $\sigma(\theta_c) = 2\text{mrad}$, a fused silica radiator ($n = 1.474$), or a fluorocarbon gas radiator (C_5F_{12} , $n = 1.0017$), would separate π/K 's from the threshold region starting around 0.15(3) GeV/ c through the imaging region up to about 4.2(18) GeV/ c at better than 3σ .

Many different imaging counters have been built during the last several decades [57]. Among the earliest examples of this class of counters are the very limited acceptance Differential Cherenkov detectors, designed for particle selection in high momentum beam lines. These devices use optical focusing and/or geometrical masking to select particles having velocities in a specified region. With careful design, a velocity resolution of $\sigma_\beta/\beta \approx 10^{-4}$ – 10^{-5} can be obtained [54].

Practical multi-track Ring-Imaging Cherenkov detectors (generically called RICH counters) are a more recent development. RICH counters are sometimes further classified by ‘generations’ that differ based on historical timing, performance, design, and photodetection techniques.

Prototypical examples of first generation RICH counters are those used in the DELPHI and SLD detectors at the LEP and SLC Z factory e^+e^- colliders [57]. They have both liquid (C_6F_{14} , $n = 1.276$) and gas (C_5F_{12} , $n = 1.0017$) radiators, the former being proximity imaged with the latter using mirrors. The phototransducers are a TPC/wire-chamber combination. They are made sensitive to photons by doping the TPC gas (usually, ethane/methane) with $\sim 0.05\%$ TMAE (tetrakis(dimethylamino)ethylene). Great attention to detail is required, (1) to avoid absorbing the UV photons to which TMAE is sensitive, (2) to avoid absorbing the single photoelectrons as they drift in the long TPC, and (3) to keep the chemically active TMAE vapor from interacting with materials in the system. In spite of their unforgiving operational characteristics, these counters attained good $e/\pi/K/p$ separation over wide momentum ranges (from about 0.25 to 20 GeV/ c) during several years of operation at LEP and SLC. Related but smaller acceptance devices include the OMEGA RICH at the CERN SPS, and the RICH in the balloon-borne CAPRICE detector [57].

Later generation counters [57] generally operate at much higher rates, with more detection channels, than the first generation detectors just described. They also utilize faster, more forgiving photon detectors, covering different photon detection bandwidths. Radiator choices have broadened to include materials such as lithium fluoride, fused silica, and aerogel. Vacuum based photodetection systems (*e.g.*, single or multi anode PMTs, MCP PMTs, or hybrid photodiodes (HPD)) have become increasingly common (see Sec. 31.2 of this *Review*). They handle high rates, and can be used with a wide choice of radiators. Examples include (1) the SELEX RICH at Fermilab, which mirror focuses the Cherenkov photons from a neon radiator onto a camera array made of ~ 2000 PMTs to separate hadrons over a wide momentum range (to well above 200 GeV/ c for heavy hadrons); (2) the HERMES RICH at HERA, which mirror focuses photons from C_4F_{10} ($n = 1.00137$) and aerogel ($n = 1.0304$) radiators within the same volume onto a PMT camera array to separate hadrons in the momentum range from 2 to 15 GeV/ c ; and (3) the LHCb detector now being brought into operation at the LHC. It uses two separate counters. One volume, like HERMES, contains two radiators (aerogel and C_4F_{10}) while the second volume contains CF_4 . Photons are mirror focused onto detector arrays of HPDs to cover a π/K separation momentum range between 1 and 150 GeV/ c .

Other fast detection systems that use solid cesium iodide (CsI) photocathodes or triethylamine (TEA) doping in proportional chambers are useful with certain radiator types and geometries. Examples include (1) the CLEO-III RICH at CESR that uses a LiF radiator with TEA doped proportional chambers; (2) the ALICE detector at the LHC that uses proximity focused liquid (C_6F_{14}) radiators and solid CSI photocathodes (similar photodetectors have been used for several years by the HADES and COMPASS detectors), and the hadron blind detector (HBD) in the PHENIX detector at RHIC that couples a low index CF_4 radiator to a photodetector based on electron multiplier (GEM) chambers with reflective CSI photocathodes [57].

A DIRC (Detection [of] Internally Reflected Cherenkov [light]) is a distinctive, compact RICH subtype first used in the BaBar detector [52]. A DIRC “inverts” the usual RICH principle for use of light from the radiator by collecting and imaging the total internally reflected light rather than the transmitted light. It utilizes the optical material of the radiator in two ways, simultaneously; first as a Cherenkov radiator, and second, as a light pipe. The magnitudes of the photon angles are preserved during transport by the flat, rectangular cross section radiators, allowing the photons to be efficiently transported to a detector outside the path of the particle where they may be imaged in up to three independent dimensions (the usual two in space and, due to the long photon paths lengths, one in time). Because the index of refraction in the radiator is large (~ 1.48 for fused silica), the momentum range with good π/K separation is rather low. The BaBar DIRC range extends up to ~ 4 GeV/ c . It is plausible, but difficult, to extend it up to about 10 GeV/ c with an improved design. New DIRC detectors are being developed that take advantage of the new, very fast, pixelated photodetectors becoming available, such as flat panel PMTs and MCP PMTs. They

typically utilize either time imaging or mirror focused optics, or both, leading not only to a precision measurement of the Cherenkov angle, but in some cases, to a precise measurement of the particle time of flight, and/or to correction of the chromatic dispersion in the radiator. Examples include (1) the time of propagation (TOP) counter being developed for the BELLE-II upgrade at KEKB which emphasizes precision timing for both Cherenkov imaging and TOF; (2) the full 3-dimensional imaging FDIRC for the SuperB detector at the Italian SuperB collider which uses precision timing not only for improving the angle reconstruction and TOF, but also to correct the chromatic dispersion; and (3) the DIRCs being developed for the PANDA detector at FAIR that use elegant focusing optics and fast timing [57].

31.6. Gaseous detectors

31.6.1. Energy loss and charge transport in gases : Revised March 2010 by F. Sauli (CERN) and M. Titov (CEA Saclay).

Gas-filled detectors localize the ionization produced by charged particles, generally after charge multiplication. The statistics of ionization processes having asymmetries in the ionization trails, affect the coordinate determination deduced from the measurement of drift time, or of the center of gravity of the collected charge. For thin gas layers, the width of the energy loss distribution can be larger than its average, requiring multiple sample or truncated mean analysis to achieve good particle identification. In the truncated mean method for calculating $\langle dE/dx \rangle$, the ionization measurements along the track length are broken into many samples and then a fixed fraction of high-side (and sometimes also low-side) values are rejected [58].

The energy loss of charged particles and photons in matter is discussed in Sec. 30. Table 31.5 provides values of relevant parameters in some commonly used gases at NTP (normal temperature, 20° C, and pressure, 1 atm) for unit-charge minimum-ionizing particles (MIPs) [59–65]. Values often differ, depending on the source, so those in the table should be taken only as approximate. For different conditions and for mixtures, and neglecting internal energy transfer processes (*e.g.*, Penning effect), one can scale the density, N_P , and N_T with temperature and pressure assuming a perfect gas law.

Table 31.5: Properties of noble and molecular gases at normal temperature and pressure (NTP: 20° C, one atm). E_X , E_I : first excitation, ionization energy; W_I : average energy per ion pair; $dE/dx|_{\min}$, N_P , N_T : differential energy loss, primary and total number of electron-ion pairs per cm, for unit charge minimum ionizing particles.

Gas	Density, mg cm ⁻³	E_x eV	E_I eV	W_I eV	$dE/dx _{\min}$ keV cm ⁻¹	N_P cm ⁻¹	N_T cm ⁻¹
He	0.179	19.8	24.6	41.3	0.32	3.5	8
Ne	0.839	16.7	21.6	37	1.45	13	40
Ar	1.66	11.6	15.7	26	2.53	25	97
Xe	5.495	8.4	12.1	22	6.87	41	312
CH ₄	0.667	8.8	12.6	30	1.61	28	54
C ₂ H ₆	1.26	8.2	11.5	26	2.91	48	112
iC ₄ H ₁₀	2.49	6.5	10.6	26	5.67	90	220
CO ₂	1.84	7.0	13.8	34	3.35	35	100
CF ₄	3.78	10.0	16.0	54	6.38	63	120

When an ionizing particle passes through the gas it creates electron-ion pairs, but often the ejected electrons have sufficient energy to further ionize the medium. As shown in Table 31.5, the total number of electron-ion pairs (N_T) is usually a few times larger than the number of primaries (N_P).

The probability for a released electron to have an energy E or larger follows an approximate $1/E^2$ dependence (Rutherford law), shown in Fig. 31.3 for Ar/CH₄ at NTP (dotted line, left scale). More detailed estimates taking into account the electronic structure of the medium are shown in the figure, for three values of the particle velocity factor $\beta\gamma$ [60]. The dot-dashed line provides, on the right scale, the

practical range of electrons (including scattering) of energy E . As an example, about 0.6% of released electrons have 1 keV or more energy, substantially increasing the ionization loss rate. The practical range of 1 keV electrons in argon (dot-dashed line, right scale) is 70 μ m and this can contribute to the error in the coordinate determination.

Figure 31.3: Probability of single collisions in which released electrons have an energy E or larger (left scale) and practical range of electrons in Ar/CH₄ (P10) at NTP (dot-dashed curve, right scale) [60].

The number of electron-ion pairs per primary ionization, or cluster size, has an exponentially decreasing probability; for argon, there is about 1% probability for primary clusters to contain ten or more electron-ion pairs [61].

Once released in the gas, and under the influence of an applied electric field, electrons and ions drift in opposite directions and diffuse towards the electrodes. The scattering cross section is determined by the details of atomic and molecular structure. Therefore, the drift velocity and diffusion of electrons depend very strongly on the nature of the gas, specifically on the inelastic cross-section involving the rotational and vibrational levels of molecules. In noble gases, the inelastic cross section is zero below excitation and ionization thresholds. Large drift velocities are achieved by adding polyatomic gases (usually CH₄, CO₂, or CF₄) having large inelastic cross sections at moderate energies, which results in “cooling” electrons into the energy range of the Ramsauer-Townsend minimum (at ~ 0.5 eV) of the elastic cross-section of argon. The reduction in both the total electron scattering cross-section and the electron energy results in a large increase of electron drift velocity (for a compilation of electron-molecule cross sections see Ref. 62). Another principal role of the polyatomic gas is to absorb the ultraviolet photons emitted by the excited noble gas atoms. Extensive collections of experimental data [63] and theoretical calculations based on transport theory [64] permit estimates of drift and diffusion properties in pure gases and their mixtures. In a simple approximation, gas kinetic theory provides the drift velocity v as a function of the mean collision time τ and the electric field E : $v = eE\tau/m_e$ (Townsend’s expression). Values of drift velocity and diffusion for some commonly used gases at NTP are given in Fig. 31.4 and Fig. 31.5. These have been computed with the MAGBOLTZ program [65]. For different conditions, the horizontal axis must be scaled inversely with the gas density. Standard deviations for longitudinal (σ_L) and transverse diffusion (σ_T) are given for one cm of drift, and scale with the the square root of the drift distance. Since the collection time is inversely proportional to the drift velocity, diffusion is less in gases such as CF₄ that have high drift velocities. In the presence of an external magnetic field, the Lorentz force acting on electrons between collisions deflects the drifting electrons and modifies the drift properties. The electron trajectories, velocities and diffusion parameters can be computed with MAGBOLTZ. A simple theory, the friction force model, provides an expression for the vector drift velocity v as a function of electric and magnetic field vectors \mathbf{E} and \mathbf{B} , of the

Larmor frequency $\omega = eB/m_e$, and of the mean collision time τ :

$$v = \frac{e}{m_e} \frac{\tau}{1 + \omega^2 \tau^2} \left(E + \frac{\omega \tau}{B} (E \times B) + \frac{\omega^2 \tau^2}{B^2} (E \cdot B) B \right) \quad (31.13)$$

To a good approximation, and for moderate fields, one can assume that the energy of the electrons is not affected by B , and use for τ the values deduced from the drift velocity at $B = 0$ (the Townsend expression). For E perpendicular to B , the drift angle to the relative to the electric field vector is $\tan \theta_B = \omega \tau$ and $v = (E/B)(\omega \tau / \sqrt{1 + \omega^2 \tau^2})$. For parallel electric and magnetic fields, drift velocity and longitudinal diffusion are not affected, while the transverse diffusion can be strongly reduced: $\sigma_T(B) = \sigma_T(B=0) / \sqrt{1 + \omega^2 \tau^2}$. The dotted line in Fig. 31.5 represents σ_T for the classic Ar/CH₄ (90:10) mixture at 4 T. Large values of $\omega \tau \sim 20$ at 5 T are consistent with the measurement of diffusion coefficient in Ar/CF₄/iC₄H₁₀ (95:3:2). This reduction is exploited in time projection chambers (Sec. 31.6.5) to improve spatial resolution.

Figure 31.4: Computed electron drift velocity as a function of electric field in several gases at NTP and $B = 0$ [65].

In mixtures containing electronegative molecules, such as O₂ or H₂O, electrons can be captured to form negative ions. Capture cross-sections are strongly energy-dependent, and therefore the capture probability is a function of applied field. For example, the electron is attached to the oxygen molecule at energies below 1 eV. The three-body electron attachment coefficients may differ greatly for the same additive in different mixtures. As an example, at moderate fields (up to 1 kV/cm) the addition of 0.1% of oxygen to an Ar/CO₂ mixture results in an electron capture probability about twenty times larger than the same addition to Ar/CH₄.

Carbon tetrafluoride is not electronegative at low and moderate fields, making its use attractive as drift gas due to its very low diffusion. However, CF₄ has a large electron capture cross section at fields above ~ 8 kV/cm, before reaching avalanche field strengths. Depending on detector geometry, some signal reduction and resolution loss can be expected using this gas.

If the electric field is increased sufficiently, electrons gain enough energy between collisions to ionize molecules. Above a gas-dependent threshold, the mean free path for ionization, λ_i , decreases exponentially with the field; its inverse, $\alpha = 1/\lambda_i$, is the first Townsend coefficient. In wire chambers, most of the increase of avalanche particle density occurs very close to the anode wires, and a simple electrostatic consideration shows that the largest fraction of the detected signal is due to the motion of positive ions receding from the wires. The electron component, although very fast, contributes very little to the signal. This determines the characteristic shape of the detected signals in the proportional mode: a fast rise followed by a gradual increase. The slow component, the so-called “ion tail” that limits the time resolution of the detector, is usually removed by differentiation of the signal. In uniform fields, N_0 initial electrons multiply over a length x forming an electron avalanche of size $N = N_0 e^{\alpha x}$; N/N_0 is the gain of the detector. Fig. 31.6 shows examples of Townsend coefficients for several gas mixtures, computed with MAGBOLTZ [65].

Figure 31.5: Electron longitudinal diffusion (σ_L) (dashed lines) and transverse diffusion (σ_T) (full lines) for 1 cm of drift at NTP and $B = 0$. The dotted line shows σ_T for the P10 mixture at 4 T [65].

Figure 31.6: Computed first Townsend coefficient α as a function of electric field in several gases at NTP [65].

Positive ions released by the primary ionization or produced in the avalanches drift and diffuse under the influence of the electric field. Negative ions may also be produced by electron attachment to gas molecules. The drift velocity of ions in the fields encountered in gaseous detectors (up to few kV/cm) is typically about three orders of magnitude less than for electrons. The ion mobility μ , the ratio of drift velocity to electric field, is constant for a given ion type up to very high fields. Values of mobility at NTP for ions in their own and other gases are given in Table 31.6 [66]. For different temperatures and pressures, the mobility can be scaled inversely with the density assuming an ideal gas law. For mixtures, due to a very effective charge transfer mechanism, only ions with the lowest ionization potential survive after a short path in the gas. Both the lateral and transverse diffusion of ions are proportional to the square root of the drift time, with a coefficient that depends on temperature but not on the ion mass. Accumulation of ions in the gas drift volume may induce field distortions (see Sec. 31.6.5).

Table 31.6: Mobility of ions in gases at NTP [66].

Gas	Ion	Mobility μ (cm ² V ⁻¹ s ⁻¹)
He	He ⁺	10.4
Ne	Ne ⁺	4.7
Ar	Ar ⁺	1.54
Ar/CH ₄	CH ₄ ⁺	1.87
Ar/CO ₂	CO ₂ ⁺	1.72
CH ₄	CH ₄ ⁺	2.26
CO ₂	CO ₂ ⁺	1.09

31.6.2. Multi-Wire Proportional and Drift Chambers : Revised March 2010 by Fabio Sauli (CERN) and Maxim Titov (CEA Saclay).

Single-wire counters that detect the ionization produced in a gas by a charged particle, followed by charge multiplication and collection around a thin wire have been used for decades. Good energy resolution is obtained in the proportional amplification mode, while very large saturated pulses can be detected in the streamer and Geiger modes [3].

Multiwire proportional chambers (MWPCs) [67,68], introduced in the late '60's, detect, localize and measure energy deposit by charged particles over large areas. A mesh of parallel anode wires at a suitable potential, inserted between two cathodes, acts almost as a set of independent proportional counters (see Fig. 31.7a). Electrons released in the gas volume drift towards the anodes and produce avalanches in the increasing field. Analytic expressions for the electric field can be found in many textbooks. The fields close to the wires $E(r)$, in the drift region E_D , and the capacitance C per unit length of anode wire are approximately given by

$$E(r) = \frac{CV_0}{2\pi\epsilon_0} \frac{1}{r} \quad E_D = \frac{CV_0}{2\epsilon_0 s} \quad C = \frac{2\pi\epsilon_0}{\pi(\ell/s) - \ln(2\pi a/s)}, \quad (31.14)$$

where r is the distance from the center of the anode, s the wire spacing, ℓ and V_0 the distance and potential difference between anode and cathode, and a the anode wire radius.

Because of electrostatic forces, anode wires are in equilibrium only for a perfect geometry. Small deviations result in forces displacing the wires alternatively below and above the symmetry plane, sometimes with catastrophic results. These displacement forces are countered by the mechanical tension of the wire, up to a maximum unsupported stable length, L_M [58], above which the wire deforms:

$$L_M = \frac{s}{CV_0} \sqrt{4\pi\epsilon_0 T_M} \quad (31.15)$$

The maximum tension T_M depends on the wire diameter and modulus of elasticity. Table 31.7 gives approximate values for tungsten and the corresponding maximum stable wire length under reasonable assumptions for the operating voltage ($V_0 = 5$ kV) [69]. Internal supports and spacers can be used in the construction of longer detectors to overcome limits on the wire length imposed by Eq. (31.15).

Table 31.7: Maximum tension T_M and stable unsupported length L_M for tungsten wires with spacing s , operated at $V_0 = 5$ kV. No safety factor is included.

Wire diameter (μm)	T_M (newton)	s (mm)	L_M (cm)
10	0.16	1	25
20	0.65	2	85

Detection of charge on the wires over a predefined threshold provides the transverse coordinate to the wire with an accuracy comparable to that of the wire spacing. The coordinate along each wire can be obtained by measuring the ratio of collected charge at the two ends of resistive wires. Making use of the charge profile induced on segmented cathodes, the so-called center-of gravity (COG) method, permits localization of tracks to sub-mm accuracy. Due to the statistics of energy loss and asymmetric ionization clusters, the position accuracy is $\sim 50 \mu\text{m}$ rms for tracks perpendicular to the wire plane, but degrades to $\sim 250 \mu\text{m}$ at 30° to the normal [70]. The intrinsic bi-dimensional characteristic of the COG readout has found numerous applications in medical imaging.

Drift chambers, developed in the early '70's, can be used to estimate the longitudinal position of a track by exploiting the arrival time of electrons at the anodes if the time of interaction is known [71]. The distance between anode wires is usually several cm, allowing coverage of large areas at reduced cost. In the original design, a thicker wire (the field wire) at the proper voltage, placed between the anode wires, reduces the field at the mid-point between anodes and improves

Figure 31.7: Electric field lines and equipotentials in (a) a multiwire proportional chamber and (b) a drift chamber.

charge collection (Fig. 31.7b). In some drift chamber designs, and with the help of suitable voltages applied to field-shaping electrodes, the electric field structure is adjusted to improve the linearity of space-to-drift-time relation, resulting in better spatial resolution [72].

Drift chambers can reach a longitudinal spatial resolution from timing measurement of order $100 \mu\text{m}$ (rms) or better for minimum ionizing particles, depending on the geometry and operating conditions. However, a degradation of resolution is observed [73] due to primary ionization statistics for tracks close to the anode wires, caused by the spread in arrival time of the nearest ionization clusters. The effect can be reduced by operating the detector at higher pressures. Sampling the drift time on rows of anodes led to the concept of multiple arrays such as the multi-drift module [74] and the JET chamber [75]. A measurement of drift time, together with the recording of charge sharing from the two ends of the anode wires provides the coordinates of segments of tracks. The total charge gives information on the differential energy loss and is exploited for particle identification. The time projection chamber (TPC) [76] combines a measurement of drift time and charge induction on cathodes, to obtain excellent tracking for high multiplicity topologies occurring at moderate rates (see Sec. 31.6.5). In all cases, a good knowledge of electron drift velocity and diffusion properties is required. This has to be combined with the knowledge of the electric fields in the structures, computed with commercial or custom-developed software [65,77]. For an overview of detectors exploiting the drift time for coordinate measurement see Refs. 6 and 58.

Multiwire and drift chambers have been operated with a variety of gas fillings and operating modes, depending on experimental requirements. The so-called "Magic Gas," a mixture of argon, isobutane and Freon [68], permits very high and saturated gains ($\sim 10^6$). This gas mixture was used in early wire chambers, but was found to be susceptible to severe aging processes. With present-day electronics, proportional gains around 10^4 are sufficient for detection of minimum ionizing particles, and noble gases with moderate amounts of polyatomic gases, such as methane or carbon dioxide, are used.

Although very powerful in terms of performance, multi-wire structures have reliability problems when used in harsh or hard-to-access environments, since a single broken wire can disable the entire detector. Introduced in the '80's, straw and drift tube systems make use of large arrays of wire counters encased in individual enclosures, each acting as an independent wire counter [78]. Techniques for low-cost mass production of these detectors have been developed for large experiments, such as the Transition Radiation Tracker and the Drift Tubes arrays for CERN's LHC experiments [79].

31.6.3. High Rate Effects : Revised March 2010 by Fabio Sauli (CERN) and Maxim Titov (CEA Saclay).

The production of positive ions in the avalanches and their slow drift before neutralization result in a rate-dependent accumulation of positive charge in the detector. This may result in significant field distortion, gain reduction and degradation of spatial resolution. As shown in Fig. 31.8 [80], the proportional gain drops above a charge production rate around 10^9 electrons per second and mm of wire, independently of the avalanche size. For a proportional gain of 10^4 and 100 electrons per track, this corresponds to a particle flux of $10^3 \text{ s}^{-1} \text{ mm}^{-1}$ (1 kHz/mm² for 1 mm wire spacing).

Figure 31.8: Charge rate dependence of normalized gas gain G/G_0 (relative to zero counting rate) in proportional thin-wire detectors [80]. Q is the total charge in single avalanche; N is the particle rate per wire length.

At high radiation fluxes, a fast degradation of detectors due to the formation of polymers deposits (aging) is often observed. The process has been extensively investigated, often with conflicting results. Several causes have been identified, including organic pollutants and silicone oils. Addition of small amounts of water in many (but not all) cases has been shown to extend the lifetime of the detectors. Addition of fluorinated gases (*e.g.*, CF_4) or oxygen may result in an etching action that can overcome polymer formation, or even eliminate already existing deposits. However, the issue of long-term survival of gas detectors with these gases is controversial [81]. Under optimum operating conditions, a total collected charge of a few coulombs per cm of wire can usually be reached before noticeable degradation occurs. This corresponds, for one mm spacing and at a gain of 10^4 , to a total particle flux of $\sim 10^{14}$ MIPs/cm².

31.6.4. Micro-Pattern Gas Detectors : Revised March 2010 by Fabio Sauli (CERN) and Maxim Titov (CEA Saclay)

Despite various improvements, position-sensitive detectors based on wire structures are limited by basic diffusion processes and space charge effects to localization accuracies of 50–100 μm [82]. Modern photolithographic technology led to the development of novel Micro-Pattern Gas Detector (MPGD) concepts [83], revolutionizing cell size limitations for many gas detector applications. By using pitch size of a few hundred μm , an order of magnitude improvement in granularity over wire chambers, these detectors offer intrinsic high rate capability ($> 10^6 \text{ Hz/mm}^2$), excellent spatial resolution ($\sim 30 \mu\text{m}$), multi-particle resolution ($\sim 500 \mu\text{m}$), and single photo-electron time resolution in the ns range.

The Micro-Strip Gas Chamber (MSGC), invented in 1988, was the first of the micro-structure gas chambers [84]. It consists of a set of tiny parallel metal strips laid on a thin resistive support, alternatively connected as anodes and cathodes. Owing to the small anode-to-cathode distance ($\sim 100 \mu\text{m}$), the fast collection of positive ions reduces space charge build-up, and provides a greatly increased rate capability. Unfortunately, the fragile electrode structure of the MSGC turned out to be easily destroyed by discharges induced by heavily ionizing particles [85]. Nevertheless, detailed studies of their properties, and in particular, on the radiation-induced processes

leading to discharge breakdown, led to the development of the more powerful devices: GEM and Micromegas. These have improved reliability and radiation hardness. The absence of space-charge effects in GEM detectors at the highest rates reached so far and the fine granularity of MPGDs improve the maximum rate capability by more than two orders of magnitude (Fig. 31.9) [72,86]. Even larger rate capability has been reported for Micromegas [87].

Figure 31.9: Normalized gas gain as a function of particle rate for MWPC [72] and GEM [86].

The Gas Electron Multiplier (GEM) detector consists of a thin-foil copper-insulator-copper sandwich chemically perforated to obtain a high density of holes in which avalanches occur [88]. The hole diameter is typically between 25 μm and 150 μm , while the corresponding distance between holes varies between 50 μm and 200 μm . The central insulator is usually (in the original design) the polymer Kapton, with a thickness of 50 μm . Application of a potential difference between the two sides of the GEM generates the electric fields indicated in Fig. 31.10. Each hole acts as an independent proportional counter. Electrons released by the primary ionization particle in the upper conversion region (above the GEM foil) drift into the holes, where charge multiplication occurs in the high electric field (50–70 kV/cm). Most of avalanche electrons are transferred into the gap below the GEM. Several GEM foils can be cascaded, allowing the multi-layer GEM detectors to operate at overall gas gain above 10^4 in the presence of highly ionizing particles, while strongly reducing the risk of discharges. This is a major advantage of the GEM technology [89]. Localization can then be performed by collecting the charge on a patterned one- or two-dimensional readout board of arbitrary pattern, placed below the last GEM.

The micro-mesh gaseous structure (Micromegas) is a thin parallel-plate avalanche counter, as shown in Fig. 31.11 [90]. It consists of a drift region and a narrow multiplication gap (25–150 μm) between a thin metal grid (micromesh) and the readout electrode (strips or pads of conductor printed on an insulator board). Electrons from the primary ionization drift through the holes of the mesh into the narrow multiplication gap, where they are amplified. The electric field is homogeneous both in the drift (electric field $\sim 1 \text{ kV/cm}$) and amplification (50–70 kV/cm) gaps. In the narrow multiplication region, gain variations due to small variations of the amplification gap are approximately compensated by an inverse variation of the amplification coefficient, resulting in a more uniform gain. The small amplification gap produces a narrow avalanche, giving rise to excellent spatial resolution: 12 μm accuracy, limited by the micro-mesh pitch, has been achieved for MIPs, as well as very good time resolution and energy resolution ($\sim 12\%$ FWHM with 6 keV x rays) [91].

The performance and robustness of GEM and Micromegas have encouraged their use in high-energy and nuclear physics, UV and visible photon detection, astroparticle and neutrino physics, neutron detection and medical physics. Most structures were originally optimized for high-rate particle tracking in nuclear and high-energy physics experiments. COMPASS, a high-luminosity experiment at CERN, pioneered the use of large-area ($\sim 40 \times 40 \text{ cm}^2$) GEM and

Figure 31.10: Schematic view and typical dimensions of the hole structure in the GEM amplification cell. Electric field lines (solid) and equipotentials (dashed) are shown.

Figure 31.11: Schematic drawing of the Micromegas detector.

Micromegas detectors close to the beam line with particle rates of 25 kHz/mm². Both technologies achieved a tracking efficiency of close to 100% at gas gains of about 10⁴, a spatial resolution of 70–100 μm and a time resolution of ~10 ns. GEM detectors are also used for triggering in the LHCb Muon System and for tracking in the TOTEM Telescopes. Both GEM and Micromegas devices are foreseen for the upgrade of the LHC experiments and for one of the readout options for the Time Projection Chamber (TPC) at the International Linear Collider (ILC). The development of new fabrication techniques—“bulk” Micromegas technology [92] and single-mask GEMs [93]—is a big step toward industrial production of large-size MPGDs. In some applications requiring very large-area coverage with moderate spatial resolution, coarse macro-patterned detectors, such as Thick GEMs (THGEM) [94] or patterned resistive-plate devices [95] might offer economically interesting solutions.

Sensitive and low-noise electronics enlarge the range of the MPGD applications. Recently, the GEM and Micromegas detectors were read out by high-granularity (~50 μm pitch) CMOS chips assembled directly below the GEM or Micromegas amplification structures [96]. These detectors use the bump-bonding pads of a pixel chip as an integrated charge collecting anode. With this arrangement signals are induced at the input gate of a charge-sensitive preamplifier (top metal layer of the CMOS chip). Every pixel is then directly connected to the amplification and digitization circuits, integrated in the underlying active layers of the CMOS technology, yielding timing and charge measurements as well as precise spatial information in 3D.

The operation of a MPGD with a Timepix CMOS chip has

demonstrated the possibility of reconstructing 3D-space points of individual primary electron clusters with ~30 μm spatial resolution and event-time resolution with nanosecond precision. This has become indispensable for tracking and triggering and also for discriminating between ionizing tracks and photon conversions. The GEM, in conjunction with a CMOS ASIC,* can directly view the absorption process of a few keV x-ray quanta and simultaneously reconstruct the direction of emission, which is sensitive to the x-ray polarization. Thanks to these developments, a micro-pattern device with finely segmented CMOS readout can serve as a high-precision “electronic bubble chamber.” This may open new opportunities for x-ray polarimeters, detection of weakly interacting massive particles (WIMPs) and axions, Compton telescopes, and 3D imaging of nuclear recoils.

An elegant solution for the construction of the Micromegas with pixel readout is the integration of the amplification grid and CMOS chip by means of an advanced “wafer post-processing” technology [97]. This novel concept is called “Ingrid” (see Fig. 31.12). With this technique, the structure of a thin (1 μm) aluminum grid is fabricated on top of an array of insulating pillars, which stands ~50 μm above the CMOS chip. The sub-μm precision of the grid dimensions and avalanche gap size results in a uniform gas gain. The grid hole size, pitch and pattern can be easily adapted to match the geometry of any pixel readout chip.

Figure 31.12: Photo of the Micromegas “Ingrid” detector. The grid holes can be accurately aligned with readout pixels of CMOS chip. The insulating pillars are centered between the grid holes, thus avoiding dead regions.

Recent developments in radiation hardness research with state-of-the-art MPGDs are reviewed in Ref. 98. Earlier aging studies of GEM and Micromegas concepts revealed that they might be even less vulnerable to radiation-induced performance degradation than standard silicon microstrip detectors.

The RD51 collaboration was established in 2008 to further advance technological developments of micro-pattern detectors and associated electronic-readout systems for applications in basic and applied research [99].

* Application Specific Integrated Circuit

31.6.5. Time-projection chambers : Reviser October 2011 by D. Karlen (U. of Victoria and TRIUMF, Canada)

The Time Projection Chamber (TPC) concept, invented by David Nygren in the late 1970's [76], is the basis for charged particle tracking in a large number of particle and nuclear physics experiments. A uniform electric field drifts tracks of electrons produced by charged particles traversing a medium, either gas or liquid, towards a surface segmented into 2D readout pads. The signal amplitudes and arrival times are recorded to provide full 3D measurements of the particle trajectories. The intrinsic 3D segmentation gives the TPC a distinct advantage over other large volume tracking detector designs which record information only in a 2D projection with less overall segmentation, particularly for pattern recognition in events with large numbers of particles.

Gaseous TPC's are often designed to operate within a strong magnetic field (typically parallel to the drift field) so that particle momenta can be estimated from the track curvature. For this application, precise spatial measurements in the plane transverse to the magnetic field are most important. Since the amount of ionization along the length of the track depends on the velocity of the particle, ionization and momentum measurements can be combined to identify the types of particles observed in the TPC. The estimator for the energy deposit by a particle is usually formed as the truncated mean of the energy deposits, using the 50%–70% of the samples with the smallest signals. Variance due to energetic δ -ray production is thus reduced.

Gas amplification of 10^3 – 10^4 at the readout endplate is usually required in order to provide signals with sufficient amplitude for conventional electronics to sense the drifted ionization. Until recently, the gas amplification system used in TPC's have exclusively been planes of anode wires operated in proportional mode placed close to the readout pads. Performance has been recently improved by replacing these wire planes with micro-pattern gas detectors, namely GEM [88] and Micromegas [90] devices. Advances in electronics miniaturization have been important in this development, allowing pad areas to be reduced to the 10 mm^2 scale or less, well matched to the narrow extent of signals produced with micro-pattern gas detectors. Presently, the ultimate in fine segmentation TPC readout are silicon sensors, with $0.05 \text{ mm} \times 0.05 \text{ mm}$ pixels, in combination with GEM or Micromegas [100]. With such fine granularity it is possible to count the number of ionization clusters along the length of a track which, in principle, can improve the particle identification capability.

Examples of two modern large volume gaseous TPC's are shown in Fig. 31.13 and Fig. 31.14. The particle identification performance is illustrated in Fig. 31.15, for the original TPC in the PEP-4/9 experiment [101].

Figure 31.13: The ALICE TPC shown in a cutaway view [102]. The drift volume is 5 m long with a 5 m diameter. Gas amplification is provided by planes of anode wires.

Figure 31.14: One of the 3 TPC modules for the near detector of the T2K experiment [103]. The drift volume is $2 \text{ m} \times 2 \text{ m} \times 0.8 \text{ m}$. Micromegas devices are used for gas amplification and readout.

Figure 31.15: The PEP4/9-TPC energy deposit measurements (185 samples, 8.5 atm Ar-CH₄ 80:20). The ionization rate at the Fermi plateau (at high β) is 1.4 times that for the minimum at lower β . This ratio increases to 1.6 at atmospheric pressure.

The greatest challenges for a large TPC arise from the long drift distance, typically 100 times further than in a comparable wire chamber design. In particular, the long drift distance can make the device sensitive to small distortions in the electric field. Distortions can arise from a number of sources, such as imperfections in the TPC construction, deformations of the readout surface, or the presence of ions in the active medium.

For a gaseous TPC operated in a magnetic field, the electron drift velocity v is defined by Eq. (31.13). With a strong magnetic field parallel to the electric field and a gas with a large value of $\omega\tau$ (also favored to reduce transverse diffusion as discussed below), the transverse displacements of the drifting electrons due to electric field distortions are reduced. In this mode of operation, it is essential to precisely map the magnetic field as the electron drift lines closely follow the magnetic field lines. Corrections for electric and/or magnetic field non-uniformities can be determined from control samples of electrons produced by ionizing the gas with UV laser beams, from photoelectrons produced on the cathode, or from tracks emanating from calibration reactions.

The long drift distance means that there is a delay, typically 10–100 μs in a large gaseous TPC, for signals to arrive at the endplate. For experiments with shorter intervals between events, this

can produce ambiguities in the starting time for the drift of ionization. This can be resolved by matching the TPC data with that from an auxiliary detector providing additional spatial or timing information.

In a gaseous TPC, the motion of positive ions is much slower than the electrons, and so the positive ions produced by many events may exist in the active volume. Of greatest concern is the ions produced in the gas amplification stage. Large gaseous TPC's built until now with wire planes have included a gating grid that prevent the positive ions from escaping into the drift volume in the interval between event triggers. Micro-pattern gas detectors release much less positive ions than wire planes operating at the same gain, which may allow operation of a TPC without a gating grid.

Given the long drift distance in a large TPC, the active medium must remain very pure, as small amounts of contamination can absorb the ionization signal. For example, in a typical large gaseous TPC, O_2 must be kept below a few parts in 10^5 , otherwise a large fraction of the drifting electrons will become attached. Special attention must be made in the choice of construction materials in order to avoid the release of other electronegative contaminants.

Diffusion degrades the position information of ionization that drifts a long distance. For a gaseous TPC, the effect can be alleviated by the choice of a gas with low intrinsic diffusion or by operating in a strong magnetic field parallel to the drift field with a gas which exhibits a significant reduction in transverse diffusion with magnetic field. For typical operation without magnetic field, the transverse extent of the electrons, σ_{Dx} , is a few mm after drifting 1 m due to diffusion. With a strong magnetic field, σ_{Dx} can be reduced by as much as a factor of 10,

$$\sigma_{Dx}(B)/\sigma_{Dx}(0) = \frac{1}{\sqrt{1 + \omega^2 \tau^2}} \quad (31.16)$$

where $\omega\tau$ is defined above. The diffusion limited position resolution from the information collected by a single row of pads is

$$\sigma_x = \frac{\sigma_{Dx}}{\sqrt{n}} \quad (31.17)$$

where n is the effective number of electrons collected by the pad row, giving an ultimate single row resolution of order $100 \mu\text{m}$.

Diffusion is significantly reduced in a negative-ion TPC [104], which uses a special gas mixture that attaches electrons immediately as they are produced. The drifting negative ions exhibit much less diffusion than electrons. The slow drift velocity and small $\omega\tau$ of negative ions must be compatible with the experimental environment.

The spatial resolution achieved by a TPC is determined by a number of factors in addition to diffusion. Non-uniform ionization along the length of the track is a particularly important factor, and is responsible for the so-called “track angle” and “ $\mathbf{E} \times \mathbf{B}$ ” effects. If the boundaries between pads in a row are not parallel to the track, the ionization fluctuations will increase the variance in the position estimate from that row. For this reason, experiments with a preferred track direction should have pad boundaries aligned with that direction. Traditional TPC's with wire plane amplification suffer from the effects of non-parallel electric and magnetic fields near the wires that rotate ionization segments, thereby degrading the resolution because of the non-uniform ionization. Micro-pattern gas detectors exhibit a much smaller $\mathbf{E} \times \mathbf{B}$ effect, since their feature size is much smaller than that of a wire grid.

31.6.6. Transition radiation detectors (TRD's): Written August 2007 by P. Nevski (BNL) and A. Romaniouk (Moscow Eng. & Phys. Inst.)

Transition radiation (TR) x rays are produced when a highly relativistic particle ($\gamma \gtrsim 10^3$) crosses a refractive index interface, as discussed in Sec. 30.7. The x rays, ranging from a few keV to a few dozen keV, are emitted at a characteristic angle $1/\gamma$ from the particle trajectory. Since the TR yield is about 1% per boundary crossing, radiation from multiple surface crossings is used in practical detectors. In the simplest concept, a detector module might consist of low- Z foils followed by a high- Z active layer made of proportional counters filled with a Xe-rich gas mixture. The atomic number considerations follow from the dominant photoelectric absorption cross section per atom going roughly as Z^n/E_x^3 , where n varies between 4 and 5 over

the region of interest, and the x-ray energy is E_x .^{*} To minimize self-absorption, materials such as polypropylene, Mylar, carbon, and (rarely) lithium are used as radiators. The TR signal in the active regions is in most cases superimposed upon the particle's ionization losses. These drop a little faster than Z/A with increasing Z , providing another reason for active layers with high Z .

The TR intensity for a single boundary crossing always increases with γ , but for multiple boundary crossings interference leads to saturation near a Lorentz factor $\gamma_{\text{sat}} = 0.6 \omega_1 \sqrt{\ell_1 \ell_2} / c$ [105], where ω_1 is the radiator plasma frequency, ℓ_1 is its thickness, and ℓ_2 the spacing. In most of the detectors used in particle physics the radiator parameters are chosen to provide $\gamma_{\text{sat}} \approx 2000$. Those detectors normally work as threshold devices, ensuring the best electron/pion separation in the momentum range $1 \text{ GeV}/c \lesssim p \lesssim 150 \text{ GeV}/c$.

One can distinguish two design concepts—“thick” and “thin” detectors:

1. The radiator, optimized for a minimum total radiation length at maximum TR yield and total TR absorption, consists of few hundred foils (for instance 300 $20 \mu\text{m}$ thick polypropylene foils). A dominant fraction of the soft TR photons is absorbed in the radiator itself. To increase the average TR photon energy further, part of the radiator far from the active layers is often made of thicker foils. The detector thickness, about 2 cm for Xe-filled gas chambers, is optimized to absorb the shaped x-ray spectrum. A classical detector is composed of several similar modules which respond nearly independently. Such detectors were used in the NA34 [106], and are being used in the ALICE experiment [107].
2. In another TRD concept a fine granular radiator/detector structure exploits the soft part of the TR spectrum more efficiently. This can be achieved, for instance, by distributing small-diameter straw-tube detectors uniformly or in thin layers throughout the radiator material (foils or fibers). Even with a relatively thin radiator stack, radiation below 5 keV is mostly lost in the radiators themselves. However for photon energies above this value the absorption becomes smaller and the radiation can be registered by several consecutive detector layers, thus creating a strong TR build-up effect. Descriptions of detectors using this approach can be found in both accelerator and space experiments [107]. For example, in the ATLAS TR tracker charged particles cross about 35 effective straw tube layers embedded in the radiator material [107]. The effective thickness of the Xe gas per straw is about 2.3 mm and the average number of foils per straw is about 40 with an effective foil thickness of about $20 \mu\text{m}$.

Both TR photon absorption and the TR build-up significantly affect the detector performance. Although the values mentioned above are typical for most of the plastic radiators used with Xe-based detectors, they vary significantly depending on detector parameters: radiator material, thickness and spacing, the construction of the sensitive chambers, their position, *etc.* Thus careful simulations are usually needed to build a detector optimized for a particular application.

The discrimination between electrons and pions can be based on the charge deposition measured in each detection module, on the number of clusters—energy depositions observed above an optimal threshold (usually in the 5 to 7 keV region), or on more sophisticated methods analyzing the pulse shape as a function of time. The total energy measurement technique is more suitable for thick gas volumes, which absorb most of the TR radiation and where the ionization loss fluctuations are small. The cluster-counting method works better for detectors with thin gas layers, where the fluctuations of the ionization losses are big. Cluster-counting replaces the Landau-Vavilov distribution of background ionization energy losses with the Poisson statistics of δ -electrons, responsible for the distribution tails. The latter distribution is narrower than the Landau-Vavilov distribution.

The major factor in the performance of any TRD is its overall length. This is illustrated in Fig. 31.16, which shows, for a variety of detectors, the pion efficiency at a fixed electron efficiency of 90% as a function of the overall detector length. The experimental data, covering a range of particle energies from a few GeV to 40 GeV, are

^{*} Photon absorption coefficients for the elements (via a NIST link), and $dE/dx|_{\text{min}}$ and plasma energies for many materials are given in pdg.lbl.gov/AtomicNuclearProperties.

Figure 31.16: Pion efficiency measured (or predicted) for different TRDs as a function of the detector length for a fixed electron efficiency of 90%. The plot is taken from [106] with efficiencies of more recent detectors added [107].

rescaled to an energy of 10 GeV when possible. Phenomenologically, the rejection power against pions increases as $5 \cdot 10^{L/38}$, where the range of validity is $L \approx 20\text{--}100$ cm.

Many recent TRDs combine particle identification with charged-track measurement in the same detector [107]. This provides a powerful tool for electron identification even at very high particle densities. Another example of this combination is described by Brigida *et al.* in Ref. 107. In this work Si-microstrip detectors operating in a magnetic field are used both for particle and TR detection. The excellent coordinate resolution of the Si detectors allows spatial separation of the TR photons from particle ionization tracks with relatively modest distances between radiator and detector.

Recent TRDs for particle astrophysics are designed to directly measure the Lorentz factor of high-energy nuclei by using the quadratic dependence of the TR yield on nuclear charge; see Cherry and Müller papers in Ref. 107. The radiator configuration (ℓ_1, ℓ_2) is tuned to extend the TR yield rise up to $\gamma \lesssim 10^5$ using more energetic part of the TR spectrum (up to 100 keV). Exotic radiator materials such as aluminum and unusual TR detection methods (Compton scattering) are used such cases.

31.6.7. Resistive-plate chambers: Revised September 2007 by H.R. Band (U. Wisconsin).

The resistive-plate chamber (RPC) was developed by Santonico and Cardarelli in the early 1980's [108] as a low-cost alternative to large scintillator planes.* Most commonly, an RPC is constructed from two parallel high-resistivity ($10^9\text{--}10^{13}$ $\Omega\text{-cm}$) glass or phenolic (Bakelite)/melamine laminate plates with a few-mm gap between them which is filled with atmospheric-pressure gas. The gas is chosen to absorb UV photons in order to limit transverse growth of discharges. The backs of the plates are coated with a lower-resistivity paint or ink ($\sim 10^5$ Ω/\square), and a high potential (7–12 kV) is maintained between them. The passage of a charged particle initiates an electric discharge, whose size and duration are limited since the current reduces the local potential to below that needed to maintain the discharge. The sensitivity of the detector outside of this region is unaffected. The signal readout is via capacitive coupling to metallic strips on both sides of the detector which are separated from the high voltage coatings by thin insulating sheets. The x and y position of the discharge can be measured if the strips on opposite sides of the gap are orthogonal. When operated in streamer mode, the induced signals on the strips can be quite large (~ 300 mV), making sensitive electronics unnecessary. An example of an RPC structure is shown in Fig. 31.17.

* It was based on earlier work on a spark counter with one high-resistivity plate [109].

Figure 31.17: Schematic cross section of a typical RPC, in this case the single-gap streamer-mode BaBar RPC.

RPC's have inherent rate limitations since the time needed to re-establish the field after a discharge is proportional to the chamber capacitance and plate resistance. The average charge per streamer is 100–1000 pC. Typically, the efficiency of streamer-mode glass RPC's begins to fall above ~ 0.4 Hz/cm². Because of Bakelite's lower bulk resistivity, Bakelite RPC's can be efficient at 10–100 Hz/cm². The need for higher rate capability led to the development of avalanche-mode RPC's, in which the gas and high voltage have been tuned to limit the growth of the electric discharge, preventing streamer formation. Typical avalanche-mode RPC's have a signal charge of about 10 pC and can be efficient at 1 kHz/cm². The avalanche discharge produces a much smaller induced signal on the pickup strips (~ 1 mV) than streamers, and thus requires a more sophisticated and careful electronic design.

Many variations of the initial RPC design have been built for operation in either mode. Efficiencies of $\geq 92\%$ for single gaps can be improved by the use of two or more gas gaps with shared pickup strips. Non-flammable and more environmentally friendly gas mixtures have been developed. In streamer mode, various mixtures of argon with isobutane and tetrafluoroethane have been used. For avalanche mode operation, a gas mixture of tetrafluoroethane ($\text{C}_2\text{H}_2\text{F}_4$) with 2–5% isobutane and 0.4–10% sulfur hexafluoride (SF_6) is typical. An example of large-scale RPC use is provided by the muon system being built for the ATLAS detector, where three layers of pairs of RPC's are used to trigger the drift tube arrays between the pairs. The total area is about 10,000 m². These RPC's provide a spatial resolution of 1 cm and a time resolution of 1 ns at an efficiency $\geq 99\%$.

Developments of multiple-gap RPC's [110] lead to RPC designs with much better timing resolution (~ 50 ps) for use in time-of-flight particle identification systems. A pioneering design used by the HARP experiment [111] has two sets of 2 thin gas gaps (0.3 mm) separated by thin (0.7 mm) glass plates. The outer plates are connected to high voltage and ground while the inner plate is electrically isolated and floats to a stable equilibrium potential. The observed RPC intrinsic time resolution of 127 ps may have been limited by amplifier noise. Fonte provides useful review [112] of other RPC designs.

Operational experience with RPC's has been mixed. Several experiments (*e.g.*, L3 and HARP) have reported reliable performance. However, the severe problems experienced with the BaBar RPC's have raised concerns about the long-term reliability of Bakelite RPC's.

Glass RPC's have had fewer problems, as seen by the history of the BELLE chambers. A rapid growth in the noise rate and leakage current in some of the BELLE glass RPC's was observed during commissioning. It was found that water vapor in the input gas was reacting with fluorine (produced by the disassociation of the tetrafluoroethane in the streamers) to produce hydrofluoric acid. The acid etched the glass surfaces, leading to increased noise rates and lower efficiencies. The use of copper gas piping to insure the dryness of the input gas stopped the problem. The BELLE RPC's have now operated reliably for more than 5 years.

Several different failure modes diagnosed in the first-generation BaBar Bakelite RPC's caused the average efficiency of the barrel RPC's to fall from $\geq 90\%$ to 35% in five years. The linseed oil which is used in Bakelite RPC's to coat the inner surface [113] had not been completely cured. Under warm conditions (32°C)

and high voltage, oil collected on the spacers between the gaps or formed oil-drop bridges between the gaps. This led to large leakage currents (50–100 μA in some chambers) which persisted even when the temperature was regulated at 20° C. In addition, the graphite layer used to distribute the high voltage over the Bakelite became highly resistive (100 k $\Omega/\square \rightarrow$ 10 M Ω/\square), resulting in lowered efficiency in some regions and the complete death of whole chambers.

The BaBar problems and the proposed use of Bakelite RPC's in the LHC detectors prompted detailed studies of RPC aging and have led to improved construction techniques and a better understanding of RPC operational limits. The graphite layer has been improved and should be stable with integrated currents of \lesssim 600 mC/cm². Molded gas inlets and improved cleanliness during construction have reduced the noise rate of new chambers. Unlike glass RPC's, Bakelite RPC's have been found to require humid input gases to prevent drying of the Bakelite (increasing the bulk resistivity) which would decrease the rate capability. Second-generation BaBar RPC's incorporating many of the above improvements have performed reliably for over two years [114].

With many of these problems solved, new-generation RPC's are now being or soon will be used in about a dozen cosmic-ray and HEP detectors. Their comparatively low cost, ease of construction, good time resolution, high efficiency, and moderate spatial resolution make them attractive in many situations, particularly those requiring fast timing and/or large-area coverage.

31.7. Semiconductor detectors

Updated August 2011 by H. Spieler.

Semiconductor detectors provide a unique combination of energy and position resolution. In collider detectors they are most widely used as position sensing devices and photodetectors (Sec. 31.2). Integrated circuit technology allows the formation of high-density micron-scale electrodes on large (15–20 cm diameter) wafers, providing excellent position resolution. Furthermore, the density of silicon and its small ionization energy yield adequate signals with active layers only 100–300 μm thick, so the signals are also fast (typically tens of ns). The high energy resolution is a key parameter in x-ray, gamma, and charged particle spectroscopy, *e.g.*, in neutrinoless double beta decay searches. Silicon and germanium are the most commonly used materials, but gallium-arsenide, CdTe, CdZnTe, and other materials are also useful. CdZnTe provides a higher stopping power and the ratio of Cd to Zn concentrations changes the bandgap. Ge detectors are commonly operated at liquid nitrogen temperature to reduce the bias current, which depends exponentially on temperature. Semiconductor detectors depend crucially on low-noise electronics (see Sec. 31.8), so the detection sensitivity is determined by signal charge and capacitance. For a comprehensive discussion of semiconductor detectors and electronics see Ref. 115.

31.7.1. Materials Requirements :

Semiconductor detectors are essentially solid state ionization chambers. Absorbed energy forms electron-hole pairs, *i.e.*, negative and positive charge carriers, which under an applied electric field move towards their respective collection electrodes, where they induce a signal current. The energy required to form an electron-hole pair is proportional to the bandgap. In tracking detectors the energy loss in the detector should be minimal, whereas for energy spectroscopy the stopping power should be maximized, so for gamma rays high- Z materials are desirable.

Measurements on silicon photodiodes [116] show that for photon energies below 4 eV one electron-hole ($e-h$) pair is formed per incident photon. The mean energy E_i required to produce an $e-h$ pair peaks at 4.4 eV for a photon energy around 6 eV. Above \sim 1.5 keV it assumes a constant value, 3.67 eV at room temperature. It is larger than the bandgap energy because momentum conservation requires excitation of lattice vibrations (phonons). For minimum-ionizing particles, the most probable charge deposition in a 300 μm thick silicon detector is about 3.5 fC (22000 electrons). Other typical ionization energies are 2.96 eV in Ge, 4.2 eV in GaAs, and 4.43 eV in CdTe.

Since both electronic and lattice excitations are involved, the variance in the number of charge carriers $N = E/E_i$ produced by an absorbed energy E is reduced by the Fano factor F (about 0.1 in Si and Ge). Thus, $\sigma_N = \sqrt{FN}$ and the energy resolution

$\sigma_E/E = \sqrt{FE_i/E}$. However, the measured signal fluctuations are usually dominated by electronic noise or energy loss fluctuations in the detector. The electronic noise contributions depend on the pulse shaping in the signal processing electronics, so the choice of the shaping time is critical (see Sec. 31.8).

A smaller bandgap would produce a larger signal and improve energy resolution, but the intrinsic resistance of the material is critical. Thermal excitation, given by the Fermi-Dirac distribution, promotes electrons into the conduction band, so the thermally excited carrier concentration increases exponentially with decreasing bandgaps. In pure Si the carrier concentration is \sim 10¹⁰ cm⁻³ at 300 K, corresponding to a resistivity $\rho \approx$ 400 k Ω cm. In reality, crystal imperfections and minute impurity concentrations limit Si carrier concentrations to \sim 10¹¹ cm⁻³ at 300 K, corresponding to a resistivity $\rho \approx$ 40 k Ω cm. In practice, resistivities up to 20 k Ω cm are available, with mass production ranging from 5 to 10 k Ω cm. Signal currents at keV scale energies are of order μA . However, for a resistivity of 10⁴ Ω cm a 300 μm thick sensor with 1 cm² area would have a resistance of 300 Ω , so 30 V would lead to a current flow of 100 mA and a power dissipation of 3 W. On the other hand, high-quality single crystals of Si and Ge can be grown economically with suitably large volumes, so to mitigate the effect of resistivity one resorts to reverse-biased diode structures. Although this reduces the bias current relative to a resistive material, the thermally excited leakage current can still be excessive at room temperature, so Ge diodes are typically operated at liquid nitrogen temperature (77 K).

A major effort is to find high- Z materials with a bandgap that is sufficiently high to allow room-temperature operation while still providing good energy resolution. Compound semiconductors, *e.g.*, CdZnTe, can allow this, but typically suffer from charge collection problems, characterized by the product $\mu\tau$ of mobility and carrier lifetime. In Si and Ge $\mu\tau >$ 1 cm²V⁻¹ for both electrons and holes, whereas in compound semiconductors it is in the range 10⁻³–10⁻⁸. Since for holes $\mu\tau$ is typically an order of magnitude smaller than for electrons, detector configurations where the electron contribution to the charge signal dominates—*e.g.*, strip or pixel structures—can provide better performance.

31.7.2. Detector Configurations :

A $p-n$ junction operated at reverse bias forms a sensitive region depleted of mobile charge and sets up an electric field that sweeps charge liberated by radiation to the electrodes. Detectors typically use an asymmetric structure, *e.g.*, a highly doped p electrode and a lightly doped n region, so that the depletion region extends predominantly into the lightly doped volume.

In a planar device the thickness of the depleted region is

$$W = \sqrt{2\epsilon(V + V_{bi})/Ne} = \sqrt{2\rho\mu\epsilon(V + V_{bi})}, \quad (31.18)$$

where V = external bias voltage

V_{bi} = “built-in” voltage (\approx 0.5 V for resistivities typically used in Si detectors)

N = doping concentration

e = electronic charge

ϵ = dielectric constant = 11.9 $\epsilon_0 \approx$ 1 pF/cm in Si

ρ = resistivity (typically 1–10 k Ω cm in Si)

μ = charge carrier mobility

= 1350 cm² V⁻¹ s⁻¹ for electrons in Si

= 450 cm² V⁻¹ s⁻¹ for holes in Si

In Si

$$W = 0.5 [\mu\text{m}/\sqrt{\Omega\text{-cm} \cdot \text{V}}] \times \sqrt{\rho(V + V_{bi})} \text{ for } n\text{-type Si, and}$$

$$W = 0.3 [\mu\text{m}/\sqrt{\Omega\text{-cm} \cdot \text{V}}] \times \sqrt{\rho(V + V_{bi})} \text{ for } p\text{-type Si.}$$

The conductive p and n regions together with the depleted volume form a capacitor with the capacitance per unit area

$$C = \epsilon/W \approx 1 [\text{pF/cm}]/W \text{ in Si.} \quad (31.19)$$

In strip and pixel detectors the capacitance is dominated by the fringing capacitance. For example, the strip-to-strip Si fringing capacitance is \sim 1–1.5 pF cm⁻¹ of strip length at a strip pitch of 25–50 μm .

Large volume ($\sim 10^2\text{--}10^3\text{ cm}^3$) Ge detectors are commonly configured as coaxial detectors, *e.g.*, a cylindrical n-type crystal with 5–10 cm diameter and 10 cm length with an inner 5–10 mm diameter n⁺ electrode and an outer p⁺ layer forming the diode junction. Ge can be grown with very low impurity levels, $10^9\text{--}10^{10}\text{ cm}^{-3}$ (HPGe), so these large volumes can be depleted with several kV.

31.7.3. Signal Formation :

The signal pulse shape depends on the instantaneous carrier velocity $v(x) = \mu E(x)$ and the electrode geometry, which determines the distribution of induced charge (*e.g.*, see Ref. 115, pp. 71–83). Charge collection time decreases with increasing bias voltage, and can be reduced further by operating the detector with “overbias,” *i.e.*, a bias voltage exceeding the value required to fully deplete the device. The collection time is limited by velocity saturation at high fields (in Si approaching 10^7 cm/s at $E > 10^4\text{ V/cm}$); at an average field of 10^4 V/cm the collection time is about 15 ps/ μm for electrons and 30 ps/ μm for holes. In typical fully-depleted detectors 300 μm thick, electrons are collected within about 10 ns, and holes within about 25 ns.

Position resolution is limited by transverse diffusion during charge collection (typically 5 μm for 300 μm thickness) and by knock-on electrons. Resolutions of 2–4 μm (rms) have been obtained in beam tests. In magnetic fields, the Lorentz drift deflects the electron and hole trajectories and the detector must be tilted to reduce spatial spreading (see “Hall effect” in semiconductor textbooks).

Electrodes can be in the form of cm-scale pads, strips, or μm -scale pixels. Various readout structures have been developed for pixels, *e.g.*, CCDs, DEPFETs, monolithic pixel devices that integrate sensor and electronics (MAPS), and hybrid pixel devices that utilize separate sensors and readout ICs connected by two-dimensional arrays of solder bumps. For an overview and further discussion see Ref. 115.

In gamma ray spectroscopy ($E_\gamma > 10^2\text{ keV}$) Compton scattering dominates, so for a significant fraction of events the incident gamma energy is not completely absorbed, *i.e.*, the Compton scattered photon escapes from the detector and the energy deposited by the Compton electron is only a fraction of the total. Distinguishing multi-interaction events, *e.g.*, multiple Compton scatters with a final photoelectric absorption, from single Compton scatters allows background suppression. Since the individual interactions take place in different parts of the detector volume, these events can be distinguished by segmenting the outer electrode of a coaxial detector and analyzing the current pulse shapes. The different collection times can be made more distinguishable by using “point” electrodes, where most of the signal is induced when charges are close to the electrode, similarly to strip or pixel detectors. Charge clusters arriving from different positions in the detector will arrive at different times and produce current pulses whose major components are separated in time. Point electrodes also reduce the electrode capacitance, which reduces electronic noise, but careful design is necessary to avoid low-field regions in the detector volume.

31.7.4. Radiation Damage : Radiation damage occurs through two basic mechanisms:

1. Bulk damage due to displacement of atoms from their lattice sites. This leads to increased leakage current, carrier trapping, and build-up of space charge that changes the required operating voltage. Displacement damage depends on the nonionizing energy loss and the energy imparted to the recoil atoms, which can initiate a chain of subsequent displacements, *i.e.*, damage clusters. Hence, it is critical to consider both particle type and energy.
2. Surface damage due to charge build-up in surface layers, which leads to increased surface leakage currents. In strip detectors the inter-strip isolation is affected. The effects of charge build-up are strongly dependent on the device structure and on fabrication details. Since the damage is proportional to the absorbed energy (when ionization dominates), the dose can be specified in rad (or Gray) independent of particle type.

The increase in reverse bias current due to bulk damage is $\Delta I_r = \alpha\Phi$ per unit volume, where Φ is the particle fluence and α the damage coefficient ($\alpha \approx 3 \times 10^{-17}\text{ A/cm}$ for minimum ionizing protons

and pions after long-term annealing; $\alpha \approx 2 \times 10^{-17}\text{ A/cm}$ for 1 MeV neutrons). The reverse bias current depends strongly on temperature

$$\frac{I_R(T_2)}{I_R(T_1)} = \left(\frac{T_2}{T_1}\right)^2 \exp\left[-\frac{E}{2k}\left(\frac{T_1 - T_2}{T_1 T_2}\right)\right], \quad (31.20)$$

where $E = 1.2\text{ eV}$, so rather modest cooling can reduce the current substantially (~ 6 -fold current reduction in cooling from room temperature to 0°C).

Displacement damage forms acceptor-like states. These trap electrons, building up a negative space charge, which in turn requires an increase in the applied voltage to sweep signal charge through the detector thickness. This has the same effect as a change in resistivity, *i.e.*, the required voltage drops initially with fluence, until the positive and negative space charge balance and very little voltage is required to collect all signal charge. At larger fluences the negative space charge dominates, and the required operating voltage increases ($V \propto N$). The safe limit on operating voltage ultimately limits the detector lifetime. Strip detectors specifically designed for high voltages have been extensively operated at bias voltages $> 500\text{ V}$. Since the effect of radiation damage depends on the electronic activity of defects, various techniques have been applied to neutralize the damage sites. For example, additional doping with oxygen can increase the allowable charged hadron fluence roughly three-fold [117]. Detectors with columnar electrodes normal to the surface can also extend operational lifetime [118]. The increase in leakage current with fluence, on the other hand, appears to be unaffected by resistivity and whether the material is n or p-type. At fluences beyond 10^{15} cm^{-2} decreased carrier lifetime becomes critical [119,120].

Strip and pixel detectors have remained functional at fluences beyond 10^{15} cm^{-2} for minimum ionizing protons. At this damage level, charge loss due to recombination and trapping becomes significant and the high signal-to-noise ratio obtainable with low-capacitance pixel structures extends detector lifetime. The higher mobility of electrons makes them less sensitive to carrier lifetime than holes, so detector configurations that emphasize the electron contribution to the charge signal are advantageous, *e.g.*, n⁺ strips or pixels on a p- or n-substrate. The occupancy of the defect charge states is strongly temperature dependent; competing processes can increase or decrease the required operating voltage. It is critical to choose the operating temperature judiciously (-10 to 0°C in typical collider detectors) and limit warm-up periods during maintenance. For a more detailed summary see Ref. 121 and the web-sites of the ROSE and RD50 collaborations at <http://RD48.web.cern.ch/rd48> and <http://RD50.web.cern.ch/rd50>. Materials engineering, *e.g.*, introducing oxygen interstitials, can improve certain aspects and is under investigation. At high fluences diamond is an alternative, but operates as an insulator rather than a reverse-biased diode.

Currently, the lifetime of detector systems is still limited by the detectors; in the electronics use of standard “deep submicron” CMOS fabrication processes with appropriately designed circuitry has increased the radiation resistance to fluences $> 10^{15}\text{ cm}^{-2}$ of minimum ionizing protons or pions. For a comprehensive discussion of radiation effects see Ref. 122.

31.8. Low-noise electronics

Revised August 2011 by H. Spieler.

Many detectors rely critically on low-noise electronics, either to improve energy resolution or to allow a low detection threshold. A typical detector front-end is shown in Fig. 31.18.

The detector is represented by a capacitance C_d , a relevant model for most detectors. Bias voltage is applied through resistor R_b and the signal is coupled to the preamplifier through a blocking capacitor C_c . The series resistance R_s represents the sum of all resistances present in the input signal path, *e.g.* the electrode resistance, any input protection networks, and parasitic resistances in the input transistor. The preamplifier provides gain and feeds a pulse shaper, which tailors the overall frequency response to optimize signal-to-noise ratio while limiting the duration of the signal pulse to accommodate the signal pulse rate. Even if not explicitly stated, all amplifiers provide some form of pulse shaping due to their limited frequency response.

Figure 31.18: Typical detector front-end circuit.

The equivalent circuit for the noise analysis (Fig. 31.19) includes both current and voltage noise sources. The leakage current of a semiconductor detector, for example, fluctuates due to electron emission statistics. The statistical fluctuations in the charge measurement will scale with the square root of the total number of recorded charges, so this noise contribution increases with the width of the shaped output pulse. This “shot noise” i_{nd} is represented by a current noise generator in parallel with the detector. Resistors exhibit noise due to thermal velocity fluctuations of the charge carriers. This yields a constant noise power density vs. frequency, so increasing the bandwidth of the shaped output pulse, *i.e.* reducing the shaping time, will increase the noise. This noise source can be modeled either as a voltage or current generator. Generally, resistors shunting the input act as noise current sources and resistors in series with the input act as noise voltage sources (which is why some in the detector community refer to current and voltage noise as “parallel” and “series” noise). Since the bias resistor effectively shunts the input, as the capacitor C_b passes current fluctuations to ground, it acts as a current generator i_{nb} and its noise current has the same effect as the shot noise current from the detector. Any other shunt resistances can be incorporated in the same way. Conversely, the series resistor R_s acts as a voltage generator. The electronic noise of the amplifier is described fully by a combination of voltage and current sources at its input, shown as e_{na} and i_{na} .

Figure 31.19: Equivalent circuit for noise analysis.

Shot noise and thermal noise have a “white” frequency distribution, *i.e.* the spectral power densities $dP_n/df \propto di_n^2/df \propto de_n^2/df$ are constant with the magnitudes

$$\begin{aligned} i_{nd}^2 &= 2eI_d, \\ i_{nb}^2 &= \frac{4kT}{R_b}, \\ e_{ns}^2 &= 4kTR_s, \end{aligned} \quad (31.21)$$

where e is the electronic charge, I_d the detector bias current, k the Boltzmann constant and T the temperature. Typical amplifier noise parameters e_{na} and i_{na} are of order $\text{nV}/\sqrt{\text{Hz}}$ and $\text{pA}/\sqrt{\text{Hz}}$. Trapping and detrapping processes in resistors, dielectrics and semiconductors can introduce additional fluctuations whose noise power frequently exhibits a $1/f$ spectrum. The spectral density of the $1/f$ noise voltage is

$$e_{nf}^2 = \frac{A_f}{f}, \quad (31.22)$$

where the noise coefficient A_f is device specific and of order 10^{-10} – 10^{-12}V^2 .

A fraction of the noise current flows through the detector capacitance, resulting in a frequency-dependent noise voltage $i_n/(\omega C_d)$, which is added to the noise voltage in the input circuit. Thus, the current noise contribution increases with lowering frequency, so its contribution increases with shaping pulse width. Since the individual noise contributions are random and uncorrelated, they add in quadrature. The total noise at the output of the pulse shaper is obtained by integrating over the full bandwidth of the system. Superimposed on repetitive detector signal pulses of constant magnitude, purely random noise produces a Gaussian signal distribution.

Since radiation detectors typically convert the deposited energy into charge, the system’s noise level is conveniently expressed as an equivalent noise charge Q_n , which is equal to the detector signal that yields a signal-to-noise ratio of one. The equivalent noise charge is commonly expressed in Coulombs, the corresponding number of electrons, or the equivalent deposited energy (eV). For a capacitive sensor

$$Q_n^2 = i_n^2 F_i T_S + e_n^2 F_v \frac{C^2}{T_S} + F_{vf} A_f C^2, \quad (31.23)$$

where C is the sum of all capacitances shunting the input, F_i , F_v , and F_{vf} depend on the shape of the pulse determined by the shaper and T_s is a characteristic time, for example, the peaking time of a semi-gaussian pulse or the sampling interval in a correlated double sampler. The form factors F_i , F_v are easily calculated

$$F_i = \frac{1}{2T_S} \int_{-\infty}^{\infty} [W(t)]^2 dt, \quad F_v = \frac{T_S}{2} \int_{-\infty}^{\infty} \left[\frac{dW(t)}{dt} \right]^2 dt, \quad (31.24)$$

where for time-invariant pulse-shaping $W(t)$ is simply the system’s impulse response (the output signal seen on an oscilloscope) for a short input pulse with the peak output signal normalized to unity. For more details see Refs. 123 and 124.

A pulse shaper formed by a single differentiator and integrator with equal time constants has $F_i = F_v = 0.9$ and $F_{vf} = 4$, independent of the shaping time constant. The overall noise bandwidth, however, depends on the time constant, *i.e.* the characteristic time T_s . The contribution from noise currents increases with shaping time, *i.e.*, pulse duration, whereas the voltage noise decreases with increasing shaping time. Noise with a $1/f$ spectrum depends only on the ratio of upper to lower cutoff frequencies (integrator to differentiator time constants), so for a given shaper topology the $1/f$ contribution to Q_n is independent of T_s . Furthermore, the contribution of noise voltage sources to Q_n increases with detector capacitance. Pulse shapers can be designed to reduce the effect of current noise, *e.g.*, mitigate radiation damage. Increasing pulse symmetry tends to decrease F_i and increase F_v (*e.g.*, to 0.45 and 1.0 for a shaper with one CR differentiator and four cascaded integrators). For the circuit shown in Fig. 31.19,

$$\begin{aligned} Q_n^2 &= \left(2eI_d + 4kT/R_b + i_{na}^2 \right) F_i T_S \\ &\quad + (4kTR_s + e_{na}^2) F_v C_d^2 / T_S + F_{vf} A_f C_d^2. \end{aligned} \quad (31.25)$$

As the characteristic time T_s is changed, the total noise goes through a minimum, where the current and voltage contributions are equal. Fig. 31.20 shows a typical example. At short shaping times the current noise dominates, whereas at long shaping times the current noise takes over. The noise minimum is flattened by the presence of $1/f$ noise. Increasing the detector capacitance will increase the voltage noise and shift the noise minimum to longer shaping times.

For quick estimates, one can use the following equation, which assumes an FET amplifier (negligible i_{na}) and a simple CR – RC shaper with time constants τ (equal to the peaking time):

$$\begin{aligned} (Q_n/e)^2 &= 12 \left[\frac{1}{\text{nA} \cdot \text{ns}} \right] I_d \tau + 6 \times 10^5 \left[\frac{\text{k}\Omega}{\text{ns}} \right] \frac{\tau}{R_b} \\ &\quad + 3.6 \times 10^4 \left[\frac{\text{ns}}{(\text{pF})^2 (\text{nV})^2 / \text{Hz}} \right] e_n^2 \frac{C^2}{\tau}. \end{aligned} \quad (31.26)$$

Figure 31.20: Equivalent noise charge vs shaping time. Changing the voltage or current noise contribution shifts the noise minimum. Increased voltage noise is shown as an example.

Noise is improved by reducing the detector capacitance and leakage current, judiciously selecting all resistances in the input circuit, and choosing the optimum shaping time constant.

The noise parameters of the amplifier depend primarily on the input device. In field effect transistors, the noise current contribution is very small, so reducing the detector leakage current and increasing the bias resistance will allow long shaping times with correspondingly lower noise. In bipolar transistors, the base current sets a lower bound on the noise current, so these devices are best at short shaping times. In special cases where the noise of a transistor scales with geometry, *i.e.*, decreasing noise voltage with increasing input capacitance, the lowest noise is obtained when the input capacitance of the transistor is equal to the detector capacitance, albeit at the expense of power dissipation. Capacitive matching is useful with field-effect transistors, but not bipolar transistors. In bipolar transistors, the minimum obtainable noise is independent of shaping time, but only at the optimum collector current I_C , which does depend on shaping time.

$$Q_{n,\min}^2 = 4kT \frac{C}{\sqrt{\beta_{DC}}} \sqrt{F_i F_v} \text{ at } I_c = \frac{kT}{e} C \sqrt{\beta_{DC}} \sqrt{\frac{F_v}{F_i}} \frac{1}{T_S}, \quad (31.27)$$

where β_{DC} is the DC current gain. For a CR - RC shaper and $\beta_{DC} = 100$,

$$Q_{n,\min}/e \approx 250 \sqrt{C/\text{pF}}. \quad (31.28)$$

Practical noise levels range from $\sim 1e$ for CCD's at long shaping times to $\sim 10^4 e$ in high-capacitance liquid argon calorimeters. Silicon strip detectors typically operate at $\sim 10^3$ electrons, whereas pixel detectors with fast readout provide noise of several hundred electrons.

In timing measurements, the slope-to-noise ratio must be optimized, rather than the signal-to-noise ratio alone, so the rise time t_r of the pulse is important. The "jitter" σ_t of the timing distribution is

$$\sigma_t = \frac{\sigma_n}{(dS/dt)_{S_T}} \approx \frac{t_r}{S/N}, \quad (31.29)$$

where σ_n is the rms noise and the derivative of the signal dS/dt is evaluated at the trigger level S_T . To increase dS/dt without incurring excessive noise, the amplifier bandwidth should match the rise-time of the detector signal. The 10 to 90% rise time of an amplifier with bandwidth f_U is $0.35/f_U$. For example, an oscilloscope with 350 MHz bandwidth has a 1 ns rise time. When amplifiers are cascaded, which is invariably necessary, the individual rise times add in quadrature.

$$t_r \approx \sqrt{t_{r1}^2 + t_{r2}^2 + \dots + t_{rn}^2}. \quad (31.30)$$

Increasing signal-to-noise ratio also improves time resolution, so minimizing the total capacitance at the input is also important. At high signal-to-noise ratios, the time jitter can be much smaller than the rise time. The timing distribution may shift with signal

level ("walk"), but this can be corrected by various means, either in hardware or software [8].

The basic principles discussed above apply to both analog and digital signal processing. In digital signal processing the pulse shaper shown in Fig. 31.18 is replaced by an analog to digital converter (ADC) followed by a digital processor that determines the pulse shape. Digital signal processing allows great flexibility in implementing filtering functions. The software can be changed readily to adapt to a wide variety of operating conditions and it is possible to implement filters that are impractical or even impossible using analog circuitry. However, this comes at the expense of increased circuit complexity and increased demands on the ADC compared to analog shaping.

If the sampling rate of the ADC is too low, high frequency components will be transferred to lower frequencies ("aliasing"). The sampling rate of the ADC must be high enough to capture the maximum frequency component of the input signal. Apart from missing information on the fast components of the pulse, undersampling introduces spurious artifacts. If the frequency range of the input signal is much greater, the noise at the higher frequencies will be transferred to lower frequencies and increase the noise level in the frequency range of pulses formed in the subsequent digital shaper. The Nyquist criterion states that the sampling frequency must be at least twice the maximum relevant input frequency. This requires that the bandwidth of the circuitry preceding the ADC must be limited. The most reliable technique is to insert a low-pass filter.

The digitization process also introduces inherent noise, since the voltage range ΔV corresponding to a minimum bit introduces quasi-random fluctuations relative to the exact amplitude

$$\sigma_n = \frac{\Delta V}{\sqrt{12}}. \quad (31.31)$$

When the Nyquist condition is fulfilled the noise bandwidth Δf_n is spread nearly uniformly and extends to 1/2 the sampling frequency f_S , so the spectral noise density

$$e_n = \frac{\sigma_n}{\sqrt{\Delta f_n}} = \frac{\Delta V}{\sqrt{12}} \cdot \frac{1}{\sqrt{f_S/2}} = \frac{\Delta V}{\sqrt{6} f_S}. \quad (31.32)$$

Sampling at a higher frequency spreads the total noise over a larger frequency range, so oversampling can be used to increase the effective resolution. In practice, this quantization noise is increased by differential nonlinearity. Furthermore, the equivalent input noise of ADCs is often rather high, so the overall gain of the stages preceding the ADC must be sufficiently large for the preamplifier input noise to override.

When implemented properly, digital signal processing provides significant advantages in systems where the shape of detector signal pulses changes greatly, for example in large semiconductor detectors for gamma rays or in gaseous detectors (*e.g.* TPCs) where the duration of the current pulse varies with drift time, which can range over orders of magnitude. Where is analog signal processing best (most efficient)? In systems that require fast time response the high power requirements of high-speed ADCs are prohibitive. Systems that are not sensitive to pulse shape can use fixed shaper constants and rather simple filters, which can be either continuous or sampled. In high density systems that require small circuit area and low power (*e.g.* strip and pixel detectors), analog filtering often yields the required response and tends to be most efficient.

For a more detailed introduction to detector signal processing and electronics see Ref. 115.

31.9. Calorimeters

A calorimeter is designed to measure the energy deposition and its direction for a contained electromagnetic (EM) or hadronic shower. The characteristic interaction distance for an electromagnetic interaction is the radiation length X_0 , which ranges from 13.8 g cm^{-2} in iron to 6.0 g cm^{-2} in uranium.* Similarly, the characteristic nuclear interaction length λ_I varies from 132.1 g cm^{-2} (Fe) to 209 g cm^{-2} (U).† In either case, a calorimeter must be many interaction lengths deep, where “many” is determined by physical size, cost, and other factors. EM calorimeters tend to be $15\text{--}30 X_0$ deep, while hadronic calorimeters are usually compromised at $5\text{--}8 \lambda_I$. In real experiments there is likely to be an EM calorimeter in front of the hadronic section, which in turn has less sampling density in the back, so the hadronic cascade occurs in a succession of different structures.

Figure 31.21: Nuclear interaction length λ_I/ρ (circles) and radiation length X_0/ρ (+’s) in cm for the chemical elements with $Z > 20$ and $\lambda_I < 50$ cm.

In all cases there is a premium on small λ_I/ρ and X_0/ρ (both with units of length). These quantities are shown for $Z > 20$ for the chemical elements in Fig. 31.21. For the hadronic case, metallic absorbers in the W–Au region are best, followed by U. The Ru–Pd region elements are rare and expensive. Lead is a bad choice. Given cost considerations, Fe and Cu might be appropriate choices. For EM calorimeters high Z is preferred, and lead is not a bad choice.

These considerations are for *sampling calorimeters* consisting of metallic absorber sandwiched or (threaded) with an active material which generates signal. The active medium may be a scintillator, an ionizing noble liquid, a gas chamber, a semiconductor, or a Cherenkov radiator. The average interaction length is thus greater than that of the absorber alone, sometimes substantially so.

There are also *homogeneous calorimeters*, in which the entire volume is sensitive, *i.e.*, contributes signal. Homogeneous calorimeters (so far usually electromagnetic) may be built with inorganic heavy (high density, high $\langle Z \rangle$) scintillating crystals, or non-scintillating Cherenkov radiators such as lead glass and lead fluoride. Scintillation light and/or ionization in noble liquids can be detected. Nuclear interaction lengths in inorganic crystals range from 17.8 cm (LuAlO_3) to 42.2 cm (NaI). Popular choices have been BGO with $\lambda_I = 22.3 \text{ cm}$ and $X_0 = 1.12 \text{ cm}$, and PbWO_4 (20.3 cm and 0.89 cm). Properties of these and other commonly used inorganic crystal scintillators can be found in Table 31.4.

31.9.1. Electromagnetic calorimeters :

Revised October 2009 by R.-Y. Zhu (California Inst. of Technology).

The development of electromagnetic showers is discussed in the section on “Passage of Particles Through Matter” (Sec. 30 of this *Review*).

Formulae are given which approximately describe average showers, but since the physics of electromagnetic showers is well understood, detailed and reliable Monte Carlo simulation is possible. EGS4 [125] and GEANT [126] have emerged as the standards.

There are homogeneous and sampling electromagnetic calorimeters. In a homogeneous calorimeter the entire volume is sensitive, *i.e.*, contributes signal. Homogeneous electromagnetic calorimeters may be built with inorganic heavy (high- Z) scintillating crystals such as BGO, CsI, NaI, and PWO, non-scintillating Cherenkov radiators such as lead glass and lead fluoride, or ionizing noble liquids. Properties of commonly used inorganic crystal scintillators can be found in Table 31.4. A sampling calorimeter consists of an active medium which generates signal and a passive medium which functions as an absorber. The active medium may be a scintillator, an ionizing noble liquid, a gas chamber, or a semiconductor. The passive medium is usually a material of high density, such as lead, iron, copper, or depleted uranium.

The energy resolution σ_E/E of a calorimeter can be parametrized as $a/\sqrt{E} \oplus b \oplus c/E$, where \oplus represents addition in quadrature and E is in GeV. The stochastic term a represents statistics-related fluctuations such as intrinsic shower fluctuations, photoelectron statistics, dead material at the front of the calorimeter, and sampling fluctuations. For a fixed number of radiation lengths, the stochastic term a for a sampling calorimeter is expected to be proportional to $\sqrt{t/f}$, where t is plate thickness and f is sampling fraction [127,128]. While a is at a few percent level for a homogeneous calorimeter, it is typically 10% for sampling calorimeters. The main contributions to the systematic, or constant, term b are detector non-uniformity and calibration uncertainty. In the case of the hadronic cascades discussed below, non-compensation also contributes to the constant term. One additional contribution to the constant term for calorimeters built for modern high-energy physics experiments, operated in a high-beam intensity environment, is radiation damage of the active medium. This can be minimized by developing radiation-hard active media [48] and by frequent *in situ* calibration and monitoring [47,128]. With effort, the constant term b can be reduced to below one percent. The term c is due to electronic noise summed over readout channels within a few Molière radii. The best energy resolution for electromagnetic shower measurement is obtained in total absorption homogeneous calorimeters, *e.g.* calorimeters built with heavy crystal scintillators. These are used when ultimate performance is pursued.

The position resolution depends on the effective Molière radius and the transverse granularity of the calorimeter. Like the energy resolution, it can be factored as $a/\sqrt{E} \oplus b$, where a is a few to 20 mm and b can be as small as a fraction of mm for a dense calorimeter with fine granularity. Electromagnetic calorimeters may also provide direction measurement for electrons and photons. This is important for photon-related physics when there are uncertainties in event origin, since photons do not leave information in the particle tracking system. Typical photon angular resolution is about $45 \text{ mrad}/\sqrt{E}$, which can be provided by implementing longitudinal segmentation [129] for a sampling calorimeter or by adding a preshower detector [130] for a homogeneous calorimeter without longitudinal segmentation.

Novel technologies have been developed for electromagnetic calorimetry. New heavy crystal scintillators, such as PWO and LSO:Ce (see Sec. 31.4), have attracted much attention for homogeneous calorimetry. In some cases, such as PWO, it has received broad applications in high-energy and nuclear physics experiments. The “spaghetti” structure has been developed for sampling calorimetry with scintillating fibers as the sensitive medium. The “accordion” structure has been developed for sampling calorimetry with ionizing noble liquid as the sensitive medium. Table 31.8 provides a brief description of typical electromagnetic calorimeters built recently for high-energy physics experiments. Also listed in this table are calorimeter depths in radiation lengths (X_0) and the achieved energy resolution. Whenever possible, the performance of calorimeters *in*

* $X_0 = 120 \text{ g cm}^{-2} Z^{-2/3}$ to better than 5% for $Z > 23$.

† $\lambda_I = 37.8 \text{ g cm}^{-2} A^{0.312}$ to within 0.8% for $Z > 15$.

Table 31.8: Resolution of typical electromagnetic calorimeters. E is in GeV.

Technology (Experiment)	Depth	Energy resolution	Date
NaI(Tl) (Crystal Ball)	$20X_0$	$2.7\%/E^{1/4}$	1983
$\text{Bi}_4\text{Ge}_3\text{O}_{12}$ (BGO) (L3)	$22X_0$	$2\%/\sqrt{E} \oplus 0.7\%$	1993
CsI (KTeV)	$27X_0$	$2\%/\sqrt{E} \oplus 0.45\%$	1996
CsI(Tl) (BaBar)	$16\text{--}18X_0$	$2.3\%/E^{1/4} \oplus 1.4\%$	1999
CsI(Tl) (BELLE)	$16X_0$	1.7% for $E_\gamma > 3.5$ GeV	1998
PbWO_4 (PWO) (CMS)	$25X_0$	$3\%/\sqrt{E} \oplus 0.5\% \oplus 0.2/E$	1997
Lead glass (OPAL)	$20.5X_0$	$5\%/\sqrt{E}$	1990
Liquid Kr (NA48)	$27X_0$	$3.2\%/\sqrt{E} \oplus 0.42\% \oplus 0.09/E$	1998
Scintillator/depleted U (ZEUS)	$20\text{--}30X_0$	$18\%/\sqrt{E}$	1988
Scintillator/Pb (CDF)	$18X_0$	$13.5\%/\sqrt{E}$	1988
Scintillator fiber/Pb spaghetti (KLOE)	$15X_0$	$5.7\%/\sqrt{E} \oplus 0.6\%$	1995
Liquid Ar/Pb (NA31)	$27X_0$	$7.5\%/\sqrt{E} \oplus 0.5\% \oplus 0.1/E$	1988
Liquid Ar/Pb (SLD)	$21X_0$	$8\%/\sqrt{E}$	1993
Liquid Ar/Pb (H1)	$20\text{--}30X_0$	$12\%/\sqrt{E} \oplus 1\%$	1998
Liquid Ar/depl. U (DØ)	$20.5X_0$	$16\%/\sqrt{E} \oplus 0.3\% \oplus 0.3/E$	1993
Liquid Ar/Pb accordion (ATLAS)	$25X_0$	$10\%/\sqrt{E} \oplus 0.4\% \oplus 0.3/E$	1996

situ is quoted, which is usually in good agreement with prototype test beam results as well as EGS or GEANT simulations, provided that all systematic effects are properly included. Detailed references on detector design and performance can be found in Appendix C of reference [128] and Proceedings of the International Conference series on Calorimetry in Particle Physics.

31.9.2. Hadronic calorimeters : [1–5,128]

Revised October 2011 by D. E. Groom (LBNL).

Most large hadron calorimeters are parts of large 4π detectors at colliding beam facilities. At present these are sampling calorimeters: plates of absorber (Fe, Pb, Cu, or occasionally U or W) alternating with plastic scintillators (plates, tiles, bars), liquid argon (LAr), or gaseous detectors. The ionization is measured directly, as in LAr calorimeters, or via scintillation light observed by photodetectors (usually PMT's). Wavelength-shifting fibers are often used to solve difficult problems of geometry and light collection uniformity. Silicon sensors are being studied for ILC detectors; in this case e - h pairs are collected. There are as many variants of these schemes as there are calorimeters, including variations in geometry of the absorber and sensors, *e.g.*, scintillating fibers threading an absorber [131], and the “accordion” LAr detector, with zig-zag absorber plates to minimize channeling effects. Another departure from the traditional sandwich structure is the LAr-tube design shown in Fig. 31.22(a).

A relatively new variant is the detection of Cerenkov light in hadron calorimetry. Such a calorimeter is sensitive to e^\pm 's in the EM showers plus a few relativistic pions. An example is the radiation-hard forward calorimeter in CMS, with iron absorber and quartz fiber readout by PMT's.

Ideally the calorimeter is segmented in ϕ and θ (or $\eta = -\ln \tan(\theta/2)$). Fine segmentation, while desirable, is limited by cost, readout complexity, practical geometry, and the transverse size of the cascades—but see [132]. An example, a wedge of the ATLAS central barrel calorimeter, is shown in Fig. 31.22(b).

In an inelastic hadronic collision a significant fraction f_{em} of the energy is removed from further hadronic interaction by the production of secondary π^0 's and η 's, whose decay photons generate high-energy electromagnetic (EM) showers. Charged secondaries (π^\pm , p , ...) deposit energy via ionization and excitation, but also interact with

Figure 31.22: (a) ATLAS forward hadronic calorimeter structure (FCal2, 3). Tubes containing LAr are embedded in a mainly tungsten matrix. (b) ATLAS central calorimeter wedge; iron with plastic scintillator tile with wavelength-shifting fiber readout.

nuclei, producing spallation protons and neutrons, evaporation neutrons, and spallation products. The charged collision products produce detectable ionization, as do the showering γ -rays from the prompt de-excitation of highly excited nuclei. The recoiling nuclei generate little or no detectable signal. The neutrons lose kinetic energy in elastic collisions over hundreds of ns, gradually thermalize, and are captured, with the production of more γ -rays—usually outside the acceptance gate of the electronics. Between endothermic spallation losses, nuclear recoils, and late neutron capture, a significant fraction of the hadronic energy (20%–40%, depending on the absorber and energy of the incident particle) is invisible.

In contrast to EM showers, hadronic cascade processes are characterized by the production of relatively few high-energy particles. The lost energy and f_{em} , the $\pi^0 \rightarrow \gamma\gamma$ fraction are highly variable from event to event. Until there is event-by-event knowledge of both the invisible energy loss and EM deposit (to be discussed below), the energy resolution of a hadron calorimeter will remain significantly worse than that of an EM calorimeter.

It has been shown by a simple induction argument, and verified by experiment, that the decrease in the average value of the hadronic energy fraction ($\langle f_h \rangle = 1 - \langle f_{em} \rangle$) as the projectile energy E increases is fairly well described by the power law [133,135]

$$\langle f_h \rangle \approx (E/E_0)^{m-1} \quad (\text{for } E > E_0), \quad (31.33)$$

at least up to a few hundred GeV. The exponent m depends logarithmically on the mean multiplicity and the mean fractional loss to π^0 production in a single interaction. It is in the range 0.80–0.87, but must be obtained experimentally for each calorimeter configuration. E_0 is roughly the energy for the onset of inelastic collisions. It is 1 GeV or a little less for incident pions [133].

In a hadron-nucleus collision a large fraction of the incident energy is carried by a “leading particle” with the same quark content as the incident hadron. If the projectile is a charged pion, the leading particle is usually a pion, which can be neutral and hence contributes to the EM sector. This is not true for incident protons. The result is an increased mean hadronic fraction for incident protons: in Eq. (31.34b) $E_0 \approx 2.6$ GeV [133,134,136].

The EM energy deposit is usually detected more efficiently than the hadronic energy deposit. If the detection efficiency for the EM sector is e and that for the hadronic sector is h , then the ratio of the mean response to a pion to that for an electron is

$$\pi/e = \langle f_{em} \rangle + \langle f_h \rangle h/e = 1 - (1 - h/e) \langle f_h \rangle \quad (31.34a)$$

$$\approx 1 - (1 - h/e)(E/E_0)^{m-1}. \quad (31.34b)$$

If $h \neq e$ the hadronic response is not a linear function of energy. Only the product $(1 - h/e)E_0^{1-m}$ can be obtained by measuring π/e as a function of energy. Since $1 - m$ is small and $E_0 \approx 1$ GeV for the usual pion-induced cascades, this fact is usually ignored and h/e is reported.

The discussion above assumes an idealized calorimeter, with the same structure throughout and without leakage. “Real” calorimeters

usually have an EM detector in front and a coarse “catcher” in the back. Complete containment is generally impractical.

By definition, $0 \leq f_{em} \leq 1$. Its variance changes only slowly with energy, but perforce $\langle f_{em} \rangle \rightarrow 1$ as the projectile energy increases. An empirical power law $\sigma_{f_{em}} = (E/E_1)^{1-\ell}$ (where $\ell < 1$) describes the energy dependence adequately and has the right asymptotic properties. For $h/e \neq 1$, fluctuations in f_{em} significantly contribute to the resolution, in particular contributing a larger fraction of the variance at high energies. Since the f_{em} distribution has a tail on the high side, the calorimeter response is non-Gaussian with a high-energy tail if $h/e < 1$. *Noncompensation* ($h/e \neq 1$) thus seriously degrades resolution as well as producing a nonlinear response.

It is clearly desirable to *compensate* the response, *i.e.*, to design the calorimeter such that $h/e = 1$. This is possible only with a sampling calorimeter, where several variables can be chosen or tuned:

1. Decrease the EM sensitivity. EM cross sections increase with Z ,[†] and most of the energy in an EM shower is deposited by low-energy electrons. A disproportionate fraction of the EM energy is thus deposited in the higher- Z absorber. Lower- Z cladding, such as the steel cladding on ZEUS U plates, preferentially absorbs low-energy γ 's in EM showers and thus also lowers the electronic response. G10 signal boards in the DØ calorimeters had the same effect. The degree of EM signal suppression can be somewhat controlled by tuning the sensor/absorber thickness ratio.
2. Increase the hadronic sensitivity. The abundant neutrons produced in the cascade have a large n - p scattering cross section, with the production of low-energy scattered protons in hydrogenous sampling materials such as butane-filled proportional counters or plastic scintillator. (When scattering from a nucleus with mass number A , a neutron can at most lose $4/(1+A)^2$ of its kinetic energy.) The down side in the scintillator case is that the signal from a highly-ionizing proton stub can be reduced by as much as 90% by recombination and quenching (Birk's Law, Eq. (31.2)).
3. Fabjan and Willis proposed that the additional signal generated in the aftermath of fission in ^{238}U absorber plates should compensate nuclear fluctuations [137]. The production of fission fragments due to fast n capture was later observed [138]. However, while a very large amount of energy is released, it is mostly carried by low-velocity, very highly ionizing fission fragments which produce very little observable signal because of recombination and quenching. The approach seemed promising for awhile. But, for example, much of the compensation observed with the ZEUS ^{238}U /scintillator calorimeter was mainly the result of methods 2 and 3 above.

Motivated very much by the work of Brau, Gabriel, Brückmann, and Wigmans [139], several groups built calorimeters which were very nearly compensating. The degree of compensation was sensitive to the acceptance gate width, and so could be somewhat further tuned. These included

- a) HELIOS with 2.5 mm thick scintillator plates sandwiched between 2 mm thick ^{238}U plates (one of several structures); $\sigma/E = 0.34/\sqrt{E}$ was obtained,
- b) ZEUS, 2.6 cm thick scintillator plates between 3.3 mm ^{238}U plates; $\sigma/E = 0.35/\sqrt{E}$,
- c) a ZEUS prototype with 10 mm Pb plates and 2.5 mm scintillator sheets; $\sigma/E = 0.44/\sqrt{E}$, and
- d) DØ, where the sandwich cell consists of a 4–6 mm thick ^{238}U plate, 2.3 mm LAr, a G-10 signal board, and another 2.3 mm LAr gap. Given geometrical and cost constraints, the calorimeters used in modern collider detectors are not compensating: $h/e \approx 0.7$, for the ATLAS central barrel calorimeter, is typical.

A more versatile approach to compensation is provided by a *dual-readout calorimeter*, in which the signal is sensed by two readout systems with highly contrasting h/e . Although the concept is more than two decades old [140], it has only recently been implemented by the DREAM collaboration [141]. The test beam calorimeter consisted of copper tubes, each filled with scintillator and quartz fibers. If the two signals Q and S (quartz and scintillator) are both normalized to

electron response, then for each event Eq. (31.34) takes the form:

$$\begin{aligned} Q &= E[f_{em} + h/e|_Q(1 - f_{em})] \\ S &= E[f_{em} + h/e|_S(1 - f_{em})] \end{aligned} \quad (31.35)$$

These equations are linear in $1/E$ and f_{em} , and are easily solved to obtain estimators of the *corrected* energy and f_{em} for each event. Both are subject to resolution effects, but effects due to fluctuations in f_{em} are eliminated. The solution for the corrected energy is given by [135]:

$$E = \frac{RS - Q}{R - 1}, \text{ where } R = \frac{1 - h/e|_Q}{1 - h/e|_S} \quad (31.36)$$

R is the energy-independent slope of the event locus on a plot of Q vs S . It can be found either from the fitted slope or by measuring π/e as a function of E .

Although the usually-dominant contribution of the f_{em} distribution to the resolution can be minimized by compensation or the use of dual calorimetry, there remain significant contributions to the resolution:

1. Incomplete corrections for leakage, differences in light collection efficiency, and electronics calibration.
2. Readout transducer shot noise (usually photoelectron statistics), plus electronic noise.
3. Sampling fluctuations. Only a small part of the energy takes place in the scintillator or other sensor, and that fraction is subject to large fluctuations. This can be as high as $40\%/\sqrt{E}$ (lead/scintillator). It is even greater in the Fe/scint case because of the very small sampling fraction (if the calorimeter is to be compensating), and substantially lower in a U/scint calorimeter. It is obviously zero for a homogeneous calorimeter.
4. Intrinsic fluctuations. The many ways ionization can be produced in a hadronic shower have different detection efficiencies and are subject to stochastic fluctuations. In particular, a very large fraction of the hadronic energy ($\sim 20\%$ for Fe/scint, $\sim 40\%$ for U/scint) is “invisible,” going into nuclear dissociation, thermalized neutrons, etc. The lost fraction depends on readout—it will be greater for a Cherenkov readout, less for a heterogeneous active medium such as organic scintillator.

Except in a sampling calorimeter especially designed for the purpose, sampling and intrinsic resolution contributions cannot be separated. This may have been best studied by Drews *et al.* [142], who used a calorimeter in which even- and odd-numbered scintillators were separately read out. Sums and differences of the variances were used to separate sampling and intrinsic contributions.

Figure 31.23: Mean profiles of π^+ (mostly) induced cascades in the CDHS neutrino detector [143].

The fractional resolution can be represented by

$$\frac{\sigma}{E} = \frac{\alpha_1(E)}{\sqrt{E}} \oplus \left| 1 - \frac{h}{e} \right| \left(\frac{E}{E_1} \right)^{1-\ell} \quad (31.37)$$

[†] The asymptotic pair-production cross section scales roughly as $Z^{0.75}$, and $|dE/dx|$ slowly decreases with increasing Z .

The coefficient a_1 is expected to have mild energy dependence for a number of reasons. For example, the sampling variance is $(\pi/e)E$ rather than E . $(E/E_1)^{1-\ell}$ is the parameterization of σ_{fem} discussed above. At a time when data were of lower quality, a plot of $(\sigma/E)^2$ vs $1/E$ was apparently well-described by a straight line (constant a_1) with a finite intercept—the square of the right term in Eq. (31.37), then called “the constant term.” Modern data show the slight downturn [131].

After the first interaction of the incident hadron, the average longitudinal distribution rises to a smooth peak. The peak position increases slowly with energy. The distribution becomes a reasonably exponential after several interaction length. Examples from the CDHS magnetized iron-scintillator sandwich calorimeter test beam calibration runs [143] are shown in Fig. 31.23. Proton-induced cascades are somewhat shorter and broader than pion-induced cascades [136]. A gamma distribution fairly well describes the longitudinal development of an EM shower, as discussed in Sec. 30.5. Following this logic, Bock *et al.* suggested that the profile of a hadronic cascade could be fitted by the sum of two gamma distributions, one with a characteristic length X_0 and the other with length λ_I [144]. Fits to this 4-parameter function are commonly used, *e.g.*, by the ATLAS Tilecal collaboration [136]. If the interaction point is not known (the usual case), the distribution must be convoluted with an exponential in the interaction length of the incident particle. Adragna *et al.* give an analytic form for the convoluted function [136].

The transverse energy deposit is characterized by a central core dominated by EM cascades, together with a wide “skirt” produced by wide-angle hadronic interactions [145].

The CALICE collaboration has tested a “tracking” calorimeter (AHCAL) with highly granular scintillator readout [132]. Since the position of the first interaction is observed, the average longitudinal and radial shower distributions are obtained.

31.9.3. Free electron drift velocities in liquid ionization chambers :

Written August 2009 by W. Walkowiak (U. Siegen)

Figure 31.24: Drift velocity of free electrons as a function of electric field strength for LAr [146], LAr + 0.5% CH₄ [148] and LXe [147]. The average temperatures of the liquids are indicated. Results of a fit to an empirical function [152] are superimposed. In case of LAr at 91 K the error band for the global fit [146] including statistical and systematic errors as well as correlations of the data points is given. Only statistical errors are shown for the individual LAr data points.

Drift velocities of free electrons in LAr [146] are given as a function of electric field strength for different temperatures of the medium in

Fig. 31.24. The drift velocities in LAr have been measured using a double-gridded drift chamber with electrons produced by a laser pulse on a gold-plated cathode. The average temperature gradient of the drift velocity of the free electrons in LAr is described [146] by

$$\frac{\Delta v_d}{\Delta T v_d} = (-1.72 \pm 0.08) \% / \text{K}.$$

Earlier measurements [147–150] used different techniques and show systematic deviations of the drift velocities for free electrons which cannot be explained by the temperature dependence mentioned above.

Drift velocities of free electrons in LXe [148] as a function of electric field strength are also displayed in Fig. 31.24. The drift velocity saturates for $|E| > 3$ kV/cm, and decreases with increasing temperature for LXe as well as measured *e.g.* by [151].

The addition of small concentrations of other molecules like N₂, H₂ and CH₄ in solution to the liquid typically increases the drift velocities of free electrons above the saturation value [148,149], see example for CH₄ admixture to LAr in Fig. 31.24. Therefore, actual drift velocities are critically dependent on even small additions or contaminations.

31.10. Superconducting magnets for collider detectors

Revised September 2011 by A. Yamamoto (KEK); revised October 2001 by R.D. Kephart (FNAL)

31.10.1. Solenoid Magnets : In all cases SI unit are assumed, so that the magnetic field, B , is in Tesla, the stored energy, E , is in joules, the dimensions are in meters, and $\mu_0 = 4\pi \times 10^{-7}$.

The magnetic field (B) in an ideal solenoid with a flux return iron yoke, in which the magnetic field is < 2 T, is given by

$$B = \mu_0 n I \quad (31.38)$$

where n is the number of turns/meter and I is the current. In an air-core solenoid, the central field is given by

$$B(0,0) = \mu_0 n I \frac{L}{\sqrt{L^2 + 4R^2}}, \quad (31.39)$$

where L is the coil length and R is the coil radius.

In most cases, momentum analysis is made by measuring the circular trajectory of the passing particles according to $p = mv\gamma = qrB$, where p is the momentum, m the mass, q the charge, r the bending radius. The sagitta, s , of the trajectory is given by

$$s = qB\ell^2/8p, \quad (31.40)$$

where ℓ is the path length in the magnetic field. In a practical momentum measurement in colliding beam detectors, it is more effective to increase the magnetic volume than the field strength, since

$$dp/p \propto p/B\ell^2, \quad (31.41)$$

where ℓ corresponds to the solenoid coil radius R . The energy stored in the magnetic field of any magnet is calculated by integrating B^2 over all space:

$$E = \frac{1}{2\mu_0} \int B^2 dV \quad (31.42)$$

If the coil thin, (which is the case if it is to superconducting coil), then

$$E \approx (B^2/2\mu_0)\pi R^2 L. \quad (31.43)$$

For a detector in which the calorimetry is outside the aperture of the solenoid, the coil must be thin in terms of radiation and absorption lengths. This usually means that the coil is superconducting and that the vacuum vessel encasing it is of minimum real thickness and fabricated of a material with long radiation length. There are two major contributors to the thickness of a thin solenoid:

Table 31.9: Progress of superconducting magnets for particle physics detectors.

* No longer in service

† EM calorimeter is inside solenoid, so small X/X_0 is not a goal

- 1) The conductor consisting of the current-carrying superconducting material (usually NbTi/Cu) and the quench protecting stabilizer (usually aluminum) are wound on the inside of a structural support cylinder (usually aluminum also). The coil thickness scales as B^2R , so the thickness in radiation lengths (X_0) is

$$t_{\text{coil}}/X_0 = (R/\sigma_h X_0)(B^2/2\mu_0), \quad (31.44)$$

where t_{coil} is the physical thickness of the coil, X_0 the average radiation length of the coil/stabilizer material, and σ_h is the hoop stress in the coil [155]. $B^2/2\mu_0$ is the magnetic pressure. In large detector solenoids, the aluminum stabilizer and support cylinders dominate the thickness; the superconductor (NbTi/Cu) contributes a smaller fraction. The main coil and support cylinder components typically contribute about 2/3 of the total thickness in radiation lengths.

- 2) Another contribution to the material comes from the outer cylindrical shell of the vacuum vessel. Since this shell is susceptible to buckling collapse, its thickness is determined by the diameter, length and the modulus of the material of which it is fabricated. The outer vacuum shell represents about 1/3 of the total thickness in radiation length.

31.10.2. Properties of collider detector magnets :

The physical dimensions, central field stored energy and thickness in radiation lengths normal to the beam line of the superconducting solenoids associated with the major collider are given in Table 31.9 [154]. Fig. 31.25 shows thickness in radiation lengths as a function of B^2R in various collider detector solenoids.

The ratio of stored energy to cold mass (E/M) is a useful performance measure. It can also be expressed as the ratio of the stress, σ_h , to twice the equivalent density, ρ , in the coil [155]:

$$\frac{E}{M} = \frac{\int (B^2/2\mu_0)dV}{\rho V_{\text{coil}}} \approx \frac{\sigma_h}{2\rho} \quad (31.45)$$

The E/M ratio in the coil is approximately equivalent to H ,* the enthalpy of the coil, and it determines the average coil temperature rise after energy absorption in a quench:

$$E/M = H(T_2) - H(T_1) \approx H(T_2) \quad (31.46)$$

* The enthalpy, or heat content, is called H in the thermodynamics literature. It is not to be confused with the magnetic field intensity B/μ .

where T_2 is the average coil temperature after the full energy absorption in a quench, and T_1 is the initial temperature. E/M ratios of 5, 10, and 20 kJ/kg correspond to ~ 65 , ~ 80 , and ~ 100 K, respectively. The E/M ratios of various detector magnets are shown in Fig. 31.26 as a function of total stored energy. One would like the cold mass to be as small as possible to minimize the thickness, but temperature rise during a quench must also be minimized. An E/M ratio as large as 12 kJ/kg is designed into the CMS solenoid, with the possibility that about half of the stored energy can go to an external dump resistor. Thus the coil temperature can be kept below 80 K if the energy extraction system work well. The limit is set by the maximum temperature that the coil design can tolerate during a quench. This maximum local temperature should be < 130 K (50 K + 80 K), so that thermal expansion effects in the coil are manageable.

Figure 31.25: Magnet wall thickness in radiation length as a function of B^2R for various detector solenoids. Gray entries are for magnets no longer in use, and entries underlined are not listed in Table 31.9. Open circles are for magnets not designed to be “thin.” The SSC-SDC prototype provided important R&D for LHC magnets.

Figure 31.26: Ratio of stored energy to cold mass for major detector solenoids. Gray indicates magnets no longer in operation.

31.10.3. Toroidal magnets :

Toroidal coils uniquely provide a closed magnetic field without the necessity of an iron flux-return yoke. Because no field exists at the collision point and along the beam line, there is, in principle, no effect on the beam. On the other hand, the field profile generally has $1/r$ dependence. The particle momentum may be determined by measurements of the deflection angle combined with the sagitta. The deflection (bending) power BL is

$$BL \approx \int_{R_i}^{R_0} \frac{B_i R_i dR}{R \sin \theta} = \frac{B_i R_i}{\sin \theta} \ln(R_0/R_i), \quad (31.47)$$

where R_i is the inner coil radius, R_0 is the outer coil radius, and θ is the angle between the particle trajectory and the beam line axis. The momentum resolution given by the deflection may be expressed as

$$\frac{\Delta p}{p} \propto \frac{p}{BL} \approx \frac{p \sin \theta}{B_i R_i \ln(R_0/R_i)}. \quad (31.48)$$

The momentum resolution is better in the forward/backward (smaller θ) direction. The geometry has been found to be optimal when $R_0/R_i \approx 3-4$. In practical designs, the coil is divided into 6–12 lumped coils in order to have reasonable acceptance and accessibility. This causes the coil design to be much more complex. The mechanical structure needs to sustain the decentering force between adjacent coils, and the peak field in the coil is 3–5 times higher than the useful magnetic field for the momentum analysis [153].

31.11. Measurement of particle momenta in a uniform magnetic field [156,157]

The trajectory of a particle with momentum p (in GeV/c) and charge ze in a constant magnetic field \vec{B} is a helix, with radius of curvature R and pitch angle λ . The radius of curvature and momentum component perpendicular to \vec{B} are related by

$$p \cos \lambda = 0.3 z B R, \quad (31.49)$$

where B is in tesla and R is in meters.

The distribution of measurements of the curvature $k \equiv 1/R$ is approximately Gaussian. The curvature error for a large number of uniformly spaced measurements on the trajectory of a charged particle in a uniform magnetic field can be approximated by

$$(\delta k)^2 = (\delta k_{\text{res}})^2 + (\delta k_{\text{ms}})^2, \quad (31.50)$$

where δk = curvature error

δk_{res} = curvature error due to finite measurement resolution

δk_{ms} = curvature error due to multiple scattering.

If many (≥ 10) uniformly spaced position measurements are made along a trajectory in a uniform medium,

$$\delta k_{\text{res}} = \frac{\epsilon}{L'^2} \sqrt{\frac{720}{N+4}}, \quad (31.51)$$

where N = number of points measured along track

L' = the projected length of the track onto the bending plane

ϵ = measurement error for each point, perpendicular to the trajectory.

If a vertex constraint is applied at the origin of the track, the coefficient under the radical becomes 320.

For arbitrary spacing of coordinates s_i measured along the projected trajectory and with variable measurement errors ϵ_i the curvature error δk_{res} is calculated from:

$$(\delta k_{\text{res}})^2 = \frac{4}{w} \frac{V_{ss}}{V_{ss} V_s^2 s^2 - (V_{ss} s)^2}, \quad (31.52)$$

where V are covariances defined as $V_{s^m s^n} = \langle s^m s^n \rangle - \langle s^m \rangle \langle s^n \rangle$ with $\langle s^m \rangle = w^{-1} \sum (s_i^m / \epsilon_i^2)$ and $w = \sum \epsilon_i^{-2}$.

The contribution due to multiple Coulomb scattering is approximately

$$\delta k_{\text{ms}} \approx \frac{(0.016)(\text{GeV}/c)z}{Lp\beta \cos^2 \lambda} \sqrt{\frac{L}{X_0}}, \quad (31.53)$$

where p = momentum (GeV/c)

z = charge of incident particle in units of e

L = the total track length

X_0 = radiation length of the scattering medium (in units of length; the X_0 defined elsewhere must be multiplied by density)

β = the kinematic variable v/c .

More accurate approximations for multiple scattering may be found in the section on Passage of Particles Through Matter (Sec. 30 of this Review). The contribution to the curvature error is given approximately by $\delta k_{\text{ms}} \approx 8s_{\text{plane}}^{\text{rms}}/L^2$, where $s_{\text{plane}}^{\text{rms}}$ is defined there.

32.1. Introduction

Non-accelerator experiments have become increasingly important in particle physics. These include classical cosmic ray experiments, neutrino oscillation measurements, and searches for double-beta decay, dark matter candidates, and magnetic monopoles. The experimental methods are sometimes those familiar at accelerators (plastic scintillators, drift chambers, TRD's, *etc.*) but there is also instrumentation either not found at accelerators or applied in a radically different way. Examples are atmospheric scintillation detectors (Fly's Eye), massive Cherenkov detectors (Super-Kamiokande, IceCube), ultracold solid state detectors (CDMS). And, except for the cosmic ray detectors, radiologically ultra-pure materials are required.

In this section, some more important detectors special to terrestrial non-accelerator experiments are discussed. Techniques used in both accelerator and non-accelerator experiments are described in Sec. 28, Particle Detectors at Accelerators, some of which have been modified to accommodate the non-accelerator nuances.

Space-based detectors also use some unique instrumentation, but these are beyond the present scope of RPP.

32.2. High-energy cosmic-ray hadron and gamma-ray detectors

32.2.1. Atmospheric fluorescence detectors :

Updated August 2011 by L.R. Wiencke (Colorado School of Mines).

Cosmic-ray fluorescence detectors (FD) use the atmosphere as a giant calorimeter to measure isotropic scintillation light that traces the development profiles of extensive air showers (EAS). The EASs observed are produced by the interactions of high-energy ($E > 10^{17}$ eV) subatomic particles in the stratosphere and upper troposphere, independent of the primary species. Experiments with FDs include the pioneering Fly's Eye [1], HiRes [2], the Telescope Array [3], and the Pierre Auger Observatory [4]. The proposed JEM-EUSO [5] FD would tilt down to sweep across a much larger area from space.

The scintillation light is emitted between 290 and 430 nm (Fig. 32.1), when relativistic charged particles, primarily electrons and positrons, excite nitrogen molecules in air, resulting in transitions of the 1P and 2P systems. Reviews and references for the pioneering and ongoing laboratory measurements of fluorescence yield, $Y(\lambda, P, T, u)$, including dependence on wavelength (λ), temperature (T), pressure (p), and humidity (u) may be found in Refs. 6 and 7.

An FD element (telescope) consists of a non-tracking spherical mirror (3.5–13 m² and less than astronomical quality), a close-packed "camera" of PMTs (for example, Hamamatsu R9508 or Photonis XP3062) near the focal plane, and flash ADC readout system with a pulse and track-finding trigger scheme [8]. Simple reflector optics (12° × 16° degree field of view (FOV) on 256 PMTs) and Schmidt optics (30° × 30° FOV on 440 PMTs), including a correcting element, have been used. Segmented mirrors have been fabricated from slumped or slumped/polished glass with anodized aluminium coating and from chemically anodized AlMgSiO₅ affixed to shaped aluminum. A broadband UV filter (custom fabricated or Schott MUG-6) covers the camera face or much larger entrance aperture to reduce background light such as starlight, airglow, man-made light pollution, and airplane strobelights.

Figure 32.1: Measured fluorescence spectrum excited by 3 MeV electrons in dry air at 800 hPa and 293 K [9].

At 10²⁰ eV, where the flux drops below 1 EAS/km²century, the aperture for an eye of adjacent FD telescopes that span the horizon can reach 10⁴ km² sr. FD operation requires (nearly) moonless nights and clear atmospheric conditions, which imposes a duty cycle of about 10%. Arrangements of LEDs, calibrated diffuse sources [10], pulsed UV

lasers [11], LIDARs* and cloud monitors are used for photometric calibration, atmospheric calibration [12], and determination of exposure [13].

The EAS generates a track consistent with a light source moving at $v = c$ across the FOV. The number of photons (N_γ) as a function of atmospheric depth (X) can be expressed as [7]

$$\frac{dN_\gamma}{dX} = \frac{dE_{\text{dep}}^{\text{tot}}}{dX} \int Y(\lambda, P, T, u) \cdot \tau_{\text{atm}}(\lambda, X) \cdot \varepsilon_{\text{FD}}(\lambda) d\lambda, \quad (32.1)$$

where $\tau_{\text{atm}}(\lambda, X)$ is atmospheric transmission, including wavelength (λ) dependence, and $\varepsilon_{\text{FD}}(\lambda)$ is FD efficiency. $\varepsilon_{\text{FD}}(\lambda)$ includes geometric factors and collection efficiency of the optics, quantum efficiency of the PMTs, and other throughput factors. The typical systematic uncertainties, Y (10–15%), τ_{atm} (10%) and ε_{FD} (photometric calibration 10%), currently dominate the total reconstructed EAS energy uncertainty. $\Delta E/E$ of 20–25% is possible, provided the geometric fit of the EAS axis is constrained by multi-eye stereo projection, or by timing from a colocated sparse array of surface detectors.

Analysis methods to reconstruct the EAS profile and deconvolute the contributions of re-scattered scintillation light, and direct and scattered Cherenkov light are described in [1] and more recently in [14]. The EAS energy is typically obtained by integrating over the Gaisser-Hillas function [15]

$$E_{\text{cal}} = \int_0^\infty w_{\text{max}} \left(\frac{X - X_0}{X_{\text{max}} - X_0} \right)^{(X_{\text{max}} - X_0)/\lambda} e^{-(X_{\text{max}} - X)/\lambda} dX, \quad (32.2)$$

where X_{max} is the depth at which the shower reaches its maximum energy deposit w_{max} . X_0 and λ are two shape parameters.

32.2.2. Atmospheric Cherenkov telescopes for high-energy γ -ray astronomy :

Written August 2009 by J. Holder (Bartol Research Inst., Univ. of Delaware).

A wide variety of astrophysical objects are now known to produce high-energy γ -ray photons. Leptonic or hadronic particle populations, accelerated to relativistic energies in the source, produce γ rays typically through inverse Compton boosting of ambient photons, or through the decay of neutral pions produced in hadronic interactions. At energies below ~ 30 GeV, γ -ray emission can be detected directly using satellite or balloon-borne instrumentation, with an effective area approximately equal to the size of the detector ($< 1 \text{ m}^2$). At higher energies, a technique with much larger effective collection area is required to measure astrophysical γ -ray fluxes, which decrease rapidly with increasing energy. Atmospheric Cherenkov detectors achieve effective collection areas of $\sim 10^5 \text{ m}^2$ by employing the Earth's atmosphere as an intrinsic part of the detection technique.

As described in Chapter 26, a hadronic cosmic ray or high energy γ -ray incident on the Earth's atmosphere triggers a particle cascade, or air shower. Relativistic charged particles in the cascade produce Cherenkov radiation, which is emitted along the shower direction, resulting in a light pool on the ground with a radius of $\sim 130 \text{ m}$. Cherenkov light is produced throughout the cascade development, with the maximum emission occurring when the number of particles in the cascade is largest, at an altitude of $\sim 10 \text{ km}$ for primary energies of 100 GeV–1 TeV. Following absorption and scattering in the atmosphere, the Cherenkov light at ground level peaks at a wavelength, $\lambda \approx 300\text{--}350 \text{ nm}$. The photon density is typically ~ 100 photons/ m^2 at 1 TeV, arriving in a brief flash of a few nanoseconds duration. This Cherenkov pulse can be detected from any point within the light pool radius by using large reflecting surfaces to focus the Cherenkov light on to fast photon detectors (Fig. 32.2).

Modern atmospheric Cherenkov telescopes, such as those built and operated by the H.E.S.S. [17], MAGIC [18] and VERITAS [16] collaborations, consist of large ($> 100 \text{ m}^2$) segmented mirrors on steerable altitude-azimuth mounts. A camera, made from an array of

up to 1000 photomultiplier tubes (PMTs) covering a field-of-view of up to 5.0° in diameter, is placed at the mirror focus and used to record a Cherenkov image of each air shower. Images are recorded at a rate of a few hundred Hz, the vast majority of which are due to showers with hadronic cosmic-ray primaries. The shape and orientation of the Cherenkov images are used to discriminate γ -ray photon events from this cosmic-ray background, and to reconstruct the photon energy and arrival direction. γ -ray images result from purely electromagnetic cascades and appear as narrow, elongated ellipses in the camera plane. The long axis of the ellipse corresponds to the vertical extension of the air shower, and points back towards the source position in the field-of-view. If multiple telescopes are used to view the same shower (“stereoscopy”), the source position is simply the intersection point of the various image axes. Cosmic-ray primaries produce secondaries with large transverse momenta, which initiate sub-showers. Their images are consequently wider and less regular than those with γ -ray primaries and, since the original charged particle has been deflected by galactic magnetic fields before reaching the Earth, the images have no preferred orientation.

Figure 32.2: A schematic illustration of an atmospheric Cherenkov telescope array. The primary particle initiates an air shower, resulting in a cone of Cherenkov radiation. Telescopes within the Cherenkov light pool record elliptical images; the intersection of the long axes of these images indicates the arrival direction of the primary, and hence the location of a γ -ray source in the sky.

The measurable differences in Cherenkov image orientation and morphology provide the background discrimination which makes ground-based γ -ray astronomy possible. For point-like sources, such as distant Active Galactic Nuclei (AGNs), modern instruments can reject up to 99.999% of the triggered cosmic-ray events, while retaining up to 50% of the γ -ray population. In the case of spatially extended sources, such as Galactic supernova remnants (SNR), the background rejection is less efficient, but the technique can be used to produce γ -ray maps of the emission from the source. The angular resolution depends upon the energy of the primary γ -ray, but is typically 0.1° per event (68% containment radius) at energies above a few hundred GeV.

The total Cherenkov yield from the air shower is proportional to the energy of the primary particle. The image intensity, combined with the reconstructed distance of the shower core from each telescope, can therefore be used to estimate the primary energy. The energy resolution of this technique, also energy-dependent, is typically 15–20% at energies above a few hundred GeV. Energy spectra of γ -ray sources can be measured over a wide range; potentially from ~ 50 GeV to ~ 100 TeV, depending upon the instrument characteristics, source strength, and exposure time. To a first approximation, the lower energy threshold at the trigger level, E_T , depends upon the mirror area, A , the photon collection efficiency, $\eta(\lambda)$, the Cherenkov light yield, $C(\lambda)$, the night sky background light, $B(\lambda)$, the solid angle, Ω , and the trigger resolving time, τ , as follows [19]:

$$E_T \propto \frac{1}{C(\lambda)} \sqrt{\frac{B(\lambda)\Omega\tau}{\eta(\lambda)A}} \quad (32.3)$$

* This acronym for “Light Detection and Ranging,” refers here to systems that measure atmospheric properties from the light scattered backwards from laser pulses directed into the sky.

In practice, this function may be modified by the properties of the detector; for example, by complex, multi-level, combinatorial trigger systems and highly pixellated fields of view. In addition, the useful scientific threshold, after the application of analysis cuts to select γ -ray events, is always somewhat higher than this.

The first astrophysical source to be convincingly detected using the imaging atmospheric Cherenkov technique was the Crab Nebula [20], with a flux of 2.1×10^{-11} photons $\text{cm}^{-2} \text{s}^{-1}$ above 1 TeV [21]. Modern arrays have sensitivity sufficient to detect sources with 1% of the Crab Nebula's flux in a few tens of hours, and the TeV source catalog now consists of more than 80 sources. The majority of these have been detected by scanning the Galactic plane from the southern hemisphere with the H.E.S.S. telescope array [22].

32.3. Large neutrino detectors

Large water Cherenkov and scintillator detectors (see Table 32.1) usually consist of a volume of transparent liquid viewed by photomultiplier tubes (PMTs) (see Sec. 31.2); the liquid serves as active target. PMT hit charges and times are recorded and digitized, and triggering is usually based on coincidence of PMTs hits within a time window comparable to the detector's light-crossing time. Because photosensors lining an inner surface represent a driving cost that scales as surface area, very large volumes can be used for comparatively reasonable cost. Some detectors are segmented into subvolumes individually viewed by PMTs, and may include other detector elements (*e.g.*, tracking detectors). Devices to increase light collection, *e.g.*, reflectors or waveshifter plates, may be employed. A common configuration is to have at least one concentric outer layer of liquid material separated from the inner part of the detector to serve as shielding against ambient background. If optically separated and

Table 32.1: Properties of large detectors for rare processes. If total target mass is divided into large submodules, the number of subdetectors is indicated in parentheses.

Detector	Fid. mass, kton (modules)	PMTs (diameter, cm)	ξ	p.e./MeV	Dates
Baksan	0.33, scint (3150)	1/module (15)	segmented	40	1980–

SK II	22.5, H ₂ O	5182 (50)	19%	3	2002–2005
SK III+	22.5, H ₂ O	11129 (50)	39%	6	2006–
SNO	1, D ₂ O/1.7, H ₂ O	9438 (20)	31% [§]	9	1999–2006

* The 51 cm PMTs were added in 2003.

† The effective Daya Bay coverage is 12% with top and bottom reflectors.

‡ The effective Kamiokande III coverage was 25% with light collectors.

§ The effective SNO coverage was 54% with light collectors.

32.3.1. Deep liquid detectors for rare processes :

Revised November 2011 by K. Scholberg & C.W. Walter (Duke University)

Deep, large detectors for rare processes tend to be multi-purpose with physics reach that includes not only solar, reactor, supernova and atmospheric neutrinos, but also searches for baryon number violation, searches for exotic particles such as magnetic monopoles, and neutrino and cosmic ray astrophysics in different energy regimes. The detectors may also serve as targets for long-baseline neutrino beams for neutrino oscillation physics studies. In general, detector design considerations can be divided into high- and low-energy regimes, for which background and event reconstruction issues differ. The high-energy regime, from about 100 MeV to a few hundred GeV, is relevant for proton decay searches, atmospheric neutrinos and high-energy astrophysical neutrinos. The low-energy regime (a few tens of MeV or less) is relevant for supernova, solar, reactor and geological neutrinos.

instrumented with PMTs, an outer layer may also serve as an active veto against entering cosmic rays and other background events. The PMTs for large detectors typically range in size from 20 cm to 50 cm diameter, and typical quantum efficiencies are in the 20–25% range. The active liquid volume requires purification and there may be continuous recirculation of liquid. For large homogeneous detectors, the event interaction vertex is determined using relative timing of PMT hits, and energy deposition is determined from the number of recorded photoelectrons. A “fiducial volume” is usually defined within the full detector volume, some distance away from the PMT array. Inside the fiducial volume, enough PMTs are illuminated per event that reconstruction is considered reliable, and furthermore, entering background from the enclosing walls is suppressed by a buffer of self-shielding. PMT and detector optical parameters are calibrated using laser, LED, or other light sources. Quality of event reconstruction typically depends on photoelectron yield, pixelization and timing.

Because in most cases one is searching for rare events, large detectors are usually sited underground to reduce cosmic-ray related background (see Chapter 26). The minimum depth required varies according to the physics goals [23].

32.3.1.1. Liquid scintillator detectors:

Past and current large underground detectors based on hydrocarbon scintillators include LVD, MACRO, Baksan, Borexino, KamLAND and SNO+. Experiments at nuclear reactors include CHOOZ, Double CHOOZ, Daya Bay, and RENO. Organic liquid scintillators (see Sec. 31.3.0) for large detectors are chosen for high light yield and attenuation length, good stability, compatibility with other detector materials, high flash point, low toxicity, appropriate density for mechanical stability, and low cost. They may be doped with waveshifters and stabilizing agents. Popular choices are pseudocumene (1,2,4-trimethylbenzene) with a few g/L of the PPO (2,5-diphenyloxazole) fluor, and linear alkylbenzene (LAB). In a typical detector configuration there will be active or passive regions of undoped scintillator, non-scintillating mineral oil or water surrounding the inner neutrino target volume. A thin vessel or balloon made of nylon, acrylic or other material transparent to scintillation light may contain the inner target; if the scintillator is buoyant with respect to its buffer, ropes may hold the balloon in place. For phototube surface coverages in the 20–40% range, yields in the few hundreds of photoelectrons per MeV of energy deposition can be obtained. Typical energy resolution is about $7\%/\sqrt{E(\text{MeV})}$, and typical position reconstruction resolution is a few tens of cm at ~ 1 MeV, scaling as $\sim N^{-1/2}$, where N is the number of photoelectrons detected.

Shallow detectors for reactor neutrino oscillation experiments require excellent muon veto capabilities. For $\bar{\nu}_e$ detection via inverse beta decay on free protons, $\bar{\nu}_e + p \rightarrow n + e^+$, the neutron is captured by a proton on a $\sim 180 \mu\text{s}$ timescale, resulting in a 2.2 MeV γ ray, observable by Compton scattering and which can be used as a tag in coincidence with the positron signal. The positron annihilation γ rays may also contribute. Inverse beta decay tagging may be improved by addition of Gd at $\sim 0.1\%$ by mass, which for natural isotope abundance has a $\sim 49,000$ barn cross-section for neutron capture (in contrast to the 0.3 barn cross-section for capture on free protons). Gd capture takes $\sim 30 \mu\text{s}$, and is followed by a cascade of γ rays adding up to about 8 MeV. Gadolinium doping of scintillator requires specialized formulation to ensure adequate attenuation length and stability.

Scintillation detectors have an advantage over water Cherenkov detectors in the lack of Cherenkov threshold and the high light yield. However, scintillation light emission is nearly isotropic, and therefore directional capabilities are relatively weak. Liquid scintillator is especially suitable for detection of low-energy events. Radioactive backgrounds are a serious issue, and include long-lived cosmogenics. To go below a few MeV, very careful selection of materials and purification of the scintillator is required (see Sec. 32.6). Fiducialization and tagging can reduce background. A recent idea, not yet realized, is to dissolve neutrinoless double beta decay ($0\nu\beta\beta$) isotopes in scintillator (for instance ^{150}Nd in SNO+). Although energy resolution is poor compared to typical $0\nu\beta\beta$ search experiments, the quantity of isotope could be so large that the kinematic signature of $0\nu\beta\beta$ would be visible as a clear feature in the spectrum.

32.3.1.2. Water Cherenkov detectors:

Very large-imaging water detectors reconstruct ten-meter-scale Cherenkov rings produced by charged particles (see Sec. 31.5.0). The first such large detectors were IMB and Kamiokande. The only currently existing instance of this class of detector, with fiducial volume of 22.5 kton and total mass of 50 kton, is Super-Kamiokande (Super-K). For volumes of this scale, absorption and scattering of Cherenkov light are non-negligible, and a wavelength-dependent factor $\exp(-d/L(\lambda))$ (where d is the distance from emission to the sensor and $L(\lambda)$ is the attenuation length of the medium) must be included in the integral of Eq. (31.5) for the photoelectron yield. Attenuation lengths on the order of 100 meters have been achieved.

Cherenkov detectors are excellent electromagnetic calorimeters, and the number of Cherenkov photons produced by an e/γ is nearly proportional to its kinetic energy. For massive particles, the number of photons produced is also related to the energy, but not linearly. For any type of particle, the *visible energy* E_{vis} is defined as the

energy of an electron which would produce the same number of Cherenkov photons. The number of collected photoelectrons depends on the scattering and attenuation in the water along with the photocathode coverage, quantum efficiency and the optical parameters of any external light collection systems or protective material surrounding them. Event-by-event corrections are made for geometry and attenuation. For a typical case, in water $N_{\text{p.e.}} \sim 15 \xi E_{\text{vis}}(\text{MeV})$, where ξ is the effective fractional photosensor coverage. Cherenkov photoelectron yield per MeV of energy is relatively small compared to that for scintillator, *e.g.*, ~ 6 pe/MeV for Super-K with a PMT surface coverage of $\sim 40\%$. In spite of light yield and Cherenkov threshold issues, the intrinsic directionality of Cherenkov light allows individual particle tracks to be reconstructed. Vertex and direction fits are performed using PMT hit charges and times, requiring that the hit pattern be consistent with a Cherenkov ring.

High-energy (~ 100 MeV or more) neutrinos from the atmosphere or beams interact with nucleons; for the nucleons bound inside the ^{16}O nucleus, the nuclear effects both at the interaction, and as the particles leave the nucleus must be considered when reconstructing the interaction. Various event topologies can be distinguished by their timing and fit patterns, and by presence or absence of light in a veto. “Fully-contained” events are those for which the neutrino interaction final state particles do not leave the inner part of the detector; these have their energies relatively well measured. Neutrino interactions for which the lepton is not contained in the inner detector sample have higher-energy parent neutrino energy distributions. For example, in “partially-contained” events, the neutrino interacts inside the inner part of the detector but the lepton (almost always a muon, since only muons are penetrating) exits. “Upward-going muons” can arise from neutrinos which interact in the rock below the detector and create muons which enter the detector and either stop, or go all the way through (entering downward-going muons cannot be distinguished from cosmic rays). At high energies, multi-photoelectron hits are likely and the charge collected by each PMT (rather than the number of PMTs firing) must be used; this degrades the energy resolution to approximately $2\%/\sqrt{\xi E_{\text{vis}}(\text{GeV})}$. The absolute energy scale in this regime can be known to $\approx 2\text{--}3\%$ using cosmic-ray muon energy deposition, Michel electrons and π^0 from atmospheric neutrino interactions. Typical vertex resolutions for GeV energies are a few tens of cm [24]. Angular resolution for determination of the direction of a charged particle track is a few degrees. For a neutrino interaction, because some final-state particles are usually below Cherenkov threshold, knowledge of direction of the incoming neutrino direction itself is generally worse than that of the lepton direction, and dependent on neutrino energy.

Multiple particles in an interaction (so long as they are above Cherenkov threshold) may be reconstructed, allowing for the exclusive reconstruction of final states. In searches for proton decay, multiple particles can be kinematically reconstructed to form a decaying nucleon. High-quality particle identification is also possible: γ rays and electrons shower, and electrons scatter, which results in fuzzy rings, whereas muons, pions and protons make sharp rings. These patterns can be quantitatively separated with high reliability using maximum likelihood methods [25]. A e/μ misidentification probability of $\sim 0.4\%/\xi$ in the sub-GeV range is consistent with the performance of several experiments for $4\% < \xi < 40\%$. Sources of background for high energy interactions include misidentified cosmic muons and anomalous light patterns when the PMTs sometimes “flash” and emit photons themselves. The latter class of events can be removed using its distinctive PMT signal patterns, which may be repeated. More information about high energy event selection and reconstruction may be found in reference [26].

In spite of the fairly low light yield, large water Cherenkov detectors may be employed for reconstructing low-energy events, down to *e.g.* $\sim 4\text{--}5$ MeV for Super-K [27]. Low-energy neutrino interactions of solar neutrinos in water are predominantly elastic scattering off atomic electrons; single electron events are then reconstructed. At solar neutrino energies, the visible energy resolution ($\sim 30\%/\sqrt{\xi E_{\text{vis}}(\text{MeV})}$) is about 20% worse than photoelectron counting statistics would imply. Using an electron LINAC and/or nuclear sources, 0.5–1.5% determination of the absolute energy scale

has been achieved at solar neutrino energies. Angular resolution is limited by multiple scattering in this energy regime (25–30°). At these energies, radioactive backgrounds become a dominant issue. These backgrounds include radon in the water itself or emanated by detector materials, and γ rays from the rock and detector materials. In the few to tens of MeV range, radioactive products of cosmic ray muon-induced spallation are troublesome, and are removed by proximity in time and space to preceding muons, at some cost in dead time.

The Sudbury Neutrino Observatory (SNO) detector [28] is the only instance of a large heavy water detector and deserves mention here. In addition to an outer 1.7 kton of light water, SNO contained 1 kton of D₂O, giving it unique sensitivity to neutrino neutral current ($\nu_x + d \rightarrow \nu_x + p + n$), and charged current ($\nu_e + d \rightarrow p + p + e^-$) deuteron breakup reactions. The neutrons were detected in three ways: In the first phase, via the reaction $n + d \rightarrow t + \gamma + 6.25$ MeV; Cherenkov radiation from electrons Compton-scattered by the γ rays was observed. In the second phase, NaCl was dissolved in the water. ³⁵Cl captures neutrons, $n + ^{35}\text{Cl} \rightarrow ^{36}\text{Cl} + \gamma + 8.6$ MeV. The γ rays were observed via Compton scattering. In a final phase, specialized low-background ³He counters (“neutral current detectors” or NCDs) were deployed in the detector. These detected neutrons via $n + ^3\text{He} \rightarrow p + t + 0.76$ MeV, and ionization charge from energy loss of the products was recorded in proportional counters.

32.3.2. Coherent radio Cherenkov radiation detectors :

Written October 2011 by S.R. Klein (LBNL)

Figure 32.3: Representative ν flux limits from radio-detection experiments, illustrating the energy ranges for different techniques. Shown are limits from the Rice, ANITA, NuMoon and Lunaska (ATCA) collaborations. NuMoon and Lunaska are low and high frequency lunar scans respectively, showing the strengths of the two different frequency bands. The two separate limits for ATCA are for different models of the lunar regolith; their separation is a measure of the resultant uncertainty. Also shown, for comparison is the mid-range of flux predictions for GZK neutrinos from Ref. 34.

Radio detectors sensitive to coherent Cherenkov radiation provide an attractive way to search for ultra-high energy cosmic neutrinos. These neutrinos are the only long-range probe of the ultra-high energy cosmos. Protons and heavier nuclei with energies $\gtrsim 5 \times 10^{19}$ eV are limited to ranges of less than 100 Mpc by interactions with CMB photons (the GZK effect [29]), and gamma rays pair-produce from the CMB. The decay products of the particles produced in the hadronic interactions include neutrinos. To detect a useful number of these “GZK neutrinos” annually (assuming that ultra-high energy cosmic rays are protons) requires a detector of about 100 km³ in volume. This is too big for an optical Cherenkov detector. Optical attenuation lengths are less than 200 m in ice or water, so a 100 km³ detector would require a prohibitive number of sensors.

Electromagnetic and hadronic showers produce radio pulses via the Askaryan effect [30], as discussed in Sec. 30. The shower contains more electrons than positrons, leading to coherent emission. The electric field strength is proportional to the neutrino energy; the radiated power goes as its square. Detectors with antennas placed in the active volume have thresholds around 10¹⁷ eV.

The electric field strength increases linearly with frequency, up to a cut-off wavelength set by the transverse size of the shower. The cut-off is about 1 GHz in ice, and 2.5 GHz in rock/lunar regolith. The broadband spectrum argues for a wide detection bandwidth, but, dispersion during signal transmission can cause technical challenges. The angular distribution depends on the frequency. Near the cutoff frequency, radiation is emitted in a narrow cone, centered around the Cherenkov angle (about 56° in ice) [31]. At lower frequencies, the angular distribution broadens, eventually becoming largely isotropic. The signal is linearly polarized in the plane containing the shower direction and the photon direction. This polarization is a useful check that any observed signal is indeed coherent Cherenkov radiation. Polarization measurements can be used to help reconstruct the neutrino direction.

Radiodetection requires a dielectric medium, with a long absorption length for radio waves. The huge target volumes require that this be a commonly available natural material, usually Antarctic ice or the lunar regolith [32].

When viewed from near the Cherenkov angle, the experimental signal is a short wideband radio pulse coming from a shower-sized region within a solid. The initial pulse width is ≈ 1 ns, but it may be broadened by dispersion as it propagates. As long as the dispersion can be accounted for, a large bandwidth detector is the most sensitive. Because the angular distribution depends on the frequency, spectral information can be used to help reconstruct the neutrino direction.

Radio detectors have observed cosmic-ray air showers in the atmosphere. The physics of radio-wave generation in air showers is more complex because there are contributions due to charge separation by charged particles, and from synchrotron radiation from e^\pm , both due to the Earth’s magnetic field. Several experiments have also set limits on radiation due to magnetic monopoles.

32.3.2.1. The Moon as a target:

Because of its large size and non-conducting regolith, and the availability of large radio-telescopes, the moon is an attractive target [33]; several representative lunar experiments are listed in Table 32.2. Conventional radio-telescopes are reasonably well suited to lunar neutrino searches, with natural beam widths not too dissimilar from the size of the Moon. Still, there are some experimental challenges in understanding the signal. The composition of the lunar regolith is not well known, and the attenuation length for radio waves must be estimated. An attenuation length of 9/f(GHz) (m) is often used. The big limitation of lunar experiments is that the 240,000 km target-antenna separation leads to neutrino energy thresholds far above 10²⁰ eV.

Table 32.2: Experiments that have set limits on neutrino interactions in the Moon; current limits are shown in Fig. 32.3 [32].

Experiment	Year	Dish Size	Frequency	Bandwidth	Obs. Time
Parkes	1995	64 m	1425 MHz	500 MHz	10 hrs
Glue	1999+	70 m, 34 m	2200 MHz	40-150 MHz	120 hrs
NuMoon	2008	11×25 m	115–180 MHz	—	50 hrs
Lunaska	2008	3×22 m	1200–1800 MHz	—	6 nights
Resun	2008	4×25 m	1450 MHz	50 MHz	45 hours

The frequency range affects the sensitive volume. At low frequencies, radiation is relatively isotropic, so signals can be detected from most of the Moon’s surface, for most angles of incidence. At higher frequencies, the signal is stronger, but radiation is concentrated near the Cherenkov angle, and the geometry limits the sensitivity to interactions near the Moon’s limb, where the neutrino also arrives within a fairly narrow angular range. The larger high-frequency attenuation limits the depth that can be probed.

So, higher frequency searches probe lower neutrino energies, but lower frequency searches can set tighter flux limits on high-energy neutrinos. An alternative approach, increasingly viable with modern technology, is to search over a wide frequency range. This introduces a technical challenge in the form of dispersion (frequency dependent time delays) in the ionosphere. The Parkes experiment pioneered the use of de-dispersion filters; this has been taken to a high art by the Lunaska collaboration.

Lunar experiments use several techniques to reject backgrounds, which are mostly anthropogenic. Many experiments use multiple antennas, separated by at least hundreds of meters; by requiring a coincidence within a small time window, anthropogenic noise can be rejected. An alternative approach is to use beam forming with multiple receivers in a single antenna, to ensure that the signal points back to the moon. The limits set by representative lunar experiments are shown in Fig. 32.3.

These efforts have considerable scope for expansion. In the near future, several large radio detector arrays should reach significantly lower limits. The LOFAR array is beginning to take data with 36 detector clusters spread over Northwest Europe. In the longer term, the Square Kilometer Array (SKA) with 1 km² effective area will push thresholds down to near 10²⁰ eV.

32.3.2.2. The ANITA balloon experiment:

To reduce the energy threshold, it is necessary to reduce the antenna-target separation. Most of these experiments use Antarctic ice as a medium. One such experiment is the ANITA balloon experiment which made two flights around Antarctica, floating at an altitude around 35 km [34]. Its 40 (32 in the first flight) dual-polarization horn antennas scanned the surrounding ice, out to the horizon (650 km away). Because of the small angle of incidence, ANITA was able to make use of polarization information; ν signals should be vertically polarized, while most background from cosmic-ray air showers is expected to be horizontally polarized. By using the several-meter separation between antennas, ANITA achieved a pointing accuracy of 0.2-0.4^o in elevation, and 0.5-1.1^o in azimuth.

Antarctic experiments must consider the inhomogeneities in the ice: varying density in the upper ice (the firn) and the variation in radio attenuation length with temperature. ANITA also had to consider the surface roughness, which affects the transition from ice to air. All of these affect the propagation of radio-waves from the ν -induced shower to the antennas.

The ‘firn’ is the top 100-200 m of Antarctic ice, where there is a transition from packed snow at the surface to solid ice (density 0.92 g/cm³) below, where the density increases gradually with depth. The index of refraction depends on the density, so radio waves bend downward in the firn. This bending reduces the effectiveness of surface or aerial antennas. The thickness of the firn varies with location; it is thicker in central Antarctica than in the coastal ice sheets.

The attenuation length of radio waves depends on the frequency and ice temperature, with attenuation higher in warmer ice. A recent measurement, by the ARA collaboration at the South Pole found an average attenuation length of 670⁺¹⁸⁰₋₆₆ m [35]. On the Ross Ice Shelf, ARIANNA finds attenuation lengths of 300-500 m, depending on frequency [36].

ANITA verified the accuracy of their calibrations by observing radio sources that they buried in the ice. ANITA has also recently observed radio waves from cosmic-ray air showers; these showers are differentiated from neutrino showers on the basis of the radio polarization and zenith angle distribution [37].

As with the lunar experiments, ANITA had to contend with anthropogenic backgrounds. They used their good pointing accuracy to remove all candidate events that pointed toward known or suspected areas of human habitation. The limit from their two flights is shown in Fig. 32.3. These are the most stringent limits on GZK neutrinos to date. Because of the significant target to detector separation, ANITA is most sensitive at energies above 10¹⁹ eV, above the peak of the GZK neutrino spectrum.

32.3.2.3. Active Volume Detectors:

The use of radio antennas located in the active volume was pioneered by the RICE experiment, which buried radio antennas in holes drilled for AMANDA [38] at the South Pole. RICE was comprised of 18 half-wave dipole antennas, sensitive from 200 MHz to 1 GHz, buried between 100 and 300 m deep. Each antenna fed an in-situ preamplifier which transmitted the signals to surface digitizing electronics. The array triggered when four or more stations fired discriminators within 1.2 μ s, giving it a threshold of about 10¹⁷ eV.

Two groups are prototyping detectors, with the goal of a detector with an active volume in the 100 km³ range. Both techniques are modular, so the detector volume scales roughly linearly with the available funding. The Askaryan Radio Array (ARA) is located at the South Pole, while the Antarctic Ross Iceshelf ANTenna Neutrino Array (ARIANNA) is on the Ross Ice Shelf. Both experiments use local triggers based on a coincidence between multiple antennas in a single station/cluster.

One big difference between the two experiments is the depth of their antennas. ARA buries antennas up to 200 m deep in the ice, to avoid the firn. Because of the refraction, a surface antenna cannot ‘see’ a signal from a near-surface interaction some distance away. Burying antennas avoids this problem. However, drilling holes has costs, and the limited hole diameter (15 cm in ARA) requires compromises between antenna design (particularly for horizontally polarized waves), mechanical support, power and communications. In contrast, ARIANNA places antennas in shallow, near-surface holes. This greatly simplifies deployment and avoid limitations on antenna design, but at a cost of reduced sensitivity to neutrino interactions near the surface.

The current ARA proposal, ARA-37 [35], calls for an array of 37 stations, each consisting of 16 embedded antennas deployed up to 200 m deep below the firn in several 15-cm diameter boreholes. ARA will detect signals in the frequency range from 150 to 850 MHz for vertical polarization, and 250 MHz to 850 MHz for horizontal polarization. ARA plans to use bicone antennas for vertical polarization, and quad-slotted cylinders for horizontal polarization. The collaboration uses notch filters and surface veto antennas to eliminate most anthropogenic noise, and vetos events when aircraft are in the area, or weather balloons are being launched.

ARIANNA will be located in Moore’s Bay, on the Ross Ice Shelf, where \approx 575 m of ice sits atop the Ross Sea [36]. The site was chosen because the ice-seawater interface is smooth there, so the interface acts as a mirror for radio waves. The major advantage of this approach is that ARIANNA is sensitive to downward going neutrinos, and should be able to see more of the Cherenkov cone for horizontal neutrinos. One disadvantage of the site is that the ice is warmer, so the radio attenuation length will be shorter. Each ARIANNA station will use 8 log-periodic dipole antennas, pointing downward and arranged in an octagon. The multiple antennas allow for single-station directional and polarization measurements. The ARIANNA site is about 110 km from McMurdo station, and is shielded by Minna Bluff.

32.4. Large time-projection chambers for rare event detection

Written August 2009 by M. Heffner (LLNL).

The Time Projection Chamber (TPC) concept (Sec. 31.6.5) has been applied to many projects outside of particle physics and the accelerator-based experiments for which it was initially developed. TPCs in non-accelerator particle physics experiments are principally focused on rare event detection (*e.g.*, neutrino and dark matter experiments) and the physics of these experiments can place dramatically different constraints on the TPC design (only extensions of the traditional TPCs are discussed here). The drift gas or liquid is usually the target or matter under observation and due to very low signal rates a TPC with the largest possible active mass is desired. The large mass complicates particle tracking of short and sometimes very low-energy particles. Other special design issues include efficient light collection, background rejection, internal triggering, and optimal energy resolution.

Backgrounds from γ rays and neutrons are significant design issues in the construction of these TPCs. These are generally placed

deep underground to shield them from cosmogenic particles and are surrounded with shielding to reduce radiation from the local surroundings. The construction materials are carefully screened for radiopurity, as they are in close contact with the active mass and can be a significant source of background. The TPC excels in reducing this internal background because the mass inside the field cage forms one monolithic volume from which fiducial cuts can be made *ex post facto* to isolate quiet drift mass. The liquid (gas) can be circulated and purified to a very high level. Self-shielding in these large mass systems can be significant and the effect improves with density and size. (See Sec. 32.6.)

The liquid-phase TPC can have a high density at low pressure that results in very good self-shielding and compact installation with lightweight containment. The down sides are the need for cryogenics, slower charge drift, tracks shorter than typical electron diffusion distances, lower-energy resolution (*e.g.*, xenon) and limited charge readout options. Slower charge drift requires long electron lifetimes, placing strict limits on the oxygen and other impurities with high electron affinity. A significant variation of the liquid-phase TPC that improves the charge readout is the dual-phase TPC, where a gas phase layer is formed above the liquid into which the drifting electrons are extracted and amplified, typically with electroluminescence (*i.e.*, secondary scintillation or proportional scintillation (Fig. 32.4)). The careful transfer of electrons across the phase boundary requires careful control of its position and setting up an appropriate electric field.

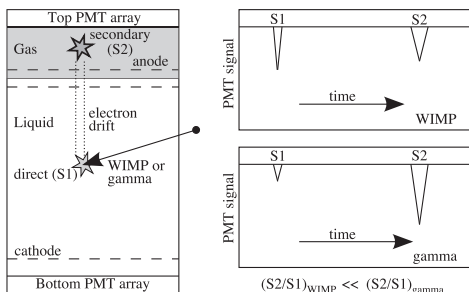

Figure 32.4: The configuration of a dual phase detector is shown on the left with the locations of where the primary and secondary light are generated. On the right is a schematic view of the signals of both an electron and nuclear interaction illustrating the discrimination power of this method. This figure is slightly modified from Ref. 39.

A high-pressure gas phase TPC has no cryogenics and density is easily optimized for the signal, but a large heavy-pressure vessel is required. Although self shielding is reduced, it can in some cases approach that of the liquid phase; in xenon at 50 atm the density is about half that of water or about 1/6 of liquid xenon. A significant feature of high pressure xenon gas is the energy resolution. Below a density of about 0.5 g cm^{-3} the intrinsic resolution is only a few times that of high purity germanium [40]. A neutrinoless double beta decay ($0\nu 2\beta$) search with a TPC operated below this density limit could enjoy excellent energy resolution and maintain particle tracking for background rejection.

An observable interaction with the TPC results in a charged particle that travels in the drift matter, exciting and ionizing the atoms until the initial energy is converted into ionization, scintillation, or heat with relatively large fluctuations around the mean. Rare-event TPCs can be designed to detect scintillation light as well as charge to exploit the anti-correlation to improve energy resolution and/or signal to noise [41]. An electric drift field separates the electrons and positive ions from the ionization although the separation is not complete and some electrons are captured, exciting atoms and releasing more light than the primary excitation alone. The average partition between the scintillation and ionization can be manipulated to increase the ionization (at the expense of scintillation) by a number of methods, such as increasing the strength of the electric field up to saturation of the ionization yield, increasing the temperature to enhance the diffusion of the ionized electrons, and adding dopants

such as triethylamine that can be photoionized by the scintillation photons releasing more ionization.

Scintillation light is typically collected with photomultiplier tubes (PMTs) and avalanche photo diodes (APDs) although any fast (compared to the ionization drift speed) light collector capable of detecting the typically UV photons, maintaining high radiopurity, and perhaps withstanding pressure would work. (CCDs are slow and therefore only record two dimensions, integrating over the time direction. Some of the 3D information can be recovered by a few PMTs.) In most cases, coating the optics or adding a wavelength shifter is required [41], although some work has been done to directly readout the 175 nm light from xenon with a silicon detector. In a typical cylindrical geometry, the light detectors are placed at the ends on an equipotential of the field cage simplifying the design, but limiting the collection efficiency. The field cage can be made of UV-reflective materials such as Teflon, to increase the light-collection efficiency.

Charge collection can be accomplished with proportional avalanche in the manner used in a traditional TPC (even in the liquid state), although the final signal suffers from rather large fluctuations caused by small fluctuations early in the avalanche that are amplified by the process. Inductive readout of passing charges and direct collection of the unamplified charge do not rely on an avalanche, and are effective where energy resolution is of paramount importance, but depend on low-noise amplifiers and relatively large signals (*e.g.*, in $0\nu 2\beta$ decay).

Electroluminescence can be used to proportionally amplify the drifted ionization, and it does not suffer the fluctuations of an avalanche or the small signals of direct collection. It works by setting up at the positive end of the drift volume parallel meshes or wire arrays with an electric field larger than the drift field, but less than the field needed for avalanche. In xenon, this is $3\text{--}6 \text{ kV cm}^{-1} \text{ bar}^{-1}$ for good energy resolution. Eq. (32.4) shows the dependence of the yield (Y) in xenon in units of photons/(electron cm bar) as a function of pressure (p) in units of bar and electric field (E) in units of kV/cm [42]:

$$Y/p = 140 E/p - 116 . \quad (32.4)$$

The amplification can be adjusted with the length of the electroluminescence region, pressure and electric field.

Figure 32.5: An example of pulse-shape discrimination of nuclear recoils and electrons in argon. The prompt fraction is a measure of the pulse shape that clearly separates the two interactions down to very low energy. Figure from Ref. 43.

Differentiation of nuclear and electron recoils at low-energy deposition is important as a means of background rejection. The nuclear recoil deposits a higher density of ionization than an electron recoil and this results in a higher geminate recombination resulting in a higher output of primary scintillation and lower charge. The ratio of scintillation to charge can be used to distinguish the two. In the case of an electroluminescence readout, this is done simply with the ratio of primary light to secondary light. Optically transparent grids with PMT or APD readout combine to make an elegant setup wherein the same array can measure the primary scintillation (S1), and the electroluminescence (S2) eliminating the necessity of two sets of readout detectors. Fig. 32.4 illustrates this method that works in

the gas phase and in dual phase detectors. The time evolution of the primary light is also affected by the type of recoil that results from different populations of excimers in the singlet and triplet states [43]. This alone has resulted in excellent discrimination, particularly in gasses where the decay times are significantly different (see Table 32.3). An example of the discrimination is displayed in Fig. 32.5, where nuclear recoils and electrons can be identified down to 10's of keV_{ee}, in argon. Nuclear recoils deposit less ionization than electrons at a given energy. For this reason, nuclear recoil energy is typically reported in equivalent electron energy loss, keV_{ee}, when compared with electrons.

The composition of the drift matter is an important choice in TPC design, and the noble gasses are frequently selected as the bulk element in the mix (Table 32.3). The noble gases have no electron affinity in the ground state, resulting in good free-electron lifetime and a good amount of scintillation that is useful for particle identification and t_0 determination. In the case of argon and xenon, the low average energy to produce an ion pair results in good energy resolution. The noble gases are easily purified to a high level that, combined with moderate cost, enables the construction of large monolithic detectors. Of the noble gasses one isotope of xenon (¹³⁶Xe) is a candidate for ($0\nu 2\beta$).

Table 32.3: Properties of the noble gasses typically used in non-accelerator TPCs [44,45]. W is the average energy spent to produce one electron ion pair.

Element	W (eV)	photon yield (γ /keV)	wave- length (nm)	decay time (fast/slow)	cost* (\$/kg)
Helium	46.0	50	80	10 ns/1.6 μ s	\$52
Neon	36.6	30	77	10 ns/3.9 μ s	\$330
Argon	26.4	40	128	4 ns/1.6 μ s	\$5
Xenon	21.7	42	175	4 ns/22 ns	\$1200

* Prices from chemcool.com as updated in 2011.

The negative-ion TPC [46] uses an electronegative gas (*e.g.*, CS₂) either as the drift gas or as a dopant to the drift gas that captures the primary electrons, forming negative ions that drift in the electric field. Upon reaching the gas-gain region of the TPC, the electron is stripped from the ion in the high electric field, and the electron avalanches in the normal manner. The larger mass of the the negative ion keeps the kinetic energy of the ion thermal at high electric fields, and therefore such a TPC exhibits far less diffusion. The reduction of diffusion over large distance (time) enables detailed tracking of small tracks in a large volume without the benefit of a magnetic field to limit diffusion (which would be prohibitively expensive for a large volume). The trade-off is orders-of-magnitude slower drift, placing a limit on the trigger rate.

32.5. Sub-Kelvin detectors

Written September 2009 by S. Golwala (Caltech).

Detectors operating below 1 K, also known as “low-temperature” or “cryogenic” detectors, use \lesssim meV quanta (phonons, superconducting quasiparticles) to provide better energy resolution than is typically available from conventional technologies. Such resolution can provide unique advantages to applications reliant on energy resolution, such as beta-decay experiments seeking to measure the ν_e mass or searches for neutrinoless double-beta decay. In addition, the sub-Kelvin mode is combined with conventional (eV quanta) ionization or scintillation measurements to provide discrimination of nuclear recoils from electron recoils, critical for searches for WIMP dark matter and for coherent neutrino-nucleus scattering. We describe the techniques in generic fashion in the text and provide a list of experiments using these techniques in An excellent review [47] is available that covers this material and other applications of low-temperature detectors. The proceedings of the Low Temperature Detectors Workshops are also useful [48].

32.5.1. Thermal Phonons :

The most basic kind of low-temperature detector employs a dielectric absorber coupled to a thermal bath via a weak link. A thermistor monitors the temperature of the absorber. The energy E deposited by a particle interaction causes a calorimetric temperature change by increasing the population of thermal phonons. The fundamental sensitivity is

$$\sigma_E^2 = \xi^2 kT [TC(T) + \beta E], \quad (32.5)$$

where C is the heat capacity of the detector, T is the temperature of operation, k is Boltzmann's constant, and ξ is a dimensionless factor of order unity that is precisely calculable from the nature of the thermal link and the non-thermodynamic noises (*e.g.*, Johnson and/or readout noise). The first term is imposed by statistical fluctuations in the number of thermally excited phonons and on the energy in the absorber due to exchange with the thermal bath (see, *e.g.*, Ref. 49 and references therein). The second term is due to statistical fluctuations in the number of phonons excited by the absorbed radiation. The factor β is also dimensionless and $\mathcal{O}(1)$ and is also precisely calculable from the nature of the thermal link. The ratio of the second term to the first term is equal to the fractional absorber temperature change due to an energy deposition. Thus, the second term becomes appreciable when this fractional temperature change is appreciable, at which point nonlinear effects also come into play. The energy resolution typically acquires an additional energy dependence due to deviations from an ideal calorimetric model that cause position and/or energy dependence in the signal shape.

The rise time of response is limited by the internal thermal conductivity of the absorber. The decay time constant, describing the time required for the absorbed energy to flow out to the bath, is $\tau = C/G$, where G is the thermal conductance of the weak link. The above formula immediately suggests the use of crystalline dielectric absorbers and low temperatures because of the linear factor of T and because C for crystalline dielectrics drops as T^3 for T well below the material's Debye temperature (Θ_D , typically hundreds of K). Specifically, the Debye model indicates that a crystal consisting of N atoms has

$$C = \frac{12\pi^4}{5} N k \left(\frac{T}{\Theta_D} \right)^3 \quad (32.6)$$

which gives $\sigma_E = 5.2\xi$ eV for 1 kg of germanium operated at $T = 10$ mK. (For a detector of this size the 2nd term in Eq. (32.5) is negligible.) In practice, a number of factors degrade the above result by about an order of magnitude (thermistor heat capacity and power dissipation, readout noise, *etc.*), but the predicted energy resolution for such a large mass remains attractive.

Neutron-transmutation-doped (NTD) germanium and implanted silicon semiconductors are used for thermistors. Conduction is via phonon-assisted hopping between impurity sites, yielding an exponentially decreasing resistance as a function of temperature, $R(T)$, with negative slope, dR/dT . Attachment to the absorber is usually by eutectic bonding or epoxy or by direct implantation into the absorber. Another type of temperature sensor is the superconducting phase-transition thermometers (SPT) or transition-edge sensor (TES). A SPT or TES is a superconducting film operated in the transition from superconductive to normal resistance at the transition temperature, T_c , where its resistance is a strong function of temperature with positive dR/dT . This can provide strong electrothermal negative feedback, which improves linearity, speeds up response, and mitigates variations in T_c among multiple TESs on the same absorber. Nb_xSi_{1-x} is another thermistor material that ranges between the semiconducting and superconducting regimes as a function of the stoichiometry (defined by x). SPTs/TESs and Nb_xSi_{1-x} thermistors are frequently deposited directly onto the absorber by sputtering or evaporation.

The readout method depends on the type of thermometer used. Doped semiconductors typically have high impedances and are well matched to low-noise JFET-based readout while SPTs/TESs are low-impedance devices requiring SQUID amplifiers.

Table 32.4: Selected experiments using sub-Kelvin detectors. The table is not exhaustive. Operation mode, detector and excitation sensor construction, baseline energy resolution, and energy resolution at a particular energy of interest E_0 are given. We quote the energy and energy resolution for “total” phonon signal, where the total phonon signal includes both recoil energy and, where relevant, drift heating. Ionization and scintillation energies are normalized so that, for electron recoils, the energy in these channels is equal to the recoil energy (“electron-equivalent” energies). For scintillation energy, this is the electron-equivalent energy deposited in the target detector, not the energy received by the photon absorber. Approximate dates of operation are also given. Key to comments: “a-Si” and “a-Ge” = amorphous silicon or germanium layers in ionization electrodes. “H-a-Si” = hydrogenated amorphous silicon. “P-implanted” = phosphorous implantation. “Interdig.” = interdigitated ionization electrode design that provides some z information from ionization signal asymmetry. “Surface-event discrimination” = ability to reject events near surfaces that suffer reduced ionization yield and can be misidentified as WIMPs. “w/phonons” = using athermal phonon pulse rising edge (faster for surface events). “w/ioniz. asym.” = using the asymmetry of the ionization signal on electrodes on opposite faces of interdigitated-electrode detectors. “w/phonon asym.” = using the asymmetry of the phonon signal detected on opposite detector faces. “U” = not known by author. SuperCDMS energy resolutions have not been fully reported yet but are likely no worse than CDMS II.

32.5.2. Athermal Phonons and Superconducting Quasiparticles :

The advantage of thermal phonons is also a disadvantage: energy resolution degrades as \sqrt{M} where M is the detector mass. This motivates the use of athermal phonons. There are three steps in the development of the phonon signal. The recoiling particle deposits energy along its track, with the majority going directly into phonons. (A minority of the energy goes directly into scintillation and ionization. Energy deposited in ionization is recovered when the carriers recombine.) The recoil and bandgap energy scales (keV and higher, and eV, respectively) are much larger than phonon energies (meV), so the full energy spectrum of phonons is populated, with phase space favoring the most energetic phonons. However, these initial energetic phonons do not propagate because of isotopic scattering (scattering due to variations in lattice ion atomic mass, rate $\propto \nu^4$ where ν is the phonon frequency) and anharmonic decay (scattering wherein a single phonon splits into two phonons, rate $\propto \nu^5$). Anharmonic decay downshifts the phonon spectrum, which increases the phonon mean free path, so that eventually phonons can propagate the characteristic dimension of the detector. These phonons travel quasiballistically, preserve information about the position of the parent interaction, and are not affected by an increase in detector mass (modulo the concomitant larger distance to the surface where they can be sensed). Anharmonic decay continues until a thermal distribution is reached (μeV at mK temperatures), which is exhibited as a thermal increase in the temperature of the detector. If one can detect the athermal phonons at the crystal surface, keep the density of such sensors fixed as the detector surface area increases with mass, and the crystals are pure enough that the athermal phonons can propagate to the surface prior to thermalization, then an increase in detector mass need not degrade energy resolution, and can in fact improve position reconstruction. Sensors for athermal phonons are similar to those for superconducting quasiparticles described below.

Another mode is detection of superconducting quasiparticles in superconducting crystals. Energy absorption breaks superconducting Cooper pairs and yields quasiparticles, electron-like excitations that can diffuse through the material and that recombine after the quasiparticle lifetime. In crystals with very large mean free path against scattering, the diffusion length (distance traveled in a quasiparticle lifetime) is large enough (mm to cm) that the quasiparticles reach the surface and can be detected, usually in a superconducting tunnel junction (STJ) or TES/SPT.

A similar technique is applied to detect athermal phonons. Athermal phonons reaching a superconducting film on the detector surface generate quasiparticles as above. Such thin films have diffusion lengths much shorter than for superconducting crystalline substrates, only of order $100\ \mu\text{m}$ to 1 mm. Thus, the superconducting film must be segmented on this length scale and have a quasiparticle sensor for each segment. The sensors may, however, be connected in series or parallel in large groups to reduce readout channel count.

The readout for athermal phonon and quasiparticle sensing depends on the type of quasiparticle detector. Tunnel junctions match well to JFET-based readouts, while TESs/SPTs use SQUID amplifiers.

32.5.3. Ionization and Scintillation :

While ionization and scintillation detectors usually operate at much higher temperatures, ionization and scintillation can be measured at low temperature and can be combined with a “sub-Kelvin” technique to discriminate nuclear recoils from background interactions producing electron recoils, which is critical for WIMP searches and coherent neutrino-nucleus scattering. With ionization, such techniques are based on Lindhard theory [50], which predicts substantially reduced ionization yield for nuclear recoils relative to electron recoils. For scintillation, application of Birks’ law (Sec. 31.3.0) yields a similar prediction. (The reduced ionization or scintillation yield for nuclear recoils is frequently referred to as “quenching”.)

Specifically, consider the example of measuring thermal phonons and ionization. All the deposited energy eventually appears in the thermal phonon channel, regardless of recoil type (modulo some loss to permanent crystal defect creation). Thus, the ionization yield—the number of charge pairs detected per unit detected energy in phonons—provides a means to discriminate nuclear recoils from

electron recoils. Similar discrimination is observed with athermal phonons and ionization and with phonons and scintillation.

In semiconducting materials of sufficient purity—germanium and silicon—electron-hole pairs created by recoiling particles can be drifted to surface electrodes by applying an electric field, similar to how this is done at 77 K in high-purity germanium photon spectrometers (Sec. 31.7). There are three important differences, however, that result in the use of low fields—of order 1 V/cm—instead of the hundreds to thousands of V/cm used in 77 K detectors. First, high fields are required at 77 K to deplete the active volume of thermally excited mobile carriers. At low temperature and in crystals of purity high enough to drift ionization with negligible trapping, the population of thermally excited carriers is exponentially suppressed due to the low ambient thermal energy. Second, high fields in 77 K operation prevent trapping of drifting carriers on ionized impurities and crystalline defects and/or overcome space charge effects. At low temperatures, ionized impurities and space charge can be neutralized (using free charge created by photons from LEDs or radioactive sources) and remain in this state for minutes to hours. This reduces trapping exponentially and allows low-field drift. Third, a high field in a sub-Kelvin detector would result in a massive phonon signal from the drifting carriers, fully correlated with the ionization signal and thereby eliminating nuclear recoil discrimination. Readout of the charge signal is typically done with a conventional JFET-based transimpedance amplifier.

A number of materials that scintillate on their own (*i.e.*, without doping) continue to do so at low temperatures, including BaF_2 , BGO, CaWO_4 , ZnWO_4 , PbWO_4 , and other tungstates and molybdates. In and of itself, there is little advantage to a low-temperature scintillation measurement because detecting the scintillation is nontrivial, the quanta are large, and the detection efficiency is usually poor. Such techniques are pursued only in order to obtain nuclear-recoil discrimination. Conventional photodetectors do not operate at such low temperatures, so one typically detects the scintillation photons in an adjacent low-temperature detector that is thermally disconnected from but resides in an optically reflective cavity with the target detector.

32.6. Low-radioactivity background techniques

Written August 2009 by A. Piepke (University of Alabama).

The physics reach of low-energy rare event searches *e.g.* for dark matter, neutrino oscillations, or double beta decay is often limited by background caused by radioactivity. Depending on the chosen detector design, the separation of the physics signal from this unwanted interference can be achieved on an event-by-event basis by active event tagging, utilizing some unique event feature, or by reducing the radiation background by appropriate shielding and material selection. In both cases, the background rate is proportional to the flux of background-creating radiation. Its reduction is thus essential for realizing the full physics potential of the experiment. In this context, “low energy” may be defined as the regime of natural, anthropogenic, or cosmogenic radioactivity, all at energies up to about 10 MeV. Following the classification of [51], sources of background may be categorized into the following classes:

1. environmental radioactivity,
2. radioimpurities in detector or shielding components,
3. radon and its progeny,
4. cosmic rays,
5. neutrons from natural fission, (α , n) reactions and from cosmic-ray muon spallation and capture.

32.6.1. Defining the problem : The application defines the requirements. Background goals can be as demanding as a few low-energy events per year in a ton-size detector. The strength of the physics signal to be measured can often be estimated theoretically or from limits derived by earlier experiments. The experiments are then designed for the desired signal-to-background ratio. This requires finding the right balance between clarity of measurement, ease of construction, and budget. In a practical sense, it is important to formulate background goals that are sufficient for the task at hand but doable, in a finite time. It is now standard practice to use a detector simulation to translate the background requirements into

limits for the radioactivity content of various detector components, requirements for the radiation shielding, and allowable cosmic-ray flux. This strategy allows identifying the most critical components early and the allocation of analysis and development resources accordingly. The CERN code GEANT4 is a widely used tool for this task. It contains sufficient nuclear physics to allow accurate background estimations. Custom-written event generators, modeling particle correlations in complex decay schemes, are used as well.

Figure 32.6: γ -ray attenuation lengths in some common shielding materials. The mass attenuation data has been taken from the NIST data base XCOM; see “Atomic Nuclear Properties” at pdg.lbl.gov.

32.6.2. Environmental radioactivity: The long-lived natural radioisotopes ^{40}K , ^{232}Th , and ^{238}U have average abundances of 2.4, 9.6 and 2.7 ppm in the earth’s crust, with large local variations. In most applications, γ radiation emitted by natural radioactivity constitutes the dominant contribution to the local radiation field. Typical low-background applications require levels of natural radioactivity on the order of ppb or ppt in the detector components. Passive or active shielding is used to suppress external γ radiation down to that level. Fig. 32.6 shows the energy-dependent attenuation length $\lambda(E_\gamma)$ as a function of γ ray energy E_γ for three common shielding materials (water, copper, lead). The thickness ℓ required to reduce the external flux by a factor $f > 1$ is estimated assuming exponential damping:

$$\ell = \lambda(E_\gamma) \cdot \ln f. \quad (32.7)$$

At 100 keV, a typical energy scale for dark matter searches (or 2.615 MeV, for a typical double-beta decay experiment), attenuation by a factor $f = 10^5$ requires 67(269) cm of H_2O , 2.8(34) cm of Cu, or 0.18(23) cm of Pb. Such estimates allows for an order-of-magnitude estimate of the experiment dimensions. A precise estimation of the leakage of external γ radiation, including scattering and the effect of energy cuts, requires Monte Carlo simulations and determination of the radioactivity present in the laboratory. Detailed modeling of the γ flux in a large laboratory, or inside hermetic shielding, needs to cope with very small detector-hit efficiencies. It is often advantageous to calculate solid angle and mass attenuation separately. This approach reduces the computation time required for a statistically meaningful number of detector hits to manageable levels.

Because of its low density, water has relatively long attenuation lengths, resulting in rather voluminous shields. However, because water can be obtained relatively cheaply in large amounts, it has become the medium of choice for most large detectors. Water purification technology is effective and commercially available, an important consideration in view of the intrinsic radioactivity of the shield, to be discussed below. High-purity water, instrumented with photo multiplier tubes, can further serve as a Cherenkov cosmic-ray veto detector. Liquefied gases are being used for shielding as well.

32.6.3. Radioimpurities in detector or shielding components

: After suppressing the effect of external radioactivity, radioactive impurities contained in the detector components or attached to its surfaces become important. Any material is radioactive at some level. The activity can be natural, cosmogenic, or man-made. The determination of the activity content of a specific material or component requires case-by-case analysis, and is almost never obtainable from the manufacturer. However, there are some general rules than can be used to guide the pre-selection. For detectors designed to look for electrons (for example in double-beta decay searches or neutrino detection via inverse beta decay or elastic scattering), this is the principal source of background. For devices detecting nuclear recoils (for example in dark matter searches), this is often of secondary importance as ionization signals can be actively suppressed on an event-by-event basis.

For natural radioactivity, a rule of thumb is that synthetic substances are cleaner than natural materials. Typically, more highly processed materials have lower activity content. Substances with smaller chemical reactivity tend to be cleaner. The refining process tends to remove K, Th, and U. For example, Al is often found to contain considerable amounts of Th and U, while electrolytic Cu is very low in primordial activities. Plastics or liquid hydrocarbons, having been refined by distillation, are often quite radiopure. Tabulated radioactivity screening results for a wide range of materials can be found in Refs. 52 and 53.

The long-lived ^{238}U daughter ^{210}Pb ($T_{1/2}=22.3$ y) is found in all shielding lead, and is a background concern at low energies. This is due to the relatively high endpoint energy ($Q_\beta=1.162$ MeV) of its beta-unstable daughter ^{210}Bi . Lead parts made from selected low-U ores have specific activities of about 5–30 mBq/kg. For lower activity, ancient lead (for example from Roman ships) has been used. Because the ore processing and lead refining removed most of the ^{238}U , the ^{210}Pb decayed during the long waiting time to the level supported by the U-content of the refined lead. Lining the lead with copper to range out the low-energy radiation is another remedy. However, intermediate Z materials are an activation risk when handled above ground, as will be discussed below. ^{210}Pb is also found in solders.

The fission product ^{137}Cs can be found attached to the surface of materials. The radioactive noble gas ^{85}Kr , released into the atmosphere by nuclear reactors and nuclear fuel re-processing, is also important, especially due to its high solubility in organic materials. Post-World War II steel typically contains a few tens of mBq/kg of ^{60}Co .

Surface activity is not a material property but is added during manufacturing and handling. It can often be effectively removed by etching. Installation of low-background detectors is often done in clean rooms to avoid this contamination. Surface contamination can be quantified by means of wipe-testing with acid or alcohol wetted Whatman 41 filters. The paper filters are ashed after wiping and the residue is digested in acid. Subsequent analysis by means of mass spectroscopy or neutron activation analysis is capable of detecting less than 1 pg/cm² of Th and U. The most demanding low-rate experiments require screening of *all* components, which can be a time consuming task. The requirements for activity characterization depend on the experiment and the location and amount of a particular component. Monte Carlo simulations are used to quantify these requirements. Activities of the order $\mu\text{Bq/kg}$ or even below may need to be detected in the process. At such level of sensitivity, the characterization becomes a challenging problem in itself. Low-background α , β , and γ ray counting, mass spectroscopy, and neutron activation analysis are used.

32.6.4. Radon and its progeny: The noble gas ^{222}Rn , a pure α -emitter, is a ^{238}U decay product. Due to its half-life of 3.8 d it is released by surface soil and is found in the atmosphere everywhere. ^{220}Rn (^{232}Th decay product) is unimportant because of its short half-life. ^{222}Rn activity in air ranges from 10 to 100 mBq/L outdoors and 100 to thousands of mBq/L indoors. The natural radon concentration depends on the weather and shows daily and seasonal variations. Radon levels are lowest above the oceans. For electron detectors, it is not the Rn itself that creates background, but its progeny ^{214}Pb , ^{214}Bi , ^{210}Bi , which emit energetic beta and γ radiation. Thus, not

only the detector itself has to be separated from contact with air, but also internal voids in the shield which contain air can be a background concern. Radon is quite soluble in water and even more so in organic solvents. For large liquid scintillation detectors, radon mobility due to convection and diffusion is a concern. To define a scale: typical double-beta-decay searches are disturbed by a μBq (or 1/11.6 d) activity of ^{222}Rn contained in the detector medium. This corresponds to a steady-state population of 0.5 atoms in 50 μL of air (assuming 20 mBq/L of radon in the air). The criteria for leak tightness are thus quite demanding. The decay of Rn itself is a concern for some recoil type detectors, as nuclear recoil energies in α decays are substantial (76 keV in case of ^{222}Rn).

Low-activity detectors are often kept sealed from the air and continuously flushed with boil-off nitrogen, which contains only small amounts of Rn. For the most demanding applications, the nitrogen is purified by multiple distillations. Then only the Rn outgassing of the piping (due to its U internal content) determines the radon concentration. Radon diffuses readily through thin plastic barriers. If the detector is to be isolated from its environment by means of a membrane, the right choice of material is important [54].

If energies below 1 MeV are to be measured, additional care has to be taken to avoid plate-out of the long-lived radon daughter ^{210}Pb on the surfaces. This can be reduced by keeping the parts under a protective low-radon cover gas.

Radon can be detected even at the level of few atoms with solid state, scintillation, or gas detectors by exploiting the fast decay sequences of ^{214}Bi and ^{214}Po . The efficiency of these devices is sometimes boosted by electrostatic collection of charged radon into a small detector.

32.6.5. Cosmic rays: Cosmic radiation, discussed in detail in Chapter 26, is a source of background for just about any non-accelerator experiment. Primary cosmic rays are about 90% protons, 9% alpha particles, and the rest heavier nuclei (Fig. 26.1). They are totally attenuated within the first few hg/cm^2 of atmospheric thickness. At sea level secondary particles ($\pi^\pm : p : e^\pm : n : \mu^\pm$) are observed with relative intensities (1 : 13 : 340 : 480 : 1420) for $E < 1 \text{ GeV}$ (Ref. 55; also see Fig. 26.3).

All but the muon and the neutron components are readily absorbed by overburden such as building ceilings and passive shielding. Only if there is very little overburden (less than a few $\times 10 \text{ g cm}^{-2}$ in rock) do pions and protons need to be considered when estimating the production rate of cosmogenic radioactivity.

Sensitive experiments are thus operated deep underground where essentially only muons penetrate. As shown in Fig. 26.6, the muon intensity falls off rapidly with depth. Active detection systems capable of tagging events correlated in time with cosmic-ray activity are needed, depending on the overburden. Such experiments are described in Sec. 32.3.1.

The muonic background is only related to low-radioactivity techniques insofar as photonuclear interactions of muons can produce long-lived radioactivity. This happens at any depth, and it constitutes an essentially irreducible background.

Cosmogenic activation of components brought from the surface is also an issue. Proper management of parts and materials above ground during machining and detector assembly minimizes the accumulation of long-lived activity. Cosmogenic activation is most important for intermediate Z materials such as Cu and Fe. For the most demanding applications, metals are stored and transported under sufficient shielding to stop the hadronic component of the cosmic rays. Parts, *e.g.*, the nickel tubes for the ^3He counters in SNO, can be stored underground for long periods before being used. Underground machine shops are also sometimes used to limit the duration of exposure at the surface.

32.6.6. Neutrons: Neutrons contribute to the background of low-energy experiments in different ways: directly through nuclear recoil in the detector medium, and indirectly, through the production of radio nuclides inside the detector and its components. The latter mechanism allows even remote materials to contribute to the background by means of penetrating γ radiation, since inelastic scattering of fast neutrons or radiative capture of slow neutrons can result in the emission of γ radiation. Neutrons are thus an important source of

low-energy background. They are produced in different ways:

1. At the earth's surface neutrons are the most frequent cosmic-ray secondaries other than muons;
2. Energetic tertiary neutrons are produced by cosmic-ray muons in nuclear spallation reactions with the detector and laboratory walls;
3. In high Z materials, often used in radiation shields, nuclear capture of negative muons results in emission of neutrons;
4. Natural radioactivity has a neutron component through spontaneous fission and (α, n) -reactions.

A calculation with the hadronic simulation code FLUKA, using the known energy distribution of secondary neutrons at the earth's surface [56], yields a mass attenuation of 1.5 hg/cm^2 in concrete for secondary neutrons. If energy-dependent neutron-capture cross sections are known, then such calculations can be used to obtain the production rate of radio nuclides.

At an overburden of only few meters, water equivalent neutron production by muons becomes the dominant mechanism. Neutron production rates are high in high- Z shielding materials. A high- Z radiation shield, discussed earlier as being effective in reducing background due to external radioactivity, thus acts as a source for cosmogenic tertiary high-energy neutrons. Depending on the overburden and the radioactivity content of the laboratory, there is an optimal shielding thickness. Water shields, although bulky, are an attractive alternative due to their low neutron production yield and self-shielding.

Neutron shields made from plastic or water are commonly used to reduce the neutron flux. The shield is sometimes doped with a substance having a high thermal neutron capture cross section (such as boron) to absorb thermal neutrons more quickly. The hydrogen serves as a target for elastic scattering, and is effective in reducing the neutron energy. Neutrons from natural radioactivity have relatively low energies and can be effectively suppressed by a neutron shield. Such a neutron shield should be inside the lead to be effective for tertiary neutrons. However, this is rarely done as it increases the neutron production target (in form of the passive shield), and costs increase as the cube of the dimensions. An active cosmic-ray veto is an effective solution, correlating a neutron with its parent muon. This solution works best if the veto system is as far removed from the detector as feasible (outside the radiation shield) to correlate as many background-producing muons with neutrons as possible. The vetoed time after a muon hit needs to be sufficiently long to assure neutron thermalization. The average thermalization and capture time in lead is about 900 μs [51]. The veto-induced deadtime, and hence muon hit rate on the veto detector, is the limiting factor for the physical size of the veto system (besides the cost). The background caused by neutron-induced radioactivity with live times exceeding the veto time cannot be addressed in this way. Moving the detector deep underground, and thus reducing the muon flux, is the only technique addressing all sources of neutron background.

33. RADIOACTIVITY AND RADIATION PROTECTION

Revised August 2011 by S. Roesler and M. Silari (CERN).

33.1. Definitions [1,2]

33.1.1. Physical quantities :

• **Fluence, Φ** (unit: $1/\text{m}^2$): The fluence is the quotient of dN by da , where dN is the number of particles incident upon a small sphere of cross-sectional area da

$$\Phi = dN/da . \quad (33.1)$$

In dosimetric calculations, fluence is frequently expressed in terms of the lengths of the particle trajectories. It can be shown that the fluence, Φ , is given by

$$\Phi = dl/dV,$$

where dl is the sum of the particle trajectory lengths in the volume dV .

• **Absorbed dose, D** (unit: gray, $1 \text{ Gy}=1 \text{ J/kg}=100 \text{ rad}$): The absorbed dose is the energy imparted by ionizing radiation in a volume element of a specified material divided by the mass of this volume element.

• **Kerma, K** (unit: gray): Kerma is the sum of the initial kinetic energies of all charged particles liberated by indirectly ionizing radiation in a volume element of the specified material divided by the mass of this volume element.

• **Linear energy transfer, L or LET** (unit: J/m , often given in $\text{keV}/\mu\text{m}$): The linear energy transfer is the mean energy, dE , lost by a charged particle owing to collisions with electrons in traversing a distance dl in matter. *Low-LET radiation*: x rays and gamma rays (accompanied by charged particles due to interactions with the surrounding medium) or light charged particles such as electrons that produce sparse ionizing events far apart at a molecular scale ($L < 10 \text{ keV}/\mu\text{m}$). *High-LET radiation*: neutrons and heavy charged particles that produce ionizing events densely spaced at a molecular scale ($L > 10 \text{ keV}/\mu\text{m}$).

• **Activity, A** (unit: becquerel, $1 \text{ Bq}=1/\text{s}=27 \text{ picocurie}$): Activity is the expectation value of the number of nuclear decays occurring in a given quantity of material per unit time.

33.1.2. Protection quantities :

Protection quantities are dose quantities developed for radiological protection that allow quantification of the extent of exposure of the human body to ionizing radiation from both whole and partial body external irradiation and from intakes of radionuclides.

• **Organ absorbed dose, D_T** (unit: gray): The mean absorbed dose in an organ or tissue T of mass m_T is defined as

$$D_T = \frac{1}{m_T} \int_{m_T} D dm .$$

• **Equivalent dose, H_T** (unit: sievert, $1 \text{ Sv}=100 \text{ rem}$): The equivalent dose H_T in an organ or tissue T is equal to the sum of the absorbed doses $D_{T,R}$ in the organ or tissue caused by different radiation types R weighted with so-called radiation weighting factors w_R :

$$H_T = \sum_R w_R \times D_{T,R} . \quad (33.2)$$

It expresses long-term risks (primarily cancer and leukemia) from low-level chronic exposure. The values for w_R recommended by ICRP [2] are given in Table 33.1.

• **Effective dose, E** (unit: sievert): The sum of the equivalent doses, weighted by the tissue weighting factors w_T ($\sum_T w_T = 1$) of several organs and tissues T of the body that are considered to be most sensitive [2], is called “effective dose”:

$$E = \sum_T w_T \times H_T . \quad (33.3)$$

Table 33.1: Radiation weighting factors, w_R .

Radiation type	w_R
Photons, electrons and muons	1
Neutrons, $E_n < 1 \text{ MeV}$	$2.5 + 18.2 \times \exp[-(\ln E_n)^2/6]$
$1 \text{ MeV} \leq E_n \leq 50 \text{ MeV}$	$5.0 + 17.0 \times \exp[-(\ln(2E_n))^2/6]$
$E_n > 50 \text{ MeV}$	$2.5 + 3.25 \times \exp[-(\ln(0.04E_n))^2/6]$
Protons and charged pions	2
Alpha particles, fission fragments, heavy ions	20

33.1.3. Operational quantities :

The body-related protection quantities, equivalent dose and effective dose, are not measurable in practice. Therefore, operational quantities are used for the assessment of effective dose or mean equivalent doses in tissues or organs. These quantities aim to provide a conservative estimate for the value of the protection quantity.

• **Ambient dose equivalent, $H^*(10)$** (unit: sievert): The dose equivalent at a point in a radiation field that would be produced by the corresponding expanded and aligned field in a 30 cm diameter sphere of unit density tissue (ICRU sphere) at a depth of 10 mm on the radius vector opposing the direction of the aligned field. Ambient dose equivalent is the operational quantity for *area monitoring*.

• **Personal dose equivalent, $H_p(d)$** (unit: sievert): The dose equivalent in ICRU tissue at an appropriate depth, d , below a specified point on the human body. The specified point is normally taken to be where the individual dosimeter is worn. For the assessment of effective dose, $H_p(10)$ with a depth $d = 10 \text{ mm}$ is chosen, and for the assessment of the dose to the skin and to the hands and feet the personal dose equivalent, $H_p(0.07)$, with a depth $d = 0.07 \text{ mm}$, is used. Personal dose equivalent is the operational quantity for *individual monitoring*.

33.1.4. Dose conversion coefficients :

Dose conversion coefficients allow direct calculation of protection or operational quantities from particle fluence and are functions of particle type, energy and irradiation configuration. The most common coefficients are those for effective dose and ambient dose equivalent. The former are based on simulations in which the dose to organs of anthropomorphic phantoms is calculated for approximate actual conditions of exposure, such as irradiation of the front of the body (antero-posterior irradiation) or isotropic irradiation.

Conversion coefficients from fluence to effective dose are given for anterior-posterior irradiation and various particles in Fig. 33.1 [3]. For example, the effective dose from an anterior-posterior irradiation in a field of 1-MeV neutrons with a fluence of 1 neutron per cm^2 is about 290 pSv. In Monte Carlo simulations such coefficients allow multiplication with fluence at scoring time such that effective dose to a human body at the considered location is directly obtained.

33.2. Radiation levels [4]

• **Natural background radiation:** On a worldwide average, the annual whole-body dose equivalent due to all sources of natural background radiation ranges from 1.0 to 13 mSv (0.1–1.3 rem) with an annual average of 2.4 mSv [5]. In certain areas values up to 50 mSv (5 rem) have been measured. A large fraction (typically more than 50%) originate from inhaled natural radioactivity, mostly radon and radon daughters. The latter can vary by more than one order of magnitude: it is 0.1–0.2 mSv in open areas, 2 mSv on average in a house and more than 20 mSv in poorly ventilated mines.

• **Cosmic ray background radiation:** At sea level, the whole-body dose equivalent due to cosmic ray background radiation is dominated by muons; at higher altitudes also nucleons contribute. Dose equivalent rates range from less than 0.1 $\mu\text{Sv/h}$ at sea level to a few $\mu\text{Sv/h}$ at aircraft altitudes. Details on cosmic ray fluence levels are given in the Cosmic Rays section (Sec. 26 of this *Review*).

Figure 33.1: Fluence to effective dose conversion coefficients for anterior-posterior irradiation and various particles [3].

• **Fluence to deposit one Gy:** *Charged particles:* The fluence necessary to deposit a dose of one Gy (in units of cm^{-2}) is about $6.24 \times 10^9 / (dE/dx)$, where dE/dx (in units of $\text{MeV g}^{-1} \text{cm}^2$) is the mean energy loss rate that may be obtained from Figs. 30.2 and 30.4 in Sec. 30 of this *Review*, and from <http://pdg.lbl.gov/AtomicNuclearProperties>. For example, it is approximately $3.5 \times 10^9 \text{ cm}^{-2}$ for minimum-ionizing singly-charged particles in carbon. *Photons:* This fluence is about $6.24 \times 10^9 / (Ef/\ell)$ for photons of energy E (in MeV), an attenuation length ℓ (in g cm^{-2}), and a fraction $f \lesssim 1$, expressing the fraction of the photon energy deposited in a small volume of thickness $\ll \ell$ but large enough to contain the secondary electrons. For example, it is approximately $2 \times 10^{11} \text{ cm}^{-2}$ for 1 MeV photons on carbon ($f \approx 1/2$).

33.3. Health effects of ionizing radiation

Radiation can cause two types of health effects, deterministic and stochastic:

- **Deterministic effects** are tissue reactions which cause injury to a population of cells if a given threshold of absorbed dose is exceeded. The severity of the reaction increases with dose. The quantity in use for tissue reactions is the absorbed dose, D . When particles other than photons and electrons (low-LET radiation) are involved, a Relative Biological Effectiveness (RBE)-weighted dose may be used. The RBE of a given radiation is the reciprocal of the ratio of the absorbed dose of that radiation to the absorbed dose of a reference radiation (usually x rays) required to produce the same degree of biological effect. It is a complex quantity that depends on many factors such as cell type, dose rate, fractionation, etc.
- **Stochastic effects** are malignant diseases and heritable effects for which the probability of an effect occurring, but not its severity, is a function of dose without threshold.
- **Lethal dose:** The whole-body dose from penetrating ionizing radiation resulting in 50% mortality in 30 days (assuming no medical treatment) is 2.5–4.5 Gy (250–450 rad)[†], as measured internally on the body longitudinal center line. The surface dose varies due to variable body attenuation and may be a strong function of energy.
- **Cancer induction:** The cancer induction probability is about 5% per Sv on average for the entire population [2].
- **Recommended effective dose limits:** The International Commission on Radiological Protection (ICRP) recommends a limit for radiation workers of 20 mSv effective dose per year averaged over 5 years, with the provision that the dose should not exceed 50 mSv in any single year [2]. The limit in the EU-countries and Switzerland is 20 mSv per year, in the U.S. it is 50 mSv per year (5 rem per year). Many physics laboratories in the U.S. and elsewhere set lower limits. The effective dose limit for general public is typically 1 mSv per year.

[†] RBE-weighted when necessary

33.4. Prompt neutrons at accelerators

Neutrons dominate the particle environment outside thick shielding (*e.g.*, > 1 m of concrete) for high energy (> a few hundred MeV) electron and hadron accelerators.

33.4.1. Electron accelerators :

At electron accelerators, neutrons are generated via photonuclear reactions from bremsstrahlung photons. In the photon energy range from threshold (few MeV) to about 30 MeV, neutron production is via the Giant Dipole Resonance (GDR) mechanism. The reaction consists in a collective excitation of the nucleus, in which neutrons and protons oscillate in the direction of the photon electric field. The oscillation is damped by friction in a few cycles, with the photon energy being transferred to the nucleus in a process similar to evaporation. Nucleons emitted in the dipolar interaction have an anisotropic angular distribution, with a maximum at 90° , while those leaving the nucleus as a result of evaporation are emitted isotropically with a Maxwellian energy distribution described as [6]:

$$\frac{dN}{dE_n} = \frac{E_n}{T^2} e^{-E_n/T}, \quad (33.4)$$

where T is a nuclear ‘temperature’ (in units of MeV) characteristic of the particular target nucleus and its excitation energy. For heavy nuclei the ‘temperature’ generally lies in the range of $T = 0.5\text{--}1.0$ MeV. For higher energy photons, the quasi-deuteron (between about 30 MeV and 250 MeV), delta resonance (250 MeV–1.2 GeV) and vector meson dominance ($\gtrsim 1.2$ GeV) mechanisms become important.

Neutron yields from semi-infinite targets per kW of electron beam power are plotted in Fig. 33.2 as a function of the electron beam energy [6].

Figure 33.2: Neutron yields from semi-infinite targets per kW of electron beam power, as a function of the electron beam energy, disregarding target self-shielding [6].

Typical neutron energy spectra outside of concrete (80 cm thick, 2.35 g/cm^3) and iron (40 cm thick) shields are shown in Fig. 33.3. In order to compare these spectra to those caused by proton beams (see below) the spectra are scaled by a factor of 100, which roughly corresponds to the difference in the high energy hadronic cross sections for photons and hadrons (*e.g.*, the fine structure constant). The shape of these spectra are generally characterized by a low-energy peak at around 1 MeV (evaporation neutrons) and a high-energy shoulder at around 70–80 MeV. In case of concrete shielding, the spectrum also shows a pronounced peak at thermal neutron energies.

Figure 33.3: Neutron energy spectra calculated with the FLUKA code [7,8] from 25 GeV proton and electron beams on a thick copper target. Spectra are evaluated at 90° to the beam direction behind 80 cm of concrete or 40 cm of iron. All spectra are normalized per beam particle. In addition, spectra for electron beam are multiplied by a factor of 100.

Figure 33.4: The variation of the attenuation length for mono-energetic neutrons in concrete as a function of neutron energy [9].

33.4.2. Proton accelerators :

At proton accelerators, neutron yields emitted per incident proton by different target materials are roughly independent of proton energy between 20 MeV and 1 GeV, and are given by the ratio C : Al : Cu-Fe : Sn : Ta-Pb = 0.3 : 0.6 : 1.0 : 1.5 : 1.7 [9]. Above about 1 GeV, the neutron yield is proportional to E^m , where $0.80 \leq m \leq 0.85$ [10].

Typical neutron energy spectra outside of concrete and iron shielding are shown in Fig. 33.3. Here, the radiation fields are caused by a 25 GeV proton beam interacting with a thick copper target. The comparison of these spectra with those for an electron beam of the same energy reflects the difference in the hadronic cross sections between photons and hadrons above a few 100 MeV. Differences are increasing towards lower energies because of different interaction mechanisms. Furthermore, the slight shift in energy above about 100 MeV follows from the fact that the energies of the interacting photons are lower than 25 GeV. Apart from this the shapes of the two spectra are similar.

The neutron-attenuation length is shown in Fig. 33.4 for concrete and mono-energetic broad-beam conditions. As can be seen in the figure it reaches a value of about 117 g/cm² above 200 MeV. As the cascade through thick shielding is carried by high-energy particles this value is equal to the equilibrium attenuation length at 90 degrees in concrete.

33.5. Photon sources

The dose equivalent rate in tissue (in mSv/h) from a gamma point source emitting one photon of energy E (in MeV) per second at a distance of 1 m is $4.6 \times 10^{-9} \mu_{en}/\rho E$, where μ_{en}/ρ is the mass energy absorption coefficient. The latter has a value of $0.029 \pm 0.004 \text{ cm}^2/\text{g}$ for photons in tissue over an energy range between 60 keV and 2 MeV (see Ref. 11 for tabulated values).

Similarly, the dose equivalent rate in tissue (in mSv/h) at the surface of a semi-infinite slab of uniformly activated material containing 1 Bq/g of a gamma emitter of energy E (in MeV) is $2.9 \times 10^{-4} R_\mu E$, where R_μ is the ratio of the mass energy absorption coefficients of the photons in tissue and in the material.

Figure 33.5: Contribution of individual gamma-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [12].

Figure 33.6: Contribution of individual positron-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [12].

33.6. Accelerator-induced radioactivity

Typical medium- and long-lived activation products in metallic components of accelerators are ²²Na, ⁴⁶Sc, ⁴⁸V, ⁵¹Cr, ⁵⁴Mn, ⁵⁵Fe, ⁵⁹Fe, ⁵⁶Co, ⁵⁷Co, ⁵⁸Co, ⁶⁰Co, ⁶³Ni and ⁶⁵Zn. Gamma-emitting nuclides dominate doses by external irradiation at longer decay times (more than one day) while at short decay times β^+ emitters are also important (through photons produced by β^+ annihilation). Due to their short range, β^- emitters are relevant, for example, only for

dose to the skin and eyes or for doses due to inhalation or ingestion. Fig. 33.5 and Fig. 33.6 show the contributions of gamma and β^+ emitters to the total dose rate at 12.4 cm distance to an activated copper sample [12]. Typically, dose rates at a certain decay time are mainly determined by radionuclides having a half-life of the order of the decay time. Extended irradiation periods might be an exception to this general rule as in this case the activity of long-lived nuclides can build up sufficiently so that it dominates that one of short-lived even at short cooling times.

Activation in concrete is dominated by ^{24}Na (short decay times) and ^{22}Na (long decay times). Both nuclides can be produced either by low-energy neutron reactions on the sodium-component in the concrete or by spallation reactions on silicon and calcium. At long decay times nuclides of radiological interest in activated concrete can also be ^{60}Co , ^{152}Eu , ^{154}Eu and ^{134}Cs , all of which produced by (n,γ) -reactions with traces of natural cobalt, europium and cesium. Thus, such trace elements might be important even if their content in concrete is only a few parts per million or less by weight.

The explicit simulation of radionuclide production with general-purpose Monte Carlo codes has become the most commonly applied method to calculate induced radioactivity and its radiological consequences. Nevertheless, other more approximative approaches, such as “ ω -factors” [9], can still be useful for fast order-of-magnitude estimates. These ω -factors give the dose rate per unit star density (inelastic reactions above a certain energy threshold, e.g. 50 MeV) on contact to an extended, uniformly activated object after a 30-day irradiation and 1-day decay. For steel or iron, $\omega \simeq 3 \times 10^{-12}$ (Sv cm^3/star). This does not include possible contributions from thermal-neutron activation.

"Emission probability" is the probability per decay of a given emission; because of cascades these may total more than 100%. Only principal emissions are listed. EC means electron capture, and e^- means monoenergetic internal conversion (Auger) electron. The intensity of 0.511 MeV e^+e^- annihilation photons depends upon the number of stopped positrons. Endpoint β^\pm energies are listed. In some cases when energies are closely spaced, the γ -ray values are approximate weighted averages. Radiation from short-lived daughter isotopes is included where relevant.

Half-lives, energies, and intensities are from E. Browne and R.B. Firestone, *Table of Radioactive Isotopes* (John Wiley & Sons, New York, 1986), recent *Nuclear Data Sheets*, and *X-ray and Gamma-ray Standards for Detector Calibration*, IAEA-TECDOC-619 (1991).

Neutron data are from *Neutron Sources for Basic Physics and Applications* (Pergamon Press, 1983).

35. PROBABILITY

Revised September 2011 by G. Cowan (RHUL).

35.1. General [1–8]

An abstract definition of probability can be given by considering a set S , called the sample space, and possible subsets A, B, \dots , the interpretation of which is left open. The probability P is a real-valued function defined by the following axioms due to Kolmogorov [9]:

1. For every subset A in S , $P(A) \geq 0$;
2. For disjoint subsets (*i.e.*, $A \cap B = \emptyset$), $P(A \cup B) = P(A) + P(B)$;
3. $P(S) = 1$.

In addition, one defines the conditional probability $P(A|B)$ (read P of A given B) as

$$P(A|B) = \frac{P(A \cap B)}{P(B)}. \quad (35.1)$$

From this definition and using the fact that $A \cap B$ and $B \cap A$ are the same, one obtains *Bayes' theorem*,

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)}. \quad (35.2)$$

From the three axioms of probability and the definition of conditional probability, one obtains the *law of total probability*,

$$P(B) = \sum_i P(B|A_i)P(A_i), \quad (35.3)$$

for any subset B and for disjoint A_i with $\cup_i A_i = S$. This can be combined with Bayes' theorem (Eq. (35.2)) to give

$$P(A|B) = \frac{P(B|A)P(A)}{\sum_i P(B|A_i)P(A_i)}, \quad (35.4)$$

where the subset A could, for example, be one of the A_i .

The most commonly used interpretation of the subsets of the sample space are outcomes of a repeatable experiment. The probability $P(A)$ is assigned a value equal to the limiting frequency of occurrence of A . This interpretation forms the basis of *frequentist statistics*.

The subsets of the sample space can also be interpreted as *hypotheses*, *i.e.*, statements that are either true or false, such as ‘The mass of the W boson lies between 80.3 and 80.5 GeV.’ In the frequency interpretation, such statements are either always or never true, *i.e.*, the corresponding probabilities would be 0 or 1. Using *subjective probability*, however, $P(A)$ is interpreted as the degree of belief that the hypothesis A is true. Subjective probability is used in *Bayesian* (as opposed to frequentist) statistics. Bayes' theorem can be written

$$P(\text{theory}|\text{data}) \propto P(\text{data}|\text{theory})P(\text{theory}), \quad (35.5)$$

where ‘theory’ represents some hypothesis and ‘data’ is the outcome of the experiment. Here $P(\text{theory})$ is the *prior* probability for the theory, which reflects the experimenter's degree of belief before carrying out the measurement, and $P(\text{data}|\text{theory})$ is the probability to have gotten the data actually obtained, given the theory, which is also called the *likelihood*.

Bayesian statistics provides no fundamental rule for obtaining the prior probability, which may depend on previous measurements, theoretical prejudices, *etc.* Once this has been specified, however, Eq. (35.5) tells how the probability for the theory must be modified in the light of the new data to give the *posterior* probability, $P(\text{theory}|\text{data})$. As Eq. (35.5) is stated as a proportionality, the probability must be normalized by summing (or integrating) over all possible hypotheses.

35.2. Random variables

A *random variable* is a numerical characteristic assigned to an element of the sample space. In the frequency interpretation of probability, it corresponds to an outcome of a repeatable experiment. Let x be a possible outcome of an observation. If x can take on any value from a continuous range, we write $f(x; \theta)dx$ as the probability that the measurement's outcome lies between x and $x + dx$. The function $f(x; \theta)$ is called the *probability density function* (p.d.f.), which may depend on one or more parameters θ . If x can take on only discrete values (*e.g.*, the non-negative integers), then $f(x; \theta)$ is itself a probability.

The p.d.f. is always normalized to unit area (unit sum, if discrete). Both x and θ may have multiple components and are then often written as vectors. If θ is unknown, we may wish to estimate its value from a given set of measurements of x ; this is a central topic of *statistics* (see Sec. 36).

The *cumulative distribution function* $F(a)$ is the probability that $x \leq a$:

$$F(a) = \int_{-\infty}^a f(x) dx. \quad (35.6)$$

Here and below, if x is discrete-valued, the integral is replaced by a sum. The endpoint a is expressly included in the integral or sum. Then $0 \leq F(x) \leq 1$, $F(x)$ is nondecreasing, and $P(a < x \leq b) = F(b) - F(a)$. If x is discrete, $F(x)$ is flat except at allowed values of x , where it has discontinuous jumps equal to $f(x)$.

Any function of random variables is itself a random variable, with (in general) a different p.d.f. The *expectation value* of any function $u(x)$ is

$$E[u(x)] = \int_{-\infty}^{\infty} u(x) f(x) dx, \quad (35.7)$$

assuming the integral is finite. For $u(x)$ and $v(x)$, any two functions of x , $E[u + v] = E[u] + E[v]$. For c and k constants, $E[cu + k] = cE[u] + k$.

The n^{th} moment of a random variable x is

$$\alpha_n \equiv E[x^n] = \int_{-\infty}^{\infty} x^n f(x) dx, \quad (35.8a)$$

and the n^{th} central moment of x (or moment about the mean, α_1) is

$$m_n \equiv E[(x - \alpha_1)^n] = \int_{-\infty}^{\infty} (x - \alpha_1)^n f(x) dx. \quad (35.8b)$$

The most commonly used moments are the mean μ and variance σ^2 :

$$\mu \equiv \alpha_1, \quad (35.9a)$$

$$\sigma^2 \equiv V[x] \equiv m_2 = \alpha_2 - \mu^2. \quad (35.9b)$$

The mean is the location of the ‘center of mass’ of the p.d.f., and the variance is a measure of the square of its width. Note that $V[cx + k] = c^2V[x]$. It is often convenient to use the *standard deviation* of x , σ , defined as the square root of the variance.

Any odd moment about the mean is a measure of the skewness of the p.d.f. The simplest of these is the dimensionless coefficient of skewness $\gamma_1 = m_3/\sigma^3$.

The fourth central moment m_4 provides a convenient measure of the tails of a distribution. For the Gaussian distribution (see Sec. 35.4), one has $m_4 = 3\sigma^4$. The *kurtosis* is defined as $\gamma_2 = m_4/\sigma^4 - 3$, *i.e.*, it is zero for a Gaussian, positive for a *leptokurtic* distribution with longer tails, and negative for a *platykurtic* distribution with tails that die off more quickly than those of a Gaussian.

The *quantile* x_α is the value of the random variable x at which the cumulative distribution is equal to α . That is, the quantile is the inverse of the cumulative distribution function, *i.e.*, $x_\alpha = F^{-1}(\alpha)$. An important special case is the *median*, x_{med} , defined by $F(x_{\text{med}}) = 1/2$, *i.e.*, half the probability lies above and half lies below x_{med} . (More rigorously, x_{med} is a median if $P(x \geq x_{\text{med}}) \geq 1/2$ and $P(x \leq x_{\text{med}}) \geq 1/2$. If only one value exists, it is called ‘the median.’)

Under a monotonic change of variable $x \rightarrow y(x)$, the quantiles of a distribution (and hence also the median) obey $y_\alpha = y(x_\alpha)$. In

general the expectation value and *mode* (most probable value) of a distribution do not, however, transform in this way.

Let x and y be two random variables with a *joint* p.d.f. $f(x, y)$. The *marginal* p.d.f. of x (the distribution of x with y unobserved) is

$$f_1(x) = \int_{-\infty}^{\infty} f(x, y) dy, \tag{35.10}$$

and similarly for the marginal p.d.f. $f_2(y)$. The *conditional* p.d.f. of y given fixed x (with $f_1(x) \neq 0$) is defined by $f_3(y|x) = f(x, y)/f_1(x)$, and similarly $f_4(x|y) = f(x, y)/f_2(y)$. From these, we immediately obtain Bayes' theorem (see Eqs. (35.2) and (35.4)),

$$f_4(x|y) = \frac{f_3(y|x)f_1(x)}{f_2(y)} = \frac{f_3(y|x)f_1(x)}{\int f_3(y|x')f_1(x') dx'}. \tag{35.11}$$

The mean of x is

$$\mu_x = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} x f(x, y) dx dy = \int_{-\infty}^{\infty} x f_1(x) dx, \tag{35.12}$$

and similarly for y . The *covariance* of x and y is

$$\text{cov}[x, y] = E[(x - \mu_x)(y - \mu_y)] = E[xy] - \mu_x \mu_y. \tag{35.13}$$

A dimensionless measure of the covariance of x and y is given by the *correlation coefficient*,

$$\rho_{xy} = \text{cov}[x, y] / \sigma_x \sigma_y, \tag{35.14}$$

where σ_x and σ_y are the standard deviations of x and y . It can be shown that $-1 \leq \rho_{xy} \leq 1$.

Two random variables x and y are *independent* if and only if

$$f(x, y) = f_1(x)f_2(y). \tag{35.15}$$

If x and y are independent, then $\rho_{xy} = 0$; the converse is not necessarily true. If x and y are independent, $E[u(x)v(y)] = E[u(x)]E[v(y)]$, and $V[x + y] = V[x] + V[y]$; otherwise, $V[x + y] = V[x] + V[y] + 2\text{cov}[x, y]$, and $E[uv]$ does not necessarily factorize.

Consider a set of n continuous random variables $\mathbf{x} = (x_1, \dots, x_n)$ with joint p.d.f. $f(\mathbf{x})$, and a set of n new variables $\mathbf{y} = (y_1, \dots, y_n)$, related to \mathbf{x} by means of a function $\mathbf{y}(\mathbf{x})$ that is one-to-one, *i.e.*, the inverse $\mathbf{x}(\mathbf{y})$ exists. The joint p.d.f. for \mathbf{y} is given by

$$g(\mathbf{y}) = f(\mathbf{x}(\mathbf{y}))|J|, \tag{35.16}$$

where $|J|$ is the absolute value of the determinant of the square matrix $J_{ij} = \partial x_i / \partial y_j$ (the Jacobian determinant). If the transformation from \mathbf{x} to \mathbf{y} is not one-to-one, the \mathbf{x} -space must be broken into regions where the function $\mathbf{y}(\mathbf{x})$ can be inverted, and the contributions to $g(\mathbf{y})$ from each region summed.

Given a set of functions $\mathbf{y} = (y_1, \dots, y_m)$ with $m < n$, one can construct $n - m$ additional independent functions, apply the procedure above, then integrate the resulting $g(\mathbf{y})$ over the unwanted y_i to find the marginal distribution of those of interest.

For a one-to-one transformation of discrete random variables, simply substitute; no Jacobian is necessary because now f is a probability rather than a probability density. If the transformation is not one-to-one, then sum the probabilities for all values of the original variable that contribute to a given value of the transformed variable. If f depends on a set of parameters θ , a change to a different parameter set $\eta(\theta)$ is made by simple substitution; no Jacobian is used.

35.3. Characteristic functions

The characteristic function $\phi(u)$ associated with the p.d.f. $f(x)$ is essentially its Fourier transform, or the expectation value of e^{iux} :

$$\phi(u) = E[e^{iux}] = \int_{-\infty}^{\infty} e^{iux} f(x) dx. \tag{35.17}$$

Once $\phi(u)$ is specified, the p.d.f. $f(x)$ is uniquely determined and vice versa; knowing one is equivalent to the other. Characteristic functions are useful in deriving a number of important results about moments and sums of random variables.

It follows from Eqs. (35.8a) and (35.17) that the n^{th} moment of a random variable x that follows $f(x)$ is given by

$$i^{-n} \left. \frac{d^n \phi}{du^n} \right|_{u=0} = \int_{-\infty}^{\infty} x^n f(x) dx = \alpha_n. \tag{35.18}$$

Thus it is often easy to calculate all the moments of a distribution defined by $\phi(u)$, even when $f(x)$ cannot be written down explicitly.

If the p.d.f.s $f_1(x)$ and $f_2(y)$ for independent random variables x and y have characteristic functions $\phi_1(u)$ and $\phi_2(u)$, then the characteristic function of the weighted sum $ax + by$ is $\phi_1(au)\phi_2(bu)$. The rules of addition for several important distributions (*e.g.*, that the sum of two Gaussian distributed variables also follows a Gaussian distribution) easily follow from this observation.

Let the (partial) characteristic function corresponding to the conditional p.d.f. $f_2(x|z)$ be $\phi_2(u|z)$, and the p.d.f. of z be $f_1(z)$. The characteristic function after integration over the conditional value is

$$\phi(u) = \int \phi_2(u|z)f_1(z) dz. \tag{35.19}$$

Suppose we can write ϕ_2 in the form

$$\phi_2(u|z) = A(u)e^{ig(u)z}. \tag{35.20}$$

Then

$$\phi(u) = A(u)\phi_1(g(u)). \tag{35.21}$$

The cumulants (semi-invariants) κ_n of a distribution with characteristic function $\phi(u)$ are defined by the relation

$$\phi(u) = \exp \left[\sum_{n=1}^{\infty} \frac{\kappa_n}{n!} (iu)^n \right] = \exp \left(i\kappa_1 u - \frac{1}{2}\kappa_2 u^2 + \dots \right). \tag{35.22}$$

The values κ_n are related to the moments α_n and m_n . The first few relations are

$$\begin{aligned} \kappa_1 &= \alpha_1 (= \mu, \text{ the mean}) \\ \kappa_2 &= m_2 = \alpha_2 - \alpha_1^2 (= \sigma^2, \text{ the variance}) \\ \kappa_3 &= m_3 = \alpha_3 - 3\alpha_1\alpha_2 + 2\alpha_1^3. \end{aligned} \tag{35.23}$$

35.4. Some probability distributions

Table 35.1 gives a number of common probability density functions and corresponding characteristic functions, means, and variances. Further information may be found in Refs. [1–8], [17], and [11], which has particularly detailed tables. Monte Carlo techniques for generating each of them may be found in our Sec. 37.4 and in Ref. 17. We comment below on all except the trivial uniform distribution.

35.4.1. Binomial distribution :

A random process with exactly two possible outcomes which occur with fixed probabilities is called a *Bernoulli* process. If the probability of obtaining a certain outcome (a “success”) in an individual trial is p , then the probability of obtaining exactly r successes ($r = 0, 1, 2, \dots, N$) in N independent trials, without regard to the order of the successes and failures, is given by the binomial distribution $f(r; N, p)$ in Table 35.1. If r and s are binomially distributed with parameters (N_r, p) and (N_s, p) , then $t = r + s$ follows a binomial distribution with parameters $(N_r + N_s, p)$.

Table 35.1. Some common probability density functions, with corresponding characteristic functions and means and variances. In the Table, $\Gamma(k)$ is the gamma function, equal to $(k - 1)!$ when k is an integer; ${}_1F_1$ is the confluent hypergeometric function of the 1st kind [11].

Distribution	Probability density function f (variable; parameters)	Characteristic function $\phi(u)$	Mean	Variance σ^2
Uniform	$f(x; a, b) = \begin{cases} 1/(b - a) & a \leq x \leq b \\ 0 & \text{otherwise} \end{cases}$	$\frac{e^{ibu} - e^{iau}}{(b - a)iu}$	$\frac{a + b}{2}$	$\frac{(b - a)^2}{12}$
Binomial	$f(r; N, p) = \frac{N!}{r!(N - r)!} p^r q^{N-r}$ $r = 0, 1, 2, \dots, N; \quad 0 \leq p \leq 1; \quad q = 1 - p$	$(q + pe^{iu})^N$	Np	Npq
Poisson	$f(n; \nu) = \frac{\nu^n e^{-\nu}}{n!}; \quad n = 0, 1, 2, \dots; \quad \nu > 0$	$\exp[\nu(e^{iu} - 1)]$	ν	ν
Normal (Gaussian)	$f(x; \mu, \sigma^2) = \frac{1}{\sigma\sqrt{2\pi}} \exp(-(x - \mu)^2/2\sigma^2)$ $-\infty < x < \infty; \quad -\infty < \mu < \infty; \quad \sigma > 0$	$\exp(i\mu u - \frac{1}{2}\sigma^2 u^2)$	μ	σ^2
Multivariate Gaussian	$f(\mathbf{x}; \boldsymbol{\mu}, V) = \frac{1}{(2\pi)^n \sqrt{ V }} \times \exp[-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu})^T V^{-1}(\mathbf{x} - \boldsymbol{\mu})]$ $-\infty < x_j < \infty; \quad -\infty < \mu_j < \infty; \quad V > 0$	$\exp[i\boldsymbol{\mu} \cdot \mathbf{u} - \frac{1}{2}\mathbf{u}^T V \mathbf{u}]$	$\boldsymbol{\mu}$	V_{jk}
χ^2	$f(z; n) = \frac{z^{n/2-1} e^{-z/2}}{2^{n/2} \Gamma(n/2)}; \quad z \geq 0$	$(1 - 2iu)^{-n/2}$	n	$2n$
Student's t	$f(t; n) = \frac{1}{\sqrt{n\pi}} \frac{\Gamma[(n+1)/2]}{\Gamma(n/2)} \left(1 + \frac{t^2}{n}\right)^{-(n+1)/2}$ $-\infty < t < \infty; \quad n$ not required to be integer	—	0 for $n > 1$	$n/(n - 2)$ for $n > 2$
Gamma	$f(x; \lambda, k) = \frac{x^{k-1} \lambda^k e^{-\lambda x}}{\Gamma(k)}; \quad 0 \leq x < \infty;$ k not required to be integer	$(1 - iu/\lambda)^{-k}$	k/λ	k/λ^2
Beta	$f(x; \alpha, \beta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1} (1 - x)^{\beta-1}$ $0 \leq x \leq 1$	${}_1F_1(\alpha; \alpha + \beta; iu)$	$\frac{\alpha}{\alpha + \beta}$	$\frac{\alpha\beta}{(\alpha + \beta)^2(\alpha + \beta + 1)}$

35.4.2. Poisson distribution :

The Poisson distribution $f(n; \nu)$ gives the probability of finding exactly n events in a given interval of x (e.g., space or time) when the events occur independently of one another and of x at an average rate of ν per the given interval. The variance σ^2 equals ν . It is the limiting case $p \rightarrow 0, N \rightarrow \infty, Np = \nu$ of the binomial distribution. The Poisson distribution approaches the Gaussian distribution for large ν .

For example, a large number of radioactive nuclei of a given type will result in a certain number of decays in a fixed time interval. If this interval is small compared to the mean lifetime, then the probability for a given nucleus to decay is small, and thus the number of decays in the time interval is well modeled as a Poisson variable.

35.4.3. Normal or Gaussian distribution :

The normal (or Gaussian) probability density function $f(x; \mu, \sigma^2)$ given in Table 35.1 has mean $E[x] = \mu$ and variance $V[x] = \sigma^2$. Comparison of the characteristic function $\phi(u)$ given in Table 35.1 with Eq. (35.22) shows that all cumulants κ_n beyond κ_2 vanish; this is a unique property of the Gaussian distribution. Some other properties are:

$P(x \text{ in range } \mu \pm \sigma) = 0.6827,$
 $P(x \text{ in range } \mu \pm 0.6745\sigma) = 0.5,$
 $E[|x - \mu|] = \sqrt{2/\pi}\sigma = 0.7979\sigma,$
 half-width at half maximum = $\sqrt{2 \ln 2}\sigma = 1.177\sigma.$

For a Gaussian with $\mu = 0$ and $\sigma^2 = 1$ (the *standard* Gaussian), the cumulative distribution, Eq. (35.6), is related to the error function $\text{erf}(y)$ by

$$F(x; 0, 1) = \frac{1}{2} \left[1 + \text{erf}(x/\sqrt{2}) \right]. \tag{35.24}$$

The error function and standard Gaussian are tabulated in many references (e.g., Ref. [11,12]) and are available in software packages such as ROOT [5]. For a mean μ and variance σ^2 , replace x by $(x - \mu)/\sigma$. The probability of x in a given range can be calculated with Eq. (36.55).

For x and y independent and normally distributed, $z = ax + by$ follows $f(z; a\mu_x + b\mu_y, a^2\sigma_x^2 + b^2\sigma_y^2)$; that is, the weighted means and variances add.

The Gaussian derives its importance in large part from the *central limit theorem*:

If independent random variables x_1, \dots, x_n are distributed according to *any* p.d.f. with finite mean and variance, then the sum $y = \sum_{i=1}^n x_i$ will have a p.d.f. that approaches a Gaussian for large n . If the p.d.f.s of the x_i are not identical, the theorem still holds under somewhat more restrictive conditions. The mean and variance are given by the sums of corresponding terms from the individual x_i . Therefore, the sum of a large number of fluctuations x_i will be distributed as a Gaussian, even if the x_i themselves are not.

(Note that the *product* of a large number of random variables is not Gaussian, but its logarithm is. The p.d.f. of the product is *log-normal*. See Ref. 8 for details.)

For a set of n Gaussian random variables \mathbf{x} with means $\boldsymbol{\mu}$ and covariances $V_{ij} = \text{cov}[x_i, x_j]$, the p.d.f. for the one-dimensional

Gaussian is generalized to

$$f(\mathbf{x}; \boldsymbol{\mu}, V) = \frac{1}{(2\pi)^{n/2} \sqrt{|V|}} \exp \left[-\frac{1}{2} (\mathbf{x} - \boldsymbol{\mu})^T V^{-1} (\mathbf{x} - \boldsymbol{\mu}) \right], \quad (35.25)$$

where the determinant $|V|$ must be greater than 0. For diagonal V (independent variables), $f(\mathbf{x}; \boldsymbol{\mu}, V)$ is the product of the p.d.f.s of n Gaussian distributions. For $n = 2$, $f(\mathbf{x}; \boldsymbol{\mu}, V)$ is

$$f(x_1, x_2; \mu_1, \mu_2, \sigma_1, \sigma_2, \rho) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \times \exp \left\{ \frac{-1}{2(1-\rho^2)} \left[\frac{(x_1 - \mu_1)^2}{\sigma_1^2} - \frac{2\rho(x_1 - \mu_1)(x_2 - \mu_2)}{\sigma_1\sigma_2} + \frac{(x_2 - \mu_2)^2}{\sigma_2^2} \right] \right\}. \quad (35.26)$$

The characteristic function for the multivariate Gaussian is

$$\phi(\mathbf{u}; \boldsymbol{\mu}, V) = \exp \left[i\boldsymbol{\mu} \cdot \mathbf{u} - \frac{1}{2} \mathbf{u}^T V \mathbf{u} \right]. \quad (35.27)$$

If the components of \mathbf{x} are independent, then Eq. (35.27) is the product of the c.f.s of n Gaussians.

For a multi-dimensional Gaussian distribution for variables x_i , $i = 1, \dots, n$, the marginal distribution for any single x_i is a one-dimensional Gaussian with mean μ_i and variance V_{ii} . V is $n \times n$, symmetric, and positive definite. For any vector \mathbf{X} , the quadratic form $\mathbf{X}^T V^{-1} \mathbf{X} = C$, where C is any positive number, traces an n -dimensional ellipsoid as \mathbf{X} varies. If $X_i = x_i - \mu_i$, then C is a random variable obeying the χ^2 distribution with n degrees of freedom, discussed in the following section. The probability that \mathbf{X} corresponding to a set of Gaussian random variables x_i lies outside the ellipsoid characterized by a given value of C ($= \chi^2$) is given by $1 - F_{\chi^2}(C; n)$, where F_{χ^2} is the cumulative χ^2 distribution. This may be read from Fig. 36.1. For example, the “ s -standard-deviation ellipsoid” occurs at $C = s^2$. For the two-variable case ($n = 2$), the point \mathbf{X} lies outside the one-standard-deviation ellipsoid with 61% probability. The use of these ellipsoids as indicators of probable error is described in Sec. 36.3.2.4; the validity of those indicators assumes that $\boldsymbol{\mu}$ and V are correct.

35.4.4. χ^2 distribution :

If x_1, \dots, x_n are independent Gaussian random variables, the sum $z = \sum_{i=1}^n (x_i - \mu_i)^2 / \sigma_i^2$ follows the χ^2 p.d.f. with n degrees of freedom, which we denote by $\chi^2(n)$. More generally, for n correlated Gaussian variables as components of a vector \mathbf{X} with covariance matrix V , $z = \mathbf{X}^T V^{-1} \mathbf{X}$ follows $\chi^2(n)$ as in the previous section. For a set of z_i , each of which follows $\chi^2(n_i)$, $\sum z_i$ follows $\chi^2(\sum n_i)$. For large n , the χ^2 p.d.f. approaches a Gaussian with a mean and variance give by $\mu = n$ and $\sigma^2 = 2n$, respectively (here the formulae for μ and σ^2 are valid for all n).

The χ^2 p.d.f. is often used in evaluating the level of compatibility between observed data and a hypothesis for the p.d.f. that the data might follow. This is discussed further in Sec. 36.2.2 on tests of goodness-of-fit.

35.4.5. Student's t distribution :

Suppose that y and x_1, \dots, x_n are independent and Gaussian distributed with mean 0 and variance 1. We then define

$$z = \sum_{i=1}^n x_i^2 \quad \text{and} \quad t = \frac{y}{\sqrt{z/n}}. \quad (35.28)$$

The variable z thus follows a $\chi^2(n)$ distribution. Then t is distributed according to Student's t distribution with n degrees of freedom, $f(t; n)$, given in Table 35.1.

The Student's t distribution resembles a Gaussian but has wider tails. As $n \rightarrow \infty$, the distribution approaches a Gaussian. If $n = 1$, it is a *Cauchy* or *Breit-Wigner* distribution. This distribution is symmetric about zero (its mode), but the expectation value is undefined. For the Student's t , the mean is well defined only for $n > 1$ and the variance is finite only for $n > 2$, so the central limit theorem is

not applicable to sums of random variables following the t distribution for $n = 1$ or 2.

As an example, consider the *sample mean* $\bar{x} = \sum x_i/n$ and the *sample variance* $s^2 = \sum (x_i - \bar{x})^2 / (n - 1)$ for normally distributed x_i with unknown mean μ and variance σ^2 . The sample mean has a Gaussian distribution with a variance σ^2/n , so the variable $(\bar{x} - \mu) / \sqrt{\sigma^2/n}$ is normal with mean 0 and variance 1. The quantity $(n - 1)s^2 / \sigma^2$ is independent of this and follows $\chi^2(n - 1)$. The ratio

$$t = \frac{(\bar{x} - \mu) / \sqrt{\sigma^2/n}}{\sqrt{(n - 1)s^2 / \sigma^2(n - 1)}} = \frac{\bar{x} - \mu}{\sqrt{s^2/n}} \quad (35.29)$$

is distributed as $f(t; n - 1)$. The unknown variance σ^2 cancels, and t can be used to test the hypothesis that the true mean is some particular value μ .

In Table 35.1, n in $f(t; n)$ is not required to be an integer. A Student's t distribution with non-integral $n > 0$ is useful in certain applications.

35.4.6. Gamma distribution :

For a process that generates events as a function of x (e.g., space or time) according to a Poisson distribution, the distance in x from an arbitrary starting point (which may be some particular event) to the k^{th} event follows a *gamma* distribution, $f(x; \lambda, k)$. The Poisson parameter μ is λ per unit x . The special case $k = 1$ (i.e., $f(x; \lambda, 1) = \lambda e^{-\lambda x}$) is called the *exponential* distribution. A sum of k' exponential random variables x_i is distributed as $f(\sum x_i; \lambda, k')$.

The parameter k is not required to be an integer. For $\lambda = 1/2$ and $k = n/2$, the gamma distribution reduces to the $\chi^2(n)$ distribution.

35.4.7. Beta distribution :

The beta distribution describes a continuous random variable x in the interval $[0, 1]$; this can easily be generalized by scaling and translation to have arbitrary endpoints. In Bayesian inference about the parameter p of a binomial process, if the prior p.d.f. is a beta distribution $f(p; \alpha, \beta)$ then the observation of r successes out of N trials gives a posterior beta distribution $f(p; r + \alpha, N - r + \beta)$ (Bayesian methods are discussed further in Sec. 36). The uniform distribution is a beta distribution with $\alpha = \beta = 1$.

36. STATISTICS

Revised September 2011 by G. Cowan (RHUL).

This chapter gives an overview of statistical methods used in high-energy physics. In statistics, we are interested in using a given sample of data to make inferences about a probabilistic model, *e.g.*, to assess the model's validity or to determine the values of its parameters. There are two main approaches to statistical inference, which we may call frequentist and Bayesian. In frequentist statistics, probability is interpreted as the frequency of the outcome of a repeatable experiment. The most important tools in this framework are parameter estimation, covered in Section 36.1, and statistical tests, discussed in Section 36.2. Frequentist confidence intervals, which are constructed so as to cover the true value of a parameter with a specified probability, are treated in Section 36.3.2. Note that in frequentist statistics one does not define a probability for a hypothesis or for a parameter.

Frequentist statistics provides the usual tools for reporting the outcome of an experiment objectively, without needing to incorporate prior beliefs concerning the parameter being measured or the theory being tested. As such, they are used for reporting most measurements and their statistical uncertainties in high-energy physics.

In Bayesian statistics, the interpretation of probability is more general and includes *degree of belief* (called subjective probability). One can then speak of a probability density function (p.d.f.) for a parameter, which expresses one's state of knowledge about where its true value lies. Bayesian methods allow for a natural way to input additional information, which in general may be subjective; in fact they *require* the *prior* p.d.f. as input for the parameters, *i.e.*, the degree of belief about the parameters' values before carrying out the measurement. Using Bayes' theorem Eq. (35.4), the prior degree of belief is updated by the data from the experiment. Bayesian methods for interval estimation are discussed in Sections 36.3.1 and 36.3.2.6

Bayesian techniques are often used to treat systematic uncertainties, where the author's beliefs about, say, the accuracy of the measuring device may enter. Bayesian statistics also provides a useful framework for discussing the validity of different theoretical interpretations of the data. This aspect of a measurement, however, will usually be treated separately from the reporting of the result. In some analyses, both the frequentist and Bayesian approaches are used together. One may, for example, treat systematic uncertainties in a model using Bayesian methods, but then construct a frequentist statistical test of that model.

For many inference problems, the frequentist and Bayesian approaches give similar numerical answers, even though they are based on fundamentally different interpretations of probability. For small data samples, however, and for measurements of a parameter near a physical boundary, the different approaches may yield different results, so we are forced to make a choice. For a discussion of Bayesian vs. non-Bayesian methods, see references written by a statistician [1], by a physicist [2], or the more detailed comparison in Ref. 3.

Following common usage in physics, the word "error" is often used in this chapter to mean "uncertainty." More specifically it can indicate the size of an interval as in "the standard error" or "error propagation," where the term refers to the standard deviation of an estimator.

36.1. Parameter estimation

Here we review *point estimation* of parameters, first with an overview of the frequentist approach and its two most important methods, maximum likelihood and least squares, treated in Sections 36.1.2 and 36.1.3. The Bayesian approach is outlined in Sec. 36.1.4.

An *estimator* $\hat{\theta}$ (written with a hat) is a function of the data used to estimate the value of the parameter θ . Sometimes the word 'estimate' is used to denote the value of the estimator when evaluated with given data. There is no fundamental rule dictating how an estimator must be constructed. One tries, therefore, to choose that estimator which has the best properties. The most important of these are (a) *consistency*, (b) *bias*, (c) *efficiency*, and (d) *robustness*.

(a) An estimator is said to be *consistent* if the estimate $\hat{\theta}$ converges to the true value θ as the amount of data increases. This property is so important that it is possessed by all commonly used estimators.

(b) The *bias*, $b = E[\hat{\theta}] - \theta$, is the difference between the expectation value of the estimator and the true value of the parameter.

The expectation value is taken over a hypothetical set of similar experiments in which $\hat{\theta}$ is constructed in the same way. When $b = 0$, the estimator is said to be unbiased. The bias depends on the chosen metric, *i.e.*, if $\hat{\theta}$ is an unbiased estimator of θ , then $\hat{\theta}^2$ is not in general an unbiased estimator for θ^2 . If we have an estimate \hat{b} for the bias, we can subtract it from $\hat{\theta}$ to obtain a new $\hat{\theta}' = \hat{\theta} - \hat{b}$. The estimate \hat{b} may, however, be subject to statistical or systematic uncertainties that are larger than the bias itself, so that the new $\hat{\theta}'$ may not be better than the original.

(c) *Efficiency* is the ratio of the minimum possible variance for any estimator of θ to the variance $V[\hat{\theta}]$ of the estimator actually used. Under rather general conditions, the minimum variance is given by the Rao-Cramér-Frechet bound,

$$\sigma_{\min}^2 = \left(1 + \frac{\partial b}{\partial \theta}\right)^2 / I(\theta), \quad (36.1)$$

where

$$I(\theta) = E \left[\left(\frac{\partial}{\partial \theta} \sum_i \ln f(x_i; \theta) \right)^2 \right] \quad (36.2)$$

is the *Fisher information*. The sum is over all data, assumed independent, and distributed according to the p.d.f. $f(x; \theta)$, b is the bias, if any, and the allowed range of x must not depend on θ .

The *mean-squared error*,

$$\text{MSE} = E[(\hat{\theta} - \theta)^2] = V[\hat{\theta}] + b^2, \quad (36.3)$$

is a measure of an estimator's quality which combines bias and variance.

(d) *Robustness* is the property of being insensitive to departures from assumptions in the p.d.f., *e.g.*, owing to uncertainties in the distribution's tails.

Simultaneously optimizing for all the measures of estimator quality described above can lead to conflicting requirements. For example, there is in general a trade-off between bias and variance. For some common estimators, the properties above are known exactly. More generally, it is possible to evaluate them by Monte Carlo simulation. Note that they will often depend on the unknown θ .

36.1.1. Estimators for mean, variance and median :

Suppose we have a set of N independent measurements, x_i , assumed to be unbiased measurements of the same unknown quantity μ with a common, but unknown, variance σ^2 . Then

$$\hat{\mu} = \frac{1}{N} \sum_{i=1}^N x_i \quad (36.4)$$

$$\hat{\sigma}^2 = \frac{1}{N-1} \sum_{i=1}^N (x_i - \hat{\mu})^2 \quad (36.5)$$

are unbiased estimators of μ and σ^2 . The variance of $\hat{\mu}$ is σ^2/N and the variance of $\hat{\sigma}^2$ is

$$V[\hat{\sigma}^2] = \frac{1}{N} \left(m_4 - \frac{N-3}{N-1} \sigma^4 \right), \quad (36.6)$$

where m_4 is the 4th central moment of x . For Gaussian distributed x_i , this becomes $2\sigma^4/(N-1)$ for any $N \geq 2$, and for large N , the standard deviation of $\hat{\sigma}^2$ (the "error of the error") is $\sigma/\sqrt{2N}$. Again, if the x_i are Gaussian, $\hat{\mu}$ is an efficient estimator for μ , and the estimators $\hat{\mu}$ and $\hat{\sigma}^2$ are uncorrelated. Otherwise the arithmetic mean (36.4) is not necessarily the most efficient estimator; this is discussed further in Sec. 8.7 of Ref. 4.

If σ^2 is known, it does not improve the estimate $\hat{\mu}$, as can be seen from Eq. (36.4); however, if μ is known, substitute it for $\hat{\mu}$ in Eq. (36.5) and replace $N-1$ by N to obtain an estimator of σ^2 still

with zero bias but smaller variance. If the x_i have different, known variances σ_i^2 , then the weighted average

$$\hat{\mu} = \frac{1}{w} \sum_{i=1}^N w_i x_i \quad (36.7)$$

is an unbiased estimator for μ with a smaller variance than an unweighted average; here $w_i = 1/\sigma_i^2$ and $w = \sum_i w_i$. The standard deviation of $\hat{\mu}$ is $1/\sqrt{w}$.

As an estimator for the median x_{med} , one can use the value \hat{x}_{med} such that half the x_i are below and half above (the sample median). If the sample median lies between two observed values, it is set by convention halfway between them. If the p.d.f. of x has the form $f(x - \mu)$ and μ is both mean and median, then for large N the variance of the sample median approaches $1/[4Nf^2(0)]$, provided $f(0) > 0$. Although estimating the median can often be more difficult computationally than the mean, the resulting estimator is generally more robust, as it is insensitive to the exact shape of the tails of a distribution.

36.1.2. The method of maximum likelihood :

Suppose we have a set of N measured quantities $\mathbf{x} = (x_1, \dots, x_N)$ described by a joint p.d.f. $f(\mathbf{x}; \boldsymbol{\theta})$, where $\boldsymbol{\theta} = (\theta_1, \dots, \theta_n)$ is set of n parameters whose values are unknown. The *likelihood function* is given by the p.d.f. evaluated with the data \mathbf{x} , but viewed as a function of the parameters, *i.e.*, $L(\boldsymbol{\theta}) = f(\mathbf{x}; \boldsymbol{\theta})$. If the measurements x_i are statistically independent and each follow the p.d.f. $f(x; \boldsymbol{\theta})$, then the joint p.d.f. for \mathbf{x} factorizes and the likelihood function is

$$L(\boldsymbol{\theta}) = \prod_{i=1}^N f(x_i; \boldsymbol{\theta}). \quad (36.8)$$

The method of maximum likelihood takes the estimators $\hat{\boldsymbol{\theta}}$ to be those values of $\boldsymbol{\theta}$ that maximize $L(\boldsymbol{\theta})$.

Note that the likelihood function is *not* a p.d.f. for the parameters $\boldsymbol{\theta}$; in frequentist statistics this is not defined. In Bayesian statistics, one can obtain the posterior p.d.f. for $\boldsymbol{\theta}$ from the likelihood, but this requires multiplying by a prior p.d.f. (see Sec. 36.3.1).

It is usually easier to work with $\ln L$, and since both are maximized for the same parameter values $\boldsymbol{\theta}$, the maximum likelihood (ML) estimators can be found by solving the *likelihood equations*,

$$\frac{\partial \ln L}{\partial \theta_i} = 0, \quad i = 1, \dots, n. \quad (36.9)$$

Often the solution must be found numerically. Maximum likelihood estimators are important because they are approximately unbiased and efficient for large data samples, under quite general conditions, and the method has a wide range of applicability.

In evaluating the likelihood function, it is important that any normalization factors in the p.d.f. that involve $\boldsymbol{\theta}$ be included. However, we will only be interested in the maximum of L and in ratios of L at different values of the parameters; hence any multiplicative factors that do not involve the parameters that we want to estimate may be dropped, including factors that depend on the data but not on $\boldsymbol{\theta}$.

Under a one-to-one change of parameters from $\boldsymbol{\theta}$ to $\boldsymbol{\eta}$, the ML estimators $\hat{\boldsymbol{\theta}}$ transform to $\boldsymbol{\eta}(\hat{\boldsymbol{\theta}})$. That is, the ML solution is invariant under change of parameter. However, other properties of ML estimators, in particular the bias, are not invariant under change of parameter.

The inverse V^{-1} of the covariance matrix $V_{ij} = \text{cov}[\hat{\theta}_i, \hat{\theta}_j]$ for a set of ML estimators can be estimated by using

$$(\hat{V}^{-1})_{ij} = - \frac{\partial^2 \ln L}{\partial \theta_i \partial \theta_j} \Big|_{\hat{\boldsymbol{\theta}}}. \quad (36.10)$$

For finite samples, however, Eq. (36.10) can result in an underestimate of the variances. In the large sample limit (or in a linear model with Gaussian errors), L has a Gaussian form and $\ln L$ is (hyper)parabolic. In this case, it can be seen that a numerically equivalent way of

determining s -standard-deviation errors is from the contour given by the $\boldsymbol{\theta}'$ such that

$$\ln L(\boldsymbol{\theta}') = \ln L_{\text{max}} - s^2/2, \quad (36.11)$$

where $\ln L_{\text{max}}$ is the value of $\ln L$ at the solution point (compare with Eq. (36.58)). The extreme limits of this contour on the θ_i axis give an approximate s -standard-deviation confidence interval for θ_i (see Section 36.3.2.4).

In the case where the size n of the data sample x_1, \dots, x_n is small, the unbinned maximum likelihood method, *i.e.*, use of equation (36.8), is preferred since binning can only result in a loss of information, and hence larger statistical errors for the parameter estimates. The sample size n can be regarded as fixed, or the analyst can choose to treat it as a Poisson-distributed variable; this latter option is sometimes called “extended maximum likelihood” (see, *e.g.*, Refs. [6–8]).

If the sample is large, it can be convenient to bin the values in a histogram, so that one obtains a vector of data $\mathbf{n} = (n_1, \dots, n_N)$ with expectation values $\boldsymbol{\nu} = E[\mathbf{n}]$ and probabilities $f(\mathbf{n}; \boldsymbol{\nu})$. Then one may maximize the likelihood function based on the contents of the bins (so i labels bins). This is equivalent to maximizing the likelihood ratio $\lambda(\boldsymbol{\theta}) = f(\mathbf{n}; \boldsymbol{\nu}(\boldsymbol{\theta}))/f(\mathbf{n}; \mathbf{n})$, or to minimizing the equivalent quantity $-2 \ln \lambda(\boldsymbol{\theta})$. For independent Poisson distributed n_i this is [9]

$$-2 \ln \lambda(\boldsymbol{\theta}) = 2 \sum_{i=1}^N \left[\nu_i(\boldsymbol{\theta}) - n_i + n_i \ln \frac{n_i}{\nu_i(\boldsymbol{\theta})} \right], \quad (36.12)$$

where for bins with $n_i = 0$, the last term in (36.12) is zero. The expression (36.12) without the terms $\nu_i - n_i$ also gives $-2 \ln \lambda(\boldsymbol{\theta})$ for multinomially distributed n_i , *i.e.*, when the total number of entries is regarded as fixed. In the limit of zero bin width, maximizing (36.12) is equivalent to maximizing the unbinned likelihood function (36.8).

A benefit of binning is that it allows for a goodness-of-fit test (see Sec. 36.2.2). Assuming the model is correct, then according to Wilks’ theorem, for sufficiently large ν_i and providing certain regularity conditions are met, the minimum of $-2 \ln \lambda$ as defined by Eq. (36.12) follows a χ^2 distribution (see, *e.g.*, Ref. 3). If there are N bins and m fitted parameters, then the number of degrees of freedom for the χ^2 distribution is $N - m$ if the data are treated as Poisson-distributed, and $N - m - 1$ if the n_i are multinomially distributed.

Suppose the n_i are Poisson-distributed and the overall normalization $\nu_{\text{tot}} = \sum_i \nu_i$ is taken as an adjustable parameter, so that $\nu_i = \nu_{\text{tot}} p_i(\boldsymbol{\theta})$, where the probability to be in the i th bin, $p_i(\boldsymbol{\theta})$, does not depend on ν_{tot} . Then by minimizing Eq. (36.12), one obtains that the area under the fitted function is equal to the sum of the histogram contents, *i.e.*, $\sum_i \nu_i = \sum_i n_i$. This is not the case for parameter estimation methods based on a least-squares procedure with traditional weights (see, *e.g.*, Ref. 8).

36.1.3. The method of least squares :

The *method of least squares* (LS) coincides with the method of maximum likelihood in the following special case. Consider a set of N independent measurements y_i at known points x_i . The measurement y_i is assumed to be Gaussian distributed with mean $F(x_i; \boldsymbol{\theta})$ and known variance σ_i^2 . The goal is to construct estimators for the unknown parameters $\boldsymbol{\theta}$. The likelihood function contains the sum of squares

$$\chi^2(\boldsymbol{\theta}) = -2 \ln L(\boldsymbol{\theta}) + \text{constant} = \sum_{i=1}^N \frac{(y_i - F(x_i; \boldsymbol{\theta}))^2}{\sigma_i^2}. \quad (36.13)$$

The set of parameters $\boldsymbol{\theta}$ which maximize L is the same as those which minimize χ^2 .

The minimum of Equation (36.13) defines the least-squares estimators $\hat{\boldsymbol{\theta}}$ for the more general case where the y_i are not Gaussian distributed as long as they are independent. If they are not independent but rather have a covariance matrix $V_{ij} = \text{cov}[y_i, y_j]$, then the LS estimators are determined by the minimum of

$$\chi^2(\boldsymbol{\theta}) = (\mathbf{y} - \mathbf{F}(\boldsymbol{\theta}))^T V^{-1} (\mathbf{y} - \mathbf{F}(\boldsymbol{\theta})), \quad (36.14)$$

where $\mathbf{y} = (y_1, \dots, y_N)$ is the vector of measurements, $\mathbf{F}(\boldsymbol{\theta})$ is the corresponding vector of predicted values (understood as a column vector in (36.14)), and the superscript T denotes the transposed (*i.e.*, row) vector.

In many practical cases, one further restricts the problem to the situation where $F(x_i; \boldsymbol{\theta})$ is a linear function of the parameters, *i.e.*,

$$F(x_i; \boldsymbol{\theta}) = \sum_{j=1}^m \theta_j h_j(x_i). \tag{36.15}$$

Here the $h_j(x)$ are m linearly independent functions, *e.g.*, $1, x, x^2, \dots, x^{m-1}$, or Legendre polynomials. We require $m < N$ and at least m of the x_i must be distinct.

Minimizing χ^2 in this case with m parameters reduces to solving a system of m linear equations. Defining $H_{ij} = h_j(x_i)$ and minimizing χ^2 by setting its derivatives with respect to the θ_i equal to zero gives the LS estimators,

$$\hat{\boldsymbol{\theta}} = (H^T V^{-1} H)^{-1} H^T V^{-1} \mathbf{y} \equiv D \mathbf{y}. \tag{36.16}$$

The covariance matrix for the estimators $U_{ij} = \text{cov}[\hat{\theta}_i, \hat{\theta}_j]$ is given by

$$U = D V D^T = (H^T V^{-1} H)^{-1}, \tag{36.17}$$

or equivalently, its inverse U^{-1} can be found from

$$(U^{-1})_{ij} = \frac{1}{2} \frac{\partial^2 \chi^2}{\partial \theta_i \partial \theta_j} \Big|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}} = \sum_{k,l=1}^N h_i(x_k) (V^{-1})_{kl} h_j(x_l). \tag{36.18}$$

The LS estimators can also be found from the expression

$$\hat{\boldsymbol{\theta}} = U \mathbf{g}, \tag{36.19}$$

where the vector \mathbf{g} is defined by

$$g_i = \sum_{j,k=1}^N y_j h_i(x_k) (V^{-1})_{jk}. \tag{36.20}$$

For the case of uncorrelated y_i , for example, one can use (36.19) with

$$(U^{-1})_{ij} = \sum_{k=1}^N \frac{h_i(x_k) h_j(x_k)}{\sigma_k^2}, \tag{36.21}$$

$$g_i = \sum_{k=1}^N \frac{y_k h_i(x_k)}{\sigma_k^2}. \tag{36.22}$$

Expanding $\chi^2(\boldsymbol{\theta})$ about $\hat{\boldsymbol{\theta}}$, one finds that the contour in parameter space defined by

$$\chi^2(\boldsymbol{\theta}) = \chi^2(\hat{\boldsymbol{\theta}}) + 1 = \chi_{\min}^2 + 1 \tag{36.23}$$

has tangent planes located at approximately plus-or-minus-one standard deviation $\sigma_{\hat{\theta}}$ from the LS estimates $\boldsymbol{\theta}$.

In constructing the quantity $\chi^2(\boldsymbol{\theta})$, one requires the variances or, in the case of correlated measurements, the covariance matrix. Often these quantities are not known *a priori* and must be estimated from the data; an important example is where the measured value y_i represents a counted number of events in the bin of a histogram. If, for example, y_i represents a Poisson variable, for which the variance is equal to the mean, then one can either estimate the variance from the predicted value, $F(x_i; \boldsymbol{\theta})$, or from the observed number itself, y_i . In the first option, the variances become functions of the fitted parameters, which may lead to calculational difficulties. The second option can be undefined if y_i is zero, and in both cases for small y_i , the variance will be poorly estimated. In either case, one should constrain the normalization of the fitted curve to the correct value, *i.e.*, one should determine the area under the fitted curve directly from the number of entries in the histogram (see Ref. 8, Section 7.4). A further alternative is to use the method of maximum likelihood; for binned data this can be done by minimizing Eq. (36.12)

As the minimum value of the χ^2 represents the level of agreement between the measurements and the fitted function, it can be used for assessing the goodness-of-fit; this is discussed further in Section 36.2.2.

36.1.4. The Bayesian approach :

In the frequentist methods discussed above, probability is associated only with data, not with the value of a parameter. This is no longer the case in Bayesian statistics, however, which we introduce in this section. Bayesian methods are considered further in Sec. 36.3.1 for interval estimation and in Sec. 36.2.3 for model selection. For general introductions to Bayesian statistics see, *e.g.*, Refs. [20–23].

Suppose the outcome of an experiment is characterized by a vector of data \mathbf{x} , whose probability distribution depends on an unknown parameter (or parameters) $\boldsymbol{\theta}$ that we wish to determine. In Bayesian statistics, all knowledge about $\boldsymbol{\theta}$ is summarized by the posterior p.d.f. $p(\boldsymbol{\theta}|\mathbf{x})$, whose integral over any given region gives the degree of belief for $\boldsymbol{\theta}$ to take on values in that region, given the data \mathbf{x} . It is obtained by using Bayes' theorem,

$$p(\boldsymbol{\theta}|\mathbf{x}) = \frac{L(\mathbf{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})}{\int L(\mathbf{x}|\boldsymbol{\theta}')\pi(\boldsymbol{\theta}') d\boldsymbol{\theta}'}, \tag{36.24}$$

where $L(\mathbf{x}|\boldsymbol{\theta})$ is the likelihood function, *i.e.*, the joint p.d.f. for the data viewed as a function of $\boldsymbol{\theta}$, evaluated with the data actually obtained in the experiment, and $\pi(\boldsymbol{\theta})$ is the prior p.d.f. for $\boldsymbol{\theta}$. Note that the denominator in Eq. (36.24) serves to normalize the posterior p.d.f. to unity.

As it can be difficult to report the full posterior p.d.f. $p(\boldsymbol{\theta}|\mathbf{x})$, one would usually summarize it with statistics such as the mean (or median), and covariance matrix. In addition one may construct intervals with a given probability content, as is discussed in Sec. 36.3.1 on Bayesian interval estimation.

36.1.4.1. Priors:

Bayesian statistics supplies no unique rule for determining the prior $\pi(\boldsymbol{\theta})$; this reflects the experimenter's subjective degree of belief (or state of knowledge) about $\boldsymbol{\theta}$ before the measurement was carried out. For the result to be of value to the broader community, whose members may not share these beliefs, it is important to carry out a sensitivity analysis, that is, to show how the result changes under a reasonable variation of the prior probabilities.

One might like to construct $\pi(\boldsymbol{\theta})$ to represent complete ignorance about the parameters by setting it equal to a constant. A problem here is that if the prior p.d.f. is flat in $\boldsymbol{\theta}$, then it is not flat for a nonlinear function of $\boldsymbol{\theta}$, and so a different parametrization of the problem would lead in general to a non-equivalent posterior p.d.f.

For the special case of a constant prior, one can see from Bayes' theorem (36.24) that the posterior is proportional to the likelihood, and therefore the mode (peak position) of the posterior is equal to the ML estimator. The posterior mode, however, will change in general upon a transformation of parameter. A summary statistic other than the mode may be used as the Bayesian estimator, such as the median, which is invariant under parameter transformation. But this will not in general coincide with the ML estimator.

The difficult and subjective nature of encoding personal knowledge into priors has led to what is called *objective Bayesian statistics*, where prior probabilities are based not on an actual degree of belief but rather derived from formal rules. These give, for example, priors which are invariant under a transformation of parameters or which result in a maximum gain in information for a given set of measurements. For an extensive review see, *e.g.*, Ref. 24.

Objective priors do not in general reflect degree of belief, but they could in some cases be taken as possible, although perhaps extreme, subjective priors. The posterior probabilities as well therefore do not necessarily reflect a degree of belief. However one may regard investigating a variety of objective priors to be an important part of the sensitivity analysis. Furthermore, use of objective priors with Bayes' theorem can be viewed as a recipe for producing estimators or intervals which have desirable frequentist properties.

An important procedure for deriving objective priors is due to Jeffreys. According to *Jeffreys' rule* one takes the prior as

$$\pi(\boldsymbol{\theta}) \propto \sqrt{\det(I(\boldsymbol{\theta}))}, \tag{36.25}$$

where

$$I_{ij}(\boldsymbol{\theta}) = -E \left[\frac{\partial^2 \ln L(\mathbf{x}|\boldsymbol{\theta})}{\partial \theta_i \partial \theta_j} \right] = - \int \frac{\partial^2 \ln L(\mathbf{x}|\boldsymbol{\theta})}{\partial \theta_i \partial \theta_j} L(\mathbf{x}|\boldsymbol{\theta}) d\mathbf{x} \quad (36.26)$$

is the *Fisher information matrix*. One can show that the Jeffreys prior leads to inference that is invariant under a transformation of parameters. One should note that the Jeffreys prior depends on the likelihood function, and thus contains information about the measurement model itself, which goes beyond one's degree of belief about the value of a parameter. As examples, the Jeffreys prior for the mean μ of a Gaussian distribution is a constant, and for the mean of a Poisson distribution one finds $\pi(\mu) \propto 1/\sqrt{\mu}$.

Neither the constant nor $1/\sqrt{\mu}$ priors can be normalized to unit area and are said to be *improper*. This can be allowed because the prior always appears multiplied by the likelihood function, and if the likelihood falls off sufficiently quickly then one may have a normalizable posterior density.

An important type of objective prior is the reference prior due to Bernardo and Berger [25]. To find the reference prior for a given problem one considers the Kullback-Leibler divergence $D_n[\pi, p]$ of the posterior $p(\boldsymbol{\theta}|\mathbf{x})$ relative to a prior $\pi(\boldsymbol{\theta})$, obtained from a set of data $\mathbf{x} = (x_1, \dots, x_n)$, which are assumed to consist of n independent and identically distributed values of x :

$$D_n[\pi, p] = \int p(\boldsymbol{\theta}|\mathbf{x}) \ln \frac{p(\boldsymbol{\theta}|\mathbf{x})}{\pi(\boldsymbol{\theta})} d\boldsymbol{\theta}. \quad (36.27)$$

This is effectively a measure of the gain in information provided by the data. The reference prior is chosen so that the expectation value of this information gain is maximized for the limiting case of $n \rightarrow \infty$, where the expectation is computed with respect to the marginal distribution of the data,

$$p(\mathbf{x}) = \int L(\mathbf{x}|\boldsymbol{\theta}) \pi(\boldsymbol{\theta}) d\boldsymbol{\theta}. \quad (36.28)$$

For a single, continuous parameter the reference prior is usually identical to Jeffreys' prior. In the multiparameter case an iterative algorithm exists, which requires sorting the parameters by order of inferential importance. Often the result does not depend on this order, but when it does, this can be part of a robustness analysis. Further discussion and applications to particle physics problems can be found in Ref. 26.

36.1.4.2. Bayesian treatment of nuisance parameters:

Bayesian statistics provides a framework for incorporating systematic uncertainties into a result. Suppose, for example, that a model depends not only on parameters of interest $\boldsymbol{\theta}$, but on *nuisance parameters* $\boldsymbol{\nu}$, whose values are known with some limited accuracy. For a single nuisance parameter ν , for example, one might have a p.d.f. centered about its nominal value with a certain standard deviation σ_ν . Often a Gaussian p.d.f. provides a reasonable model for one's degree of belief about a nuisance parameter; in other cases, more complicated shapes may be appropriate. If, for example, the parameter represents a non-negative quantity then a log-normal or gamma p.d.f. can be a more natural choice than a Gaussian truncated at zero. The likelihood function, prior, and posterior p.d.f.s then all depend on both $\boldsymbol{\theta}$ and $\boldsymbol{\nu}$, and are related by Bayes' theorem, as usual. One can obtain the posterior p.d.f. for $\boldsymbol{\theta}$ alone by integrating over the nuisance parameters, *i.e.*,

$$p(\boldsymbol{\theta}|\mathbf{x}) = \int p(\boldsymbol{\theta}, \boldsymbol{\nu}|\mathbf{x}) d\boldsymbol{\nu}. \quad (36.29)$$

Such integrals can often not be carried out in closed form, and if the number of nuisance parameters is large, then they can be difficult to compute with standard Monte Carlo methods. *Markov Chain Monte Carlo* (MCMC) is often used for computing integrals of this type (see Sec. 37.5).

If the prior joint p.d.f. for $\boldsymbol{\theta}$ and $\boldsymbol{\nu}$ factorizes, then integrating the posterior p.d.f. over $\boldsymbol{\nu}$ is equivalent to replacing the likelihood function by the *marginal likelihood* (see Ref. 27),

$$L_m(\mathbf{x}|\boldsymbol{\theta}) = \int L(\mathbf{x}|\boldsymbol{\theta}, \boldsymbol{\nu}) \pi(\boldsymbol{\nu}) d\boldsymbol{\nu}. \quad (36.30)$$

The marginal likelihood can also be used together with frequentist methods that employ the likelihood function such as ML estimation of parameters. The results then have a mixed frequentist/Bayesian character, where the systematic uncertainty due to limited knowledge of the nuisance parameters is built in (see Ref. 28). Although this may make it more difficult to disentangle statistical from systematic effects, such a hybrid approach may satisfy the objective of reporting the result in a convenient way. The marginal likelihood may be compared with the profile likelihood, which is discussed in Sec. 36.3.2.3.

36.1.5. Propagation of errors :

Consider a set of n quantities $\boldsymbol{\theta} = (\theta_1, \dots, \theta_n)$ and a set of m functions $\boldsymbol{\eta}(\boldsymbol{\theta}) = (\eta_1(\boldsymbol{\theta}), \dots, \eta_m(\boldsymbol{\theta}))$. Suppose we have estimated $\hat{\boldsymbol{\theta}} = (\hat{\theta}_1, \dots, \hat{\theta}_n)$, using, say, maximum-likelihood or least-squares, and we also know or have estimated the covariance matrix $V_{ij} = \text{cov}[\hat{\theta}_i, \hat{\theta}_j]$. The goal of *error propagation* is to determine the covariance matrix for the functions, $U_{ij} = \text{cov}[\hat{\eta}_i, \hat{\eta}_j]$, where $\hat{\boldsymbol{\eta}} = \boldsymbol{\eta}(\hat{\boldsymbol{\theta}})$. In particular, the diagonal elements $U_{ii} = V[\hat{\eta}_i]$ give the variances. The new covariance matrix can be found by expanding the functions $\boldsymbol{\eta}(\boldsymbol{\theta})$ about the estimates $\hat{\boldsymbol{\theta}}$ to first order in a Taylor series. Using this one finds

$$U_{ij} \approx \sum_{k,l} \frac{\partial \eta_i}{\partial \theta_k} \frac{\partial \eta_j}{\partial \theta_l} \Big|_{\hat{\boldsymbol{\theta}}} V_{kl}. \quad (36.31)$$

This can be written in matrix notation as $U \approx AVA^T$ where the matrix of derivatives A is

$$A_{ij} = \frac{\partial \eta_i}{\partial \theta_j} \Big|_{\hat{\boldsymbol{\theta}}}, \quad (36.32)$$

and A^T is its transpose. The approximation is exact if $\boldsymbol{\eta}(\boldsymbol{\theta})$ is linear (it holds, for example, in equation (36.17)). If this is not the case, the approximation can break down if, for example, $\boldsymbol{\eta}(\boldsymbol{\theta})$ is significantly nonlinear close to $\hat{\boldsymbol{\theta}}$ in a region of a size comparable to the standard deviations of $\hat{\boldsymbol{\theta}}$.

36.2. Statistical tests

In addition to estimating parameters, one often wants to assess the validity of certain statements concerning the data's underlying distribution. Frequentist *hypothesis tests*, described in Sec. 36.2.1, provide a rule for accepting or rejecting hypotheses depending on the outcome of a measurement. In *significance tests*, covered in Sec. 36.2.2, one gives the probability to obtain a level of incompatibility with a certain hypothesis that is greater than or equal to the level observed with the actual data. In the Bayesian approach, the corresponding procedure is based fundamentally on the posterior probabilities of the competing hypotheses. In Sec. 36.2.3 we describe a related construct called the Bayes factor, which can be used to quantify the degree to which the data prefer one or another hypothesis.

36.2.1. Hypothesis tests :

Consider an experiment whose outcome is characterized by a vector of data \mathbf{x} . A *hypothesis* is a statement about the distribution of \mathbf{x} . It could, for example, define completely the p.d.f. for the data (a simple hypothesis), or it could specify only the functional form of the p.d.f., with the values of one or more parameters left open (a composite hypothesis).

A *statistical test* is a rule that states for which values of \mathbf{x} a given hypothesis (often called the null hypothesis, H_0) should be rejected. This is done by defining a region of \mathbf{x} -space called the critical region, w , such that there is no more than a specified probability under H_0 , α , called the *size* or *significance level* of the test, to find $\mathbf{x} \in w$. If the data are discrete, it may not be possible to find a critical region with exact probability content α , and thus we require $P(\mathbf{x} \in w | H_0) \leq \alpha$. If the data are observed in the critical region, H_0 is rejected.

There are in general a large (often infinite) number of regions of the data space that have probability content α and thus qualify as possible critical regions. To choose one of them one should take into account the probabilities for the data predicted by some alternative hypothesis (or set of alternatives) H_1 . Rejecting H_0 if it is true is

called a *type-I error*, and occurs by construction with probability no greater than α . Not rejecting H_0 if an alternative H_1 is true is called a *type-II error*, and for a given test this will have a certain probability β . The quantity $1 - \beta$ is called the *power* of the test of H_0 with respect to the alternative H_1 . A strategy for defining the critical region can therefore be to maximize the power with respect to some alternative (or alternatives) given a fixed size α .

In high-energy physics, the components of \mathbf{x} might represent the measured properties of candidate events, and the critical region is defined by the cuts that one imposes in order to reject background and thus accept events likely to be of a certain desired type. Here H_0 could represent the background hypothesis and the alternative H_1 could represent the sought after signal. In other cases, H_0 could be the hypothesis that an entire event sample consists of background events only, and the alternative H_1 may represent the hypothesis of a mixture of background and signal.

Often rather than using the full set of quantities \mathbf{x} , it is convenient to define a *test statistic*, t , which can be a single number, or in any case a vector with fewer components than \mathbf{x} . Each hypothesis for the distribution of \mathbf{x} will determine a distribution for t , and the acceptance region in \mathbf{x} -space will correspond to a specific range of values of t .

To maximize the power of a test of H_0 with respect to the alternative H_1 , the *Neyman–Pearson lemma* states that the critical region w should be chosen such that for all data values \mathbf{x} inside w , the ratio

$$\lambda(\mathbf{x}) = \frac{f(\mathbf{x}|H_1)}{f(\mathbf{x}|H_0)}, \quad (36.33)$$

is greater than a given constant, the value of which is determined by the size of the test α . Here H_0 and H_1 must be simple hypotheses, i.e., they should not contain undetermined parameters.

The lemma is equivalent to the statement that (36.33) represents the optimal test statistic where the critical region is defined by a single cut on λ . This test will lead to the maximum power (e.g., probability to reject the background hypothesis if the signal hypothesis is true) for a given probability α to reject the background hypothesis if it is in fact true. It can be difficult in practice, however, to determine $\lambda(\mathbf{x})$, since this requires knowledge of the joint p.d.f.s $f(\mathbf{x}|H_0)$ and $f(\mathbf{x}|H_1)$.

In the usual case where the likelihood ratio (36.33) cannot be used explicitly, there exist a variety of other multivariate classifiers that effectively separate different types of events. Methods often used in HEP include *neural networks* or *Fisher discriminants* (see Ref. 10). Recently, further classification methods from machine-learning have been applied in HEP analyses; these include *probability density estimation (PDE)* techniques, *kernel-based PDE (KDE or Parzen window)*, *support vector machines*, and *decision trees*. Techniques such as “boosting” and “bagging” can be applied to combine a number of classifiers into a stronger one with greater stability with respect to fluctuations in the training data. Descriptions of these methods can be found in [11–13], and *Proceedings of the PHYSTAT* conference series [14]. Software for HEP includes the *TMVA* [15] and *StatPatternRecognition* [16] packages.

36.2.2. Significance tests :

Often one wants to quantify the level of agreement between the data and a hypothesis without explicit reference to alternative hypotheses. This can be done by defining a statistic t , which is a function of the data whose value reflects in some way the level of agreement between the data and the hypothesis. The analyst must decide what values of the statistic correspond to better or worse levels of agreement with the hypothesis in question; for many goodness-of-fit statistics, there is an obvious choice.

The hypothesis in question, say, H_0 , will determine the p.d.f. $g(t|H_0)$ for the statistic. The significance of a discrepancy between the data and what one expects under the assumption of H_0 is quantified by giving the p -value, defined as the probability to find t in the region of equal or lesser compatibility with H_0 than the level of compatibility observed with the actual data. For example, if t is defined such that large values correspond to poor agreement with the hypothesis, then

the p -value would be

$$p = \int_{t_{\text{obs}}}^{\infty} g(t|H_0) dt, \quad (36.34)$$

where t_{obs} is the value of the statistic obtained in the actual experiment.

The p -value should not be confused with the size (significance level) of a test, or the confidence level of a confidence interval (Section 36.3), both of which are pre-specified constants. We may formulate a hypothesis test, however, by defining the critical region to correspond to the data outcomes that give the lowest p -values, so that finding $p < \alpha$ implies that the data outcome was in the critical region. When constructing a p -value, one generally takes the region of data space deemed to have lower compatibility with the model being tested to have higher compatibility with a given alternative, and thus the corresponding test will have a high power with respect to this alternative.

The p -value is a function of the data, and is therefore itself a random variable. If the hypothesis used to compute the p -value is true, then for continuous data, p will be uniformly distributed between zero and one. Note that the p -value is not the probability for the hypothesis; in frequentist statistics, this is not defined. Rather, the p -value is the probability, under the assumption of a hypothesis H_0 , of obtaining data at least as incompatible with H_0 as the data actually observed.

When searching for a new phenomenon, one tries to reject the hypothesis H_0 that the data are consistent with known, e.g., Standard Model processes. If the p -value of H_0 is sufficiently low, then one is willing to accept that some alternative hypothesis is true. Often one converts the p -value into an equivalent significance Z , defined so that a Z standard deviation upward fluctuation of a Gaussian random variable would have an upper tail area equal to p , i.e.,

$$Z = \Phi^{-1}(1 - p). \quad (36.35)$$

Here Φ is the cumulative distribution of the Standard Gaussian, and Φ^{-1} is its inverse (quantile) function. Often in HEP, the level of significance where an effect is said to qualify as a discovery is $Z = 5$, i.e., a 5σ effect, corresponding to a p -value of 2.87×10^{-7} . One’s actual degree of belief that a new process is present, however, will depend in general on other factors as well, such as the plausibility of the new signal hypothesis and the degree to which it can describe the data, one’s confidence in the model that led to the observed p -value, and possible corrections for multiple observations out of which one focuses on the smallest p -value obtained (the “look-elsewhere effect”). For a review of how to incorporate systematic uncertainties into p -values see, e.g., Ref. 17; a computationally fast method that provides an approximate correction for the look-elsewhere effect is described in Ref. 18.

When estimating parameters using the method of least squares, one obtains the minimum value of the quantity χ^2 (36.13). This statistic can be used to test the *goodness-of-fit*, i.e., the test provides a measure of the significance of a discrepancy between the data and the hypothesized functional form used in the fit. It may also happen that no parameters are estimated from the data, but that one simply wants to compare a histogram, e.g., a vector of Poisson distributed numbers $\mathbf{n} = (n_1, \dots, n_N)$, with a hypothesis for their expectation values $\nu_i = E[n_i]$. As the distribution is Poisson with variances $\sigma_i^2 = \nu_i$, the χ^2 (36.13) becomes *Pearson’s χ^2 statistic*,

$$\chi^2 = \sum_{i=1}^N \frac{(n_i - \nu_i)^2}{\nu_i}. \quad (36.36)$$

If the hypothesis $\boldsymbol{\nu} = (\nu_1, \dots, \nu_N)$ is correct, and if the expected values ν_i in (36.36) are sufficiently large (or equivalently, if the measurements n_i can be treated as following a Gaussian distribution), then the χ^2 statistic will follow the χ^2 p.d.f. with the number of degrees of freedom equal to the number of measurements N minus the number of fitted parameters.

Figure 36.1: One minus the χ^2 cumulative distribution, $1 - F(\chi^2; n)$, for n degrees of freedom. This gives the p -value for the χ^2 goodness-of-fit test as well as one minus the coverage probability for confidence regions (see Sec. 36.3.2.4).

Alternatively, one may fit parameters and evaluate goodness-of-fit by minimizing $-2 \ln \lambda$ from Eq. (36.12). One finds that the distribution of this statistic approaches the asymptotic limit faster than does Pearson's χ^2 , and thus computing the p -value with the χ^2 p.d.f. will in general be better justified (see Ref. 9 and references therein).

Assuming the goodness-of-fit statistic follows a χ^2 p.d.f., the p -value for the hypothesis is then

$$p = \int_{\chi^2}^{\infty} f(z; n_d) dz, \quad (36.37)$$

where $f(z; n_d)$ is the χ^2 p.d.f. and n_d is the appropriate number of degrees of freedom. Values can be obtained from Fig. 36.1 or from the ROOT function `TMath::Prob`. If the conditions for using the χ^2 p.d.f. do not hold, the statistic can still be defined as before, but its p.d.f. must be determined by other means in order to obtain the p -value, e.g., using a Monte Carlo calculation.

Since the mean of the χ^2 distribution is equal to n_d , one expects in a “reasonable” experiment to obtain $\chi^2 \approx n_d$. Hence the quantity χ^2/n_d is sometimes reported. Since the p.d.f. of χ^2/n_d depends on n_d , however, one must report n_d as well if one wishes to determine the p -value. The p -values obtained for different values of χ^2/n_d are shown in Fig. 36.2.

If one finds a χ^2 value much greater than n_d , and a correspondingly small p -value, one may be tempted to expect a high degree of uncertainty for any fitted parameters. Poor goodness-of-fit, however, does not mean that one will have large statistical errors for parameter estimates. If, for example, the error bars (or covariance matrix) used in constructing the χ^2 are underestimated, then this will lead to underestimated statistical errors for the fitted parameters. The standard deviations of estimators that one finds from, say, Eq. (36.11) reflect how widely the estimates would be distributed if one were to repeat the measurement many times, assuming that the hypothesis and measurement errors used in the χ^2 are also correct. They do not include the systematic error which may result from an incorrect hypothesis or incorrectly estimated measurement errors in the χ^2 .

36.2.3. Bayesian model selection :

In Bayesian statistics, all of one's knowledge about a model is contained in its posterior probability, which one obtains using Bayes' theorem (36.24). Thus one could reject a hypothesis H if its posterior probability $P(H|\mathbf{x})$ is sufficiently small. The difficulty here is that $P(H|\mathbf{x})$ is proportional to the prior probability $P(H)$, and there will not be a consensus about the prior probabilities for the existence of new phenomena. Nevertheless one can construct a quantity called the Bayes factor (described below), which can be used to quantify the

Figure 36.2: The ‘reduced’ χ^2 , equal to χ^2/n , for n degrees of freedom. The curves show as a function of n the χ^2/n that corresponds to a given p -value.

degree to which the data prefer one hypothesis over another, and is independent of their prior probabilities.

Consider two models (hypotheses), H_i and H_j , described by vectors of parameters θ_i and θ_j , respectively. Some of the components will be common to both models and others may be distinct. The full prior probability for each model can be written in the form

$$\pi(H_i, \theta_i) = P(H_i)\pi(\theta_i|H_i), \quad (36.38)$$

Here $P(H_i)$ is the overall prior probability for H_i , and $\pi(\theta_i|H_i)$ is the normalized p.d.f. of its parameters. For each model, the posterior probability is found using Bayes' theorem,

$$P(H_i|\mathbf{x}) = \frac{\int L(\mathbf{x}|\theta_i, H_i)P(H_i)\pi(\theta_i|H_i) d\theta_i}{P(\mathbf{x})}, \quad (36.39)$$

where the integration is carried out over the internal parameters θ_i of the model. The ratio of posterior probabilities for the models is therefore

$$\frac{P(H_i|\mathbf{x})}{P(H_j|\mathbf{x})} = \frac{\int L(\mathbf{x}|\theta_i, H_i)\pi(\theta_i|H_i) d\theta_i}{\int L(\mathbf{x}|\theta_j, H_j)\pi(\theta_j|H_j) d\theta_j} \frac{P(H_i)}{P(H_j)}. \quad (36.40)$$

The Bayes factor is defined as

$$B_{ij} = \frac{\int L(\mathbf{x}|\theta_i, H_i)\pi(\theta_i|H_i) d\theta_i}{\int L(\mathbf{x}|\theta_j, H_j)\pi(\theta_j|H_j) d\theta_j}. \quad (36.41)$$

This gives what the ratio of posterior probabilities for models i and j would be if the overall prior probabilities for the two models were equal. If the models have no nuisance parameters i.e., no internal parameters described by priors, then the Bayes factor is simply the likelihood ratio. The Bayes factor therefore shows by how much the probability ratio of model i to model j changes in the light of the data, and thus can be viewed as a numerical measure of evidence supplied by the data in favour of one hypothesis over the other.

Although the Bayes factor is by construction independent of the overall prior probabilities $P(H_i)$ and $P(H_j)$, it does require priors for all internal parameters of a model, i.e., one needs the functions $\pi(\theta_i|H_i)$ and $\pi(\theta_j|H_j)$. In a Bayesian analysis where one is only interested in the posterior p.d.f. of a parameter, it may be acceptable to take an unnormalizable function for the prior (an improper prior) as long as the product of likelihood and prior can be normalized. But improper priors are only defined up to an arbitrary multiplicative constant, and so the Bayes factor would depend on this constant. Furthermore, although the range of a constant normalized prior is unimportant for parameter determination (provided it is wider than the likelihood), this is not so for the Bayes factor when such a prior

is used for only one of the hypotheses. So to compute a Bayes factor, all internal parameters must be described by normalized priors that represent meaningful probabilities over the entire range where they are defined.

An exception to this rule may be considered when the identical parameter appears in the models for both numerator and denominator of the Bayes factor. In this case one can argue that the arbitrary constants would cancel. One must exercise some caution, however, as parameters with the same name and physical meaning may still play different roles in the two models.

Both integrals in equation (36.41) are of the form

$$m = \int L(\mathbf{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta}) d\boldsymbol{\theta}, \tag{36.42}$$

which is called the *marginal likelihood* (or in some fields called the *evidence*). A review of Bayes factors including a discussion of computational issues can be found in Ref. 30.

36.3. Intervals and limits

When the goal of an experiment is to determine a parameter θ , the result is usually expressed by quoting, in addition to the point estimate, some sort of interval which reflects the statistical precision of the measurement. In the simplest case, this can be given by the parameter’s estimated value $\hat{\theta}$ plus or minus an estimate of the standard deviation of $\hat{\theta}$, $\sigma_{\hat{\theta}}$. If, however, the p.d.f. of the estimator is not Gaussian or if there are physical boundaries on the possible values of the parameter, then one usually quotes instead an interval according to one of the procedures described below.

In reporting an interval or limit, the experimenter may wish to

- communicate as objectively as possible the result of the experiment;
- provide an interval that is constructed to cover the true value of the parameter with a specified probability;
- provide the information needed by the consumer of the result to draw conclusions about the parameter or to make a particular decision;
- draw conclusions about the parameter that incorporate stated prior beliefs.

With a sufficiently large data sample, the point estimate and standard deviation (or for the multiparameter case, the parameter estimates and covariance matrix) satisfy essentially all of these goals. For finite data samples, no single method for quoting an interval will achieve all of them.

In addition to the goals listed above, the choice of method may be influenced by practical considerations such as ease of producing an interval from the results of several measurements. Of course the experimenter is not restricted to quoting a single interval or limit; one may choose, for example, first to communicate the result with a confidence interval having certain frequentist properties, and then in addition to draw conclusions about a parameter using a judiciously chosen subjective Bayesian prior.

It is recommended, however, that there be a clear separation between these two aspects of reporting a result. In the remainder of this section, we assess the extent to which various types of intervals achieve the goals stated here.

36.3.1. Bayesian intervals :

As described in Sec. 36.1.4, a Bayesian posterior probability may be used to determine regions that will have a given probability of containing the true value of a parameter. In the single parameter case, for example, an interval (called a Bayesian or credible interval) $[\theta_{lo}, \theta_{up}]$ can be determined which contains a given fraction $1 - \alpha$ of the posterior probability, *i.e.*,

$$1 - \alpha = \int_{\theta_{lo}}^{\theta_{up}} p(\theta|\mathbf{x}) d\theta. \tag{36.43}$$

Sometimes an upper or lower limit is desired, *i.e.*, θ_{lo} or θ_{up} can be set to a physical boundary or to plus or minus infinity. In other cases, one

might choose θ_{lo} and θ_{up} such that $p(\theta|\mathbf{x})$ is higher everywhere inside the interval than outside; these are called *highest posterior density* (HPD) intervals. Note that HPD intervals are not invariant under a nonlinear transformation of the parameter.

If a parameter is constrained to be non-negative, then the prior p.d.f. can simply be set to zero for negative values. An important example is the case of a Poisson variable n , which counts signal events with unknown mean s , as well as background with mean b , assumed known. For the signal mean s , one often uses the prior

$$\pi(s) = \begin{cases} 0 & s < 0 \\ 1 & s \geq 0 \end{cases}. \tag{36.44}$$

This prior is regarded as providing an interval whose frequentist properties can be studied, rather than as representing a degree of belief. In the absence of a clear discovery, (*e.g.*, if $n = 0$ or if in any case n is compatible with the expected background), one usually wishes to place an upper limit on s (see, however, Sec. 36.3.2.6 on “flip-flopping” concerning frequentist coverage). Using the likelihood function for Poisson distributed n ,

$$L(n|s) = \frac{(s + b)^n}{n!} e^{-(s+b)}, \tag{36.45}$$

along with the prior (36.44) in (36.24) gives the posterior density for s . An upper limit s_{up} at confidence level (or here, rather, credibility level) $1 - \alpha$ can be obtained by requiring

$$1 - \alpha = \int_{-\infty}^{s_{up}} p(s|n) ds = \frac{\int_{-\infty}^{s_{up}} L(n|s) \pi(s) ds}{\int_{-\infty}^{\infty} L(n|s) \pi(s) ds}, \tag{36.46}$$

where the lower limit of integration is effectively zero because of the cut-off in $\pi(s)$. By relating the integrals in Eq. (36.46) to incomplete gamma functions, the equation reduces to

$$\alpha = e^{-s_{up}} \frac{\sum_{m=0}^n (s_{up} + b)^m / m!}{\sum_{m=0}^n b^m / m!}. \tag{36.47}$$

This must be solved numerically for the limit s_{up} . For the special case of $b = 0$, the sums can be related to the quantile $F_{\chi^2}^{-1}$ of the χ^2 distribution (inverse of the cumulative distribution) to give

$$s_{up} = \frac{1}{2} F_{\chi^2}^{-1}(1 - \alpha; n_d), \tag{36.48}$$

where the number of degrees of freedom is $n_d = 2(n + 1)$. The quantile of the χ^2 distribution can be obtained using the ROOT function `TMath::ChisquareQuantile`. It so happens that for the case of $b = 0$, the upper limits from Eq. (36.48) coincide numerically with the values of the frequentist upper limits discussed in Section 36.3.2.5. Values for $1 - \alpha = 0.9$ and 0.95 are given by the values ν_{up} in Table 36.3. The frequentist properties of confidence intervals for the Poisson mean in this way are discussed in Refs. [2] and [19].

As in any Bayesian analysis, it is important to show how the result would change if one uses different prior probabilities. For example, one could consider the Jeffreys prior as described in Sec. 36.1.4. For this problem one finds the Jeffreys prior $\pi(s) \propto 1/\sqrt{s + b}$ for $s \geq 0$ and zero otherwise. As with the constant prior, one would not regard this as representing one’s prior beliefs about s , both because it is improper and also as it depends on b . Rather it is used with Bayes’ theorem to produce an interval whose frequentist properties can be studied.

36.3.2. Frequentist confidence intervals :

The unqualified phrase “confidence intervals” refers to frequentist intervals obtained with a procedure due to Neyman [29], described below. These are intervals (or in the multiparameter case, regions) constructed so as to include the true value of the parameter with a probability greater than or equal to a specified level, called the *coverage probability*. In this section, we discuss several techniques for producing intervals that have, at least approximately, this property.

36.3.2.1. The Neyman construction for confidence intervals:

Consider a p.d.f. $f(x; \theta)$ where x represents the outcome of the experiment and θ is the unknown parameter for which we want to construct a confidence interval. The variable x could (and often does) represent an estimator for θ . Using $f(x; \theta)$, we can find for a pre-specified probability $1 - \alpha$, and for every value of θ , a set of values $x_1(\theta, \alpha)$ and $x_2(\theta, \alpha)$ such that

$$P(x_1 < x < x_2; \theta) = 1 - \alpha = \int_{x_1}^{x_2} f(x; \theta) dx . \quad (36.49)$$

This is illustrated in Fig. 36.3: a horizontal line segment $[x_1(\theta, \alpha), x_2(\theta, \alpha)]$ is drawn for representative values of θ . The union of such intervals for all values of θ , designated in the figure as $D(\alpha)$, is known as the *confidence belt*. Typically the curves $x_1(\theta, \alpha)$ and $x_2(\theta, \alpha)$ are monotonic functions of θ , which we assume for this discussion.

Figure 36.3: Construction of the confidence belt (see text).

Upon performing an experiment to measure x and obtaining a value x_0 , one draws a vertical line through x_0 . The confidence interval for θ is the set of all values of θ for which the corresponding line segment $[x_1(\theta, \alpha), x_2(\theta, \alpha)]$ is intercepted by this vertical line. Such confidence intervals are said to have a *confidence level* (CL) equal to $1 - \alpha$.

Now suppose that the true value of θ is θ_0 , indicated in the figure. We see from the figure that θ_0 lies between $\theta_1(x)$ and $\theta_2(x)$ if and only if x lies between $x_1(\theta_0)$ and $x_2(\theta_0)$. The two events thus have the same probability, and since this is true for any value θ_0 , we can drop the subscript 0 and obtain

$$1 - \alpha = P(x_1(\theta) < x < x_2(\theta)) = P(\theta_2(x) < \theta < \theta_1(x)) . \quad (36.50)$$

In this probability statement, $\theta_1(x)$ and $\theta_2(x)$, *i.e.*, the endpoints of the interval, are the random variables and θ is an unknown constant. If the experiment were to be repeated a large number of times, the interval $[\theta_1, \theta_2]$ would vary, covering the fixed value θ in a fraction $1 - \alpha$ of the experiments.

The condition of coverage in Eq. (36.49) does not determine x_1 and x_2 uniquely, and additional criteria are needed. One possibility is to choose *central intervals* such that the probabilities excluded below x_1 and above x_2 are each $\alpha/2$. In other cases, one may want to report only an upper or lower limit, in which case the probability excluded below x_1 or above x_2 can be set to zero. Another principle based on *likelihood ratio ordering* for determining which values of x should be included in the confidence belt is discussed below.

When the observed random variable x is continuous, the coverage probability obtained with the Neyman construction is $1 - \alpha$, regardless of the true value of the parameter. If x is discrete, however, it is not possible to find segments $[x_1(\theta, \alpha), x_2(\theta, \alpha)]$ that satisfy Eq. (36.49) exactly for all values of θ . By convention, one constructs the confidence belt requiring the probability $P(x_1 < x < x_2)$ to be *greater than or equal to* $1 - \alpha$. This gives confidence intervals that include the true parameter with a probability greater than or equal to $1 - \alpha$.

An equivalent method of constructing confidence intervals is to consider a test (see Sec. 36.2) of the hypothesis that the parameter's true value is θ (assume one constructs a test for all physical values of θ). One then excludes all values of θ where the hypothesis would be rejected at a significance level less than α . The remaining values constitute the confidence interval at confidence level $1 - \alpha$.

In this procedure, one is still free to choose the test to be used; this corresponds to the freedom in the Neyman construction as to which values of the data are included in the confidence belt. One possibility is to use a test statistic based on the *likelihood ratio*,

$$\lambda = \frac{f(x; \theta)}{f(x; \hat{\theta})} , \quad (36.51)$$

where $\hat{\theta}$ is the value of the parameter which, out of all allowed values, maximizes $f(x; \theta)$. This results in the intervals described in Ref. 31 by Feldman and Cousins. The same intervals can be obtained from the Neyman construction described above by including in the confidence belt those values of x which give the greatest values of λ .

36.3.2.2. Parameter exclusion in cases of low sensitivity:

An important example of a statistical test arises in the search for a new signal process. Suppose the parameter μ is defined such that it is proportional to the signal cross section. A statistical test may be carried out for hypothesized values of μ , which may be done by computing a p -value, p_μ , for each hypothesized μ . Those values not rejected in a test of size α , *i.e.*, for which one does not find $p_\mu < \alpha$, constitute a confidence interval with confidence level $1 - \alpha$.

In general one will find that for some regions in the parameter space of the signal model, the predictions for data are almost indistinguishable from those of the background-only model. This corresponds to the case where μ is very small, as would occur, *e.g.*, if one searches for a Higgs boson with a mass so high that its production rate in a given experiment is negligible. That is, one has essentially no experimental sensitivity to such a model.

One would prefer that if the sensitivity to a model (or a point in a model's parameter space) is very low, then it should not be excluded. Even if the outcomes predicted with or without signal are identical, however, the probability to reject the signal model will equal α , the type-I error rate. As one often takes α to be 5%, this would mean that in a large number of searches covering a broad range of a signal model's parameter space, there would inevitably be excluded regions in which the experimental sensitivity is very small, and thus one may question whether it is justified to regard such parameter values as disfavored.

Exclusion of models to which one has little or no sensitivity occurs, for example, if the data fluctuate very low relative to the expectation of the background-only hypothesis. In this case the resulting upper limit on the predicted rate (cross section) of a signal model may be anomalously low. As a means of controlling this effect one often determines the mean or median limit under assumption of the background-only hypothesis using a simplified Monte Carlo simulation of the experiment. An upper limit found significantly below the background-only expectation may indicate a strong downward fluctuation of the data, or perhaps as well an incorrect estimate of the background rate.

The CL_s method aims to mitigate the problem of excluding models to which one is not sensitive by effectively penalizing the p -value of a tested parameter by an amount that increases with decreasing sensitivity [32,33]. The procedure is based on a statistic called CL_s, which is defined as

$$CL_s = \frac{p_\mu}{1 - p_0} , \quad (36.52)$$

where p_0 is the p -value of the background-only hypothesis. In the usual formulation of the method, the p -values for μ and 0 are defined using a single test statistic, and the definition of CL_s above assumes this statistic is continuous; more details can be found in Refs. [32,33].

A point in a model's parameter space is regarded as excluded if one finds $CL_s < \alpha$. As the denominator in Eq. (36.52) is always less than or equal to unity, the exclusion criterion based on CL_s

is more stringent than the usual requirement $p_\mu < \alpha$. In this sense the CL_s procedure is conservative, and the coverage probability of the corresponding intervals will exceed the nominal confidence level $1 - \alpha$. If the experimental sensitivity to a given value of μ is very low, then one finds that as p_μ decreases, so does the denominator $1 - p_0$, and thus the condition $CL_s < \alpha$ is effectively prevented from being satisfied. In this way the exclusion of parameters in the case of low sensitivity is suppressed.

The CL_s procedure has the attractive feature that the resulting intervals coincide with those obtained from the Bayesian method in two important cases: the mean value of a Poisson or Gaussian distributed measurement with a constant prior. The CL_s intervals overcover for all values of the parameter μ , however, by an amount that depends on μ .

The problem of excluding parameter values to which one has little sensitivity is particularly acute when one wants to set a one-sided limit, *e.g.*, an upper limit on a cross section. Here one tests a value of a rate parameter μ against the alternative of a lower rate, and therefore the critical region of the test is taken to correspond to data outcomes with a low event yield. If the number of events found in the search region fluctuates low enough, however, it can happen that all physically meaningful signal parameter values, including those to which one has very little sensitivity, are rejected by the test. Another solution to the problem, therefore, is to replace the one-sided test by one based on the likelihood ratio, where the critical region is not restricted to low rates. This is the approach followed in the Feldman-Cousins procedure described above. Further properties of Feldman-Cousins intervals are discussed below in Section 36.3.2.6.

36.3.2.3. Profile likelihood and treatment of nuisance parameters:

As mentioned in Section 36.3.1, one may have a model containing parameters that must be determined from data, but which are not of any interest in the final result (nuisance parameters). Suppose the likelihood $L(\theta, \nu)$ depends on parameters of interest θ and nuisance parameters ν . The nuisance parameters can be effectively removed from the problem by constructing the *profile likelihood*, defined by

$$L_p(\theta) = L(\theta, \hat{\nu}(\theta)), \tag{36.53}$$

where $\hat{\nu}(\theta)$ is given by the ν that maximizes the likelihood for fixed θ . The profile likelihood may then be used to construct tests of intervals for the parameters of interest. This is in contrast to the marginal likelihood (36.30) used in the Bayesian approach. For example, one may construct the profile likelihood ratio,

$$\lambda_p(\theta) = \frac{L_p(\theta)}{L_p(\hat{\theta}, \hat{\nu})}, \tag{36.54}$$

where $\hat{\theta}$ and $\hat{\nu}$ are the ML estimators. The ratio λ_p can be used in place of the likelihood ratio (36.51) for inference about θ . The resulting intervals for the parameters of interest are not guaranteed to have the exact coverage probability for all values of the nuisance parameters, but in cases of practical interest the approximation is found to be very good. Further discussion on use of the profile likelihood can be found in, *e.g.*, Refs. [37–39] and other contributions to the PHYSTAT conferences [14].

36.3.2.4. Gaussian distributed measurements:

An important example of constructing a confidence interval is when the data consists of a single random variable x that follows a Gaussian distribution; this is often the case when x represents an estimator for a parameter and one has a sufficiently large data sample. If there is more than one parameter being estimated, the multivariate Gaussian is used. For the univariate case with known σ ,

$$1 - \alpha = \frac{1}{\sqrt{2\pi}\sigma} \int_{\mu-\delta}^{\mu+\delta} e^{-(x-\mu)^2/2\sigma^2} dx = \text{erf}\left(\frac{\delta}{\sqrt{2}\sigma}\right) \tag{36.55}$$

is the probability that the measured value x will fall within $\pm\delta$ of the true value μ . From the symmetry of the Gaussian with respect to x and μ , this is also the probability for the interval $x \pm \delta$ to include μ . Fig. 36.4 shows a $\delta = 1.64\sigma$ confidence interval unshaded. The choice $\delta = \sigma$ gives an interval called the *standard error* which has $1 - \alpha = 68.27\%$ if σ is known. Values of α for other frequently used choices of δ are given in Table 36.1.

Figure 36.4: Illustration of a symmetric 90% confidence interval (unshaded) for a measurement of a single quantity with Gaussian errors. Integrated probabilities, defined by $\alpha = 0.1$, are as shown.

Table 36.1: Area of the tails α outside $\pm\delta$ from the mean of a Gaussian distribution.

α	δ	α	δ
0.3173	1σ	0.2	1.28σ
4.55×10^{-2}	2σ	0.1	1.64σ
2.7×10^{-3}	3σ	0.05	1.96σ
6.3×10^{-5}	4σ	0.01	2.58σ
5.7×10^{-7}	5σ	0.001	3.29σ
2.0×10^{-9}	6σ	10^{-4}	3.89σ

We can set a one-sided (upper or lower) limit by excluding above $x + \delta$ (or below $x - \delta$). The values of α for such limits are half the values in Table 36.1.

The relation (36.55) can be re-expressed using the cumulative distribution function for the χ^2 distribution as

$$\alpha = 1 - F(\chi^2; n), \tag{36.56}$$

for $\chi^2 = (\delta/\sigma)^2$ and $n = 1$ degree of freedom. This can be obtained from Fig. 36.1 on the $n = 1$ curve or by using the ROOT function `TMath::Prob`.

For multivariate measurements of, say, n parameter estimates $\hat{\theta} = (\hat{\theta}_1, \dots, \hat{\theta}_n)$, one requires the full covariance matrix $V_{ij} = \text{cov}[\hat{\theta}_i, \hat{\theta}_j]$, which can be estimated as described in Sections 36.1.2 and 36.1.3. Under fairly general conditions with the methods of maximum-likelihood or least-squares in the large sample limit, the estimators will be distributed according to a multivariate Gaussian centered about the true (unknown) values θ , and furthermore, the likelihood function itself takes on a Gaussian shape.

The standard error ellipse for the pair $(\hat{\theta}_i, \hat{\theta}_j)$ is shown in Fig. 36.5, corresponding to a contour $\chi^2 = \chi^2_{\min} + 1$ or $\ln L = \ln L_{\max} - 1/2$. The ellipse is centered about the estimated values $\hat{\theta}$, and the tangents to the ellipse give the standard deviations of the estimators, σ_i and σ_j . The angle of the major axis of the ellipse is given by

$$\tan 2\phi = \frac{2\rho_{ij}\sigma_i\sigma_j}{\sigma_j^2 - \sigma_i^2}, \tag{36.57}$$

where $\rho_{ij} = \text{cov}[\hat{\theta}_i, \hat{\theta}_j]/\sigma_i\sigma_j$ is the correlation coefficient.

The correlation coefficient can be visualized as the fraction of the distance σ_i from the ellipse’s horizontal center-line at which the ellipse becomes tangent to vertical, *i.e.*, at the distance $\rho_{ij}\sigma_i$ below the center-line as shown. As ρ_{ij} goes to $+1$ or -1 , the ellipse thins to a diagonal line.

It could happen that one of the parameters, say, θ_j , is known from previous measurements to a precision much better than σ_j , so that the current measurement contributes almost nothing to the knowledge of θ_j . However, the current measurement of θ_i and its dependence on θ_j may still be important. In this case, instead of quoting both parameter

Table 36.2: $\Delta\chi^2$ or $2\Delta\ln L$ corresponding to a coverage probability $1 - \alpha$ in the large data sample limit, for joint estimation of m parameters.

$(1 - \alpha)$ (%)	$m = 1$	$m = 2$	$m = 3$
68.27	1.00	2.30	3.53
90.	2.71	4.61	6.25
95.	3.84	5.99	7.82
95.45	4.00	6.18	8.03
99.	6.63	9.21	11.34
99.73	9.00	11.83	14.16

estimates and their correlation, one sometimes reports the value of θ_i , which minimizes χ^2 at a fixed value of θ_j , such as the PDG best value. This θ_i value lies along the dotted line between the points where the ellipse becomes tangent to vertical, and has statistical error σ_{inner} as shown on the figure, where $\sigma_{\text{inner}} = (1 - \rho_{ij}^2)^{1/2}\sigma_i$. Instead of the correlation ρ_{ij} , one reports the dependency $d\hat{\theta}_i/d\theta_j$ which is the slope of the dotted line. This slope is related to the correlation coefficient by $d\hat{\theta}_i/d\theta_j = \rho_{ij} \times \frac{\sigma_i}{\sigma_j}$.

Figure 36.5: Standard error ellipse for the estimators $\hat{\theta}_i$ and $\hat{\theta}_j$. In this case the correlation is negative.

As in the single-variable case, because of the symmetry of the Gaussian function between θ and $\hat{\theta}$, one finds that contours of constant $\ln L$ or χ^2 cover the true values with a certain, fixed probability. That is, the confidence region is determined by

$$\ln L(\theta) \geq \ln L_{\text{max}} - \Delta \ln L, \tag{36.58}$$

or where a χ^2 has been defined for use with the method of least-squares,

$$\chi^2(\theta) \leq \chi^2_{\text{min}} + \Delta\chi^2. \tag{36.59}$$

Values of $\Delta\chi^2$ or $2\Delta\ln L$ are given in Table 36.2 for several values of the coverage probability and number of fitted parameters.

For finite non-Gaussian data samples, the probability for the regions determined by equations (36.58) or (36.59) to cover the true value of θ will depend on θ , so these are not exact confidence regions according to our previous definition. Nevertheless, they can still have a coverage probability only weakly dependent on the true parameter, and approximately as given in Table 36.2. In any case, the coverage probability of the intervals or regions obtained according to this procedure can in principle be determined as a function of the true parameter(s), for example, using a Monte Carlo calculation.

One of the practical advantages of intervals that can be constructed from the log-likelihood function or χ^2 is that it is relatively simple to produce the interval for the combination of several experiments. If N independent measurements result in log-likelihood functions $\ln L_i(\theta)$, then the combined log-likelihood function is simply the sum,

$$\ln L(\theta) = \sum_{i=1}^N \ln L_i(\theta). \tag{36.60}$$

This can then be used to determine an approximate confidence interval or region with Eq. (36.58), just as with a single experiment.

36.3.2.5. Poisson or binomial data:

Another important class of measurements consists of counting a certain number of events, n . In this section, we will assume these are all events of the desired type, *i.e.*, there is no background. If n represents the number of events produced in a reaction with cross section σ , say, in a fixed integrated luminosity \mathcal{L} , then it follows a Poisson distribution with mean $\nu = \sigma\mathcal{L}$. If, on the other hand, one has selected a larger sample of N events and found n of them to have a particular property, then n follows a binomial distribution where the parameter p gives the probability for the event to possess the property in question. This is appropriate, *e.g.*, for estimates of branching ratios or selection efficiencies based on a given total number of events.

For the case of Poisson distributed n , the upper and lower limits on the mean value ν can be found from the Neyman procedure to be

$$\nu_{\text{lo}} = \frac{1}{2}F_{\chi^2}^{-1}(\alpha_{\text{lo}}; 2n), \tag{36.61a}$$

$$\nu_{\text{up}} = \frac{1}{2}F_{\chi^2}^{-1}(1 - \alpha_{\text{up}}; 2(n + 1)), \tag{36.61b}$$

where the upper and lower limits are at confidence levels of $1 - \alpha_{\text{lo}}$ and $1 - \alpha_{\text{up}}$, respectively, and $F_{\chi^2}^{-1}$ is the quantile of the χ^2 distribution (inverse of the cumulative distribution). The quantiles $F_{\chi^2}^{-1}$ can be obtained from standard tables or from the ROOT routine `TMath::ChisquareQuantile`. For central confidence intervals at confidence level $1 - \alpha$, set $\alpha_{\text{lo}} = \alpha_{\text{up}} = \alpha/2$.

Table 36.3: Lower and upper (one-sided) limits for the mean ν of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

n	$1 - \alpha = 90\%$		$1 - \alpha = 95\%$	
	ν_{lo}	ν_{up}	ν_{lo}	ν_{up}
0	–	2.30	–	3.00
1	0.105	3.89	0.051	4.74
2	0.532	5.32	0.355	6.30
3	1.10	6.68	0.818	7.75
4	1.74	7.99	1.37	9.15
5	2.43	9.27	1.97	10.51
6	3.15	10.53	2.61	11.84
7	3.89	11.77	3.29	13.15
8	4.66	12.99	3.98	14.43
9	5.43	14.21	4.70	15.71
10	6.22	15.41	5.43	16.96

It happens that the upper limit from Eq. (36.61b) coincides numerically with the Bayesian upper limit for a Poisson parameter, using a uniform prior p.d.f. for ν . Values for confidence levels of 90% and 95% are shown in Table 36.3. For the case of binomially distributed n successes out of N trials with probability of success p , the upper and lower limits on p are found to be

$$p_{\text{lo}} = \frac{nF_F^{-1}[\alpha_{\text{lo}}; 2n, 2(N - n + 1)]}{N - n + 1 + nF_F^{-1}[\alpha_{\text{lo}}; 2n, 2(N - n + 1)]}, \tag{36.62a}$$

$$p_{\text{up}} = \frac{(n + 1)F_F^{-1}[1 - \alpha_{\text{up}}; 2(n + 1), 2(N - n)]}{(N - n) + (n + 1)F_F^{-1}[1 - \alpha_{\text{up}}; 2(n + 1), 2(N - n)]}. \tag{36.62b}$$

Here F_F^{-1} is the quantile of the F distribution (also called the Fisher–Snedecor distribution; see Ref. 4).

36.3.2.6. Difficulties with intervals near a boundary:

A number of issues arise in the construction and interpretation of confidence intervals when the parameter can only take on values in a restricted range. An important example is where the mean of a Gaussian variable is constrained on physical grounds to be non-negative. This arises, for example, when the square of the neutrino mass is estimated from $\hat{m}^2 = \hat{E}^2 - \hat{p}^2$, where \hat{E} and \hat{p} are independent, Gaussian-distributed estimates of the energy and momentum. Although the true m^2 is constrained to be positive, random errors in \hat{E} and \hat{p} can easily lead to negative values for the estimate \hat{m}^2 .

If one uses the prescription given above for Gaussian distributed measurements, which says to construct the interval by taking the estimate plus-or-minus-one standard deviation, then this can give intervals that are partially or entirely in the unphysical region. In fact, by following strictly the Neyman construction for the central confidence interval, one finds that the interval is truncated below zero; nevertheless an extremely small or even a zero-length interval can result.

An additional important example is where the experiment consists of counting a certain number of events, n , which is assumed to be Poisson-distributed. Suppose the expectation value $E[n] = \nu$ is equal to $s + b$, where s and b are the means for signal and background processes, and assume further that b is a known constant. Then $\hat{s} = n - b$ is an unbiased estimator for s . Depending on true magnitudes of s and b , the estimate \hat{s} can easily fall in the negative region. Similar to the Gaussian case with the positive mean, the central confidence interval or even the interval that gives the upper limit for s may be of zero length.

An additional difficulty arises when a parameter estimate is not significantly far away from the boundary, in which case it is natural to report a one-sided confidence interval (often an upper limit). It is straightforward to force the Neyman prescription to produce only an upper limit by setting $x_2 = \infty$ in Eq. (36.49). Then x_1 is uniquely determined and the upper limit can be obtained. If, however, the data come out such that the parameter estimate is not so close to the boundary, one might wish to report a central confidence interval (*i.e.*, an interval based on a two-sided test with equal upper and lower tail areas). As pointed out by Feldman and Cousins [31], however, if the decision to report an upper limit or two-sided interval is made by looking at the data (“flip-flopping”), then in general there will be parameter values for which the resulting intervals have a coverage probability less than $1 - \alpha$.

With the confidence intervals suggested in [31], the prescription determines whether the interval is one- or two-sided in a way which preserves the coverage probability (and are thus said to be *unified*) and in addition they avoid the problem of null intervals. The intervals based on the Feldman-Cousins prescription are of this type. For a given choice of $1 - \alpha$, if the parameter estimate is sufficiently close to the boundary, the method gives a one-sided limit. In the case of a Poisson variable in the presence of background, for example, this would occur if the number of observed events is compatible with the expected background. For parameter estimates increasingly far away from the boundary, *i.e.*, for increasing signal significance, the interval makes a smooth transition from one- to two-sided, and far away from the boundary, one obtains a central interval.

The intervals according to this method for the mean of Poisson variable in the absence of background are given in Table 36.4. (Note that α in Ref. 31 is defined following Neyman [29] as the coverage probability; this is opposite the modern convention used here in which the coverage probability is $1 - \alpha$.) The values of $1 - \alpha$ given here refer to the coverage of the true parameter by the whole interval $[\nu_1, \nu_2]$. In Table 36.3 for the one-sided upper limit, however, $1 - \alpha$ refers to the probability to have $\nu_{\text{up}} \geq \nu$ (or $\nu_{\text{lo}} \leq \nu$ for lower limits).

A potential difficulty with unified intervals arises if, for example, one constructs such an interval for a Poisson parameter s of some yet to be discovered signal process with, say, $1 - \alpha = 0.9$. If the true signal parameter is zero, or in any case much less than the expected background, one will usually obtain a one-sided upper limit on s . In a certain fraction of the experiments, however, a two-sided interval

Table 36.4: Unified confidence intervals $[\nu_1, \nu_2]$ for the mean of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

n	$1 - \alpha = 90\%$		$1 - \alpha = 95\%$	
	ν_1	ν_2	ν_1	ν_2
0	0.00	2.44	0.00	3.09
1	0.11	4.36	0.05	5.14
2	0.53	5.91	0.36	6.72
3	1.10	7.42	0.82	8.25
4	1.47	8.60	1.37	9.76
5	1.84	9.99	1.84	11.26
6	2.21	11.47	2.21	12.75
7	3.56	12.53	2.58	13.81
8	3.96	13.99	2.94	15.29
9	4.36	15.30	4.36	16.77
10	5.50	16.50	4.75	17.82

for s will result. Since, however, one typically chooses $1 - \alpha$ to be only 0.9 or 0.95 when setting limits, the value $s = 0$ may be found below the lower edge of the interval before the existence of the effect is well established. It must then be communicated carefully that in excluding $s = 0$ from the interval, one is not necessarily claiming to have discovered the effect.

It must then be communicated carefully that in excluding $s = 0$ at, say, 90 or 95% confidence level from the interval, one is not necessarily claiming to have discovered the effect, for which one would usually require a higher level of significance (*e.g.*, 5σ).

The intervals constructed according to the unified procedure in Ref. 31 for a Poisson variable n consisting of signal and background have the property that for $n = 0$ observed events, the upper limit decreases for increasing expected background. This is counter-intuitive, since it is known that if $n = 0$ for the experiment in question, then no background was observed, and therefore one may argue that the expected background should not be relevant. The extent to which one should regard this feature as a drawback is a subject of some controversy (see, *e.g.*, Ref. 36).

Another possibility is to construct a Bayesian interval as described in Section 36.3.1. The presence of the boundary can be incorporated simply by setting the prior density to zero in the unphysical region. More specifically, the prior may be chosen using formal rules such as the reference prior or Jeffreys prior mentioned in Sec. 36.1.4. The use of such priors is currently receiving increased attention in HEP.

In HEP a widely used prior for the mean μ of a Poisson distributed measurement has been uniform for $\mu \geq 0$. This prior does not follow from any fundamental rule nor can it be regarded as reflecting a reasonable degree of belief, since the prior probability for μ to lie between any two finite limits is zero. It is more appropriately regarded as a procedure for obtaining intervals with frequentist properties that can be investigated. The resulting upper limits have a coverage probability that depends on the true value of the Poisson parameter, and is nowhere smaller than the stated probability content. Lower limits and two-sided intervals for the Poisson mean based on flat priors undercover, however, for some values of the parameter, although to an extent that in practical cases may not be too severe [2,19]. Intervals constructed in this way have the advantage of being easy to derive; if several independent measurements are to be combined then one simply multiplies the likelihood functions (cf. Eq. (36.60)).

An additional alternative is presented by the intervals found from the likelihood function or χ^2 using the prescription of Equations (36.58) or (36.59). However, the coverage probability is not, in general, independent of the true parameter, and these intervals can for some parameter values undercover. The coverage probability can, of course, be determined with some extra effort and reported with the result. These intervals are also invariant under transformation of the

parameter; this is not true for Bayesian intervals with a conventional flat prior, because a uniform distribution in, say, θ will not be uniform if transformed to $1/\theta$. A study of the coverage of different intervals for a Poisson parameter can be found in [34]. Use of the likelihood function to determine approximate confidence intervals is discussed further in [35].

In any case, it is important to always report sufficient information so that the result can be combined with other measurements. Often this means giving an unbiased estimator and its standard deviation, even if the estimated value is in the unphysical region.

It can also be useful with a frequentist interval to calculate its subjective probability content using the posterior p.d.f. based on one or several reasonable guesses for the prior p.d.f. If it turns out to be significantly less than the stated confidence level, this warns that it would be particularly misleading to draw conclusions about the parameter's value from the interval alone.

37. MONTE CARLO TECHNIQUES

Revised September 2011 by G. Cowan (RHUL).

Monte Carlo techniques are often the only practical way to evaluate difficult integrals or to sample random variables governed by complicated probability density functions. Here we describe an assortment of methods for sampling some commonly occurring probability density functions.

37.1. Sampling the uniform distribution

Most Monte Carlo sampling or integration techniques assume a “random number generator,” which generates uniform statistically independent values on the half open interval $[0, 1)$; for reviews see, e.g., [1,2].

Uniform random number generators are available in software libraries such as CERNLIB [3], CLHEP [4], and ROOT [5]. For example, in addition to a basic congruential generator `TRandom` (see below), ROOT provides three more sophisticated routines: `TRandom1` implements the RANLUX generator [6] based on the method by Lüscher, and allows the user to select different quality levels, trading off quality with speed; `TRandom2` is based on the maximally equidistributed combined Tausworthe generator by L’Ecuyer [7]; the `TRandom3` generator implements the Mersenne twister algorithm of Matsumoto and Nishimura [8]. All of the algorithms produce a periodic sequence of numbers, and to obtain effectively random values, one must not use more than a small subset of a single period. The Mersenne twister algorithm has an extremely long period of $2^{19937} - 1$.

The performance of the generators can be investigated with tests such as DIEHARD [9] or TestU01 [10]. Many commonly available congruential generators fail these tests and often have sequences (typically with periods less than 2^{32}), which can be easily exhausted on modern computers. A short period is a problem for the `TRandom` generator in ROOT, which, however, has the advantage that its state is stored in a single 32-bit word. The generators `TRandom1`, `TRandom2`, or `TRandom3` have much longer periods, with `TRandom3` being recommended by the ROOT authors as providing the best combination of speed and good random properties. For further information see, e.g., Ref. 11.

37.2. Inverse transform method

If the desired probability density function is $f(x)$ on the range $-\infty < x < \infty$, its cumulative distribution function (expressing the probability that $x \leq a$) is given by Eq. (35.6). If a is chosen with probability density $f(a)$, then the integrated probability up to point a , $F(a)$, is itself a random variable which will occur with uniform probability density on $[0, 1]$. Suppose u is generated according to a uniformly distributed in $(0, 1)$. If x can take on any value, and ignoring the endpoints, we can then find a unique x chosen from the p.d.f. $f(x)$ for a given u if we set

$$u = F(x), \tag{37.1}$$

provided we can find an inverse of F , defined by

$$x = F^{-1}(u). \tag{37.2}$$

This method is shown in Fig. 37.1a. It is most convenient when one can calculate by hand the inverse function of the indefinite integral of f . This is the case for some common functions $f(x)$ such as $\exp(x)$, $(1 - x)^n$, and $1/(1 + x^2)$ (Cauchy or Breit-Wigner), although it does not necessarily produce the fastest generator. Standard libraries contain software to implement this method numerically, working from functions or histograms in one or more dimensions, e.g., the UNU.RAN package [12], available in ROOT.

For a discrete distribution, $F(x)$ will have a discontinuous jump of size $f(x_k)$ at each allowed $x_k, k = 1, 2, \dots$. Choose u from a uniform distribution on $(0, 1)$ as before. Find x_k such that

$$F(x_{k-1}) < u \leq F(x_k) \equiv \text{Prob}(x \leq x_k) = \sum_{i=1}^k f(x_i); \tag{37.3}$$

then x_k is the value we seek (note: $F(x_0) \equiv 0$). This algorithm is illustrated in Fig. 37.1b.

Figure 37.1: Use of a random number u chosen from a uniform distribution $(0, 1)$ to find a random number x from a distribution with cumulative distribution function $F(x)$.

37.3. Acceptance-rejection method (Von Neumann)

Very commonly an analytic form for $F(x)$ is unknown or too complex to work with, so that obtaining an inverse as in Eq. (37.2) is impractical. We suppose that for any given value of x , the probability density function $f(x)$ can be computed, and further that enough is known about $f(x)$ that we can enclose it entirely inside a shape which is C times an easily generated distribution $h(x)$, as illustrated in Fig. 37.2. That is, $Ch(x) \geq f(x)$ must hold for all x .

Figure 37.2: Illustration of the acceptance-rejection method. Random points are chosen inside the upper bounding figure, and rejected if the ordinate exceeds $f(x)$. The lower figure illustrates a method to increase the efficiency (see text).

Frequently $h(x)$ is uniform or is a normalized sum of uniform distributions. Note that both $f(x)$ and $h(x)$ must be normalized to unit area, and therefore, the proportionality constant $C > 1$. To generate $f(x)$, first generate a candidate x according to $h(x)$. Calculate $f(x)$ and the height of the envelope $Ch(x)$; generate u and test if $uCh(x) \leq f(x)$. If so, accept x ; if not reject x and try again. If we regard x and $uCh(x)$ as the abscissa and ordinate of a point in a two-dimensional plot, these points will populate the entire area $Ch(x)$ in a smooth manner; then we accept those which fall under $f(x)$. The efficiency is the ratio of areas, which must equal $1/C$; therefore we must keep C as close as possible to 1.0. Therefore, we try to choose $Ch(x)$ to be as close to $f(x)$ as convenience dictates, as in the lower part of Fig. 37.2.

37.4. Algorithms

Algorithms for generating random numbers belonging to many different distributions are given for example by Press [13], Ahrens and Dieter [14], Rubinstein [15], Devroye [16], Walck [17] and Gentle [18]. For many distributions, alternative algorithms exist, varying in complexity, speed, and accuracy. For time-critical applications, these algorithms may be coded in-line to remove the significant overhead often encountered in making function calls.

In the examples given below, we use the notation for the variables and parameters given in Table 35.1. Variables named “ u ” are assumed to be independent and uniform on $[0,1]$. Denominators must be verified to be non-zero where relevant.

37.4.1. Exponential decay :

This is a common application of the inverse transform method, and uses the fact that if u is uniformly distributed in $[0,1]$, then $(1-u)$ is as well. Consider an exponential p.d.f. $f(t) = (1/\tau) \exp(-t/\tau)$ that is truncated so as to lie between two values, a and b , and renormalized to unit area. To generate decay times t according to this p.d.f., first let $\alpha = \exp(-a/\tau)$ and $\beta = \exp(-b/\tau)$; then generate u and let

$$t = -\tau \ln(\beta + u(\alpha - \beta)). \quad (37.4)$$

For $(a,b) = (0, \infty)$, we have simply $t = -\tau \ln u$. (See also Sec. 37.4.6.)

37.4.2. Isotropic direction in 3D :

Isotropy means the density is proportional to solid angle, the differential element of which is $d\Omega = d(\cos\theta)d\phi$. Hence $\cos\theta$ is uniform $(2u_1 - 1)$ and ϕ is uniform $(2\pi u_2)$. For alternative generation of $\sin\phi$ and $\cos\phi$, see the next subsection.

37.4.3. Sine and cosine of random angle in 2D :

Generate u_1 and u_2 . Then $v_1 = 2u_1 - 1$ is uniform on $(-1,1)$, and $v_2 = u_2$ is uniform on $(0,1)$. Calculate $r^2 = v_1^2 + v_2^2$. If $r^2 > 1$, start over. Otherwise, the sine (S) and cosine (C) of a random angle (*i.e.*, uniformly distributed between zero and 2π) are given by

$$S = 2v_1v_2/r^2 \quad \text{and} \quad C = (v_1^2 - v_2^2)/r^2. \quad (37.5)$$

37.4.4. Gaussian distribution :

If u_1 and u_2 are uniform on $(0,1)$, then

$$z_1 = \sin(2\pi u_1) \sqrt{-2 \ln u_2} \quad \text{and} \quad z_2 = \cos(2\pi u_1) \sqrt{-2 \ln u_2} \quad (37.6)$$

are independent and Gaussian distributed with mean 0 and $\sigma = 1$.

There are many variants of this basic algorithm, which may be faster. For example, construct $v_1 = 2u_1 - 1$ and $v_2 = 2u_2 - 1$, which are uniform on $(-1,1)$. Calculate $r^2 = v_1^2 + v_2^2$, and if $r^2 > 1$ start over. If $r^2 < 1$, it is uniform on $(0,1)$. Then

$$z_1 = v_1 \sqrt{\frac{-2 \ln r^2}{r^2}} \quad \text{and} \quad z_2 = v_2 \sqrt{\frac{-2 \ln r^2}{r^2}} \quad (37.7)$$

are independent numbers chosen from a normal distribution with mean 0 and variance 1. $z'_i = \mu + \sigma z_i$ distributes with mean μ and variance σ^2 .

For a multivariate Gaussian with an $n \times n$ covariance matrix V , one can start by generating n independent Gaussian variables, $\{\eta_j\}$, with mean 0 and variance 1 as above. Then the new set $\{x_i\}$ is obtained as $x_i = \mu_i + \sum_j L_{ij} \eta_j$, where μ_i is the mean of x_i , and L_{ij} are the components of L , the unique lower triangular matrix that fulfils $V = LL^T$. The matrix L can be easily computed by the following recursive relation (Cholesky's method):

$$L_{jj} = \left(V_{jj} - \sum_{k=1}^{j-1} L_{jk}^2 \right)^{1/2}, \quad (37.8a)$$

$$L_{ij} = \frac{V_{ij} - \sum_{k=1}^{j-1} L_{ik} L_{jk}}{L_{jj}}, \quad j = 1, \dots, n; \quad i = j + 1, \dots, n, \quad (37.8b)$$

where $V_{ij} = \rho_{ij} \sigma_i \sigma_j$ are the components of V . For $n = 2$ one has

$$L = \begin{pmatrix} \sigma_1 & 0 \\ \rho \sigma_2 & \sqrt{1 - \rho^2} \sigma_2 \end{pmatrix}, \quad (37.9)$$

and therefore the correlated Gaussian variables are generated as $x_1 = \mu_1 + \sigma_1 \eta_1$, $x_2 = \mu_2 + \rho \sigma_2 \eta_1 + \sqrt{1 - \rho^2} \sigma_2 \eta_2$.

37.4.5. $\chi^2(n)$ distribution :

To generate a variable following the χ^2 distribution for n degrees of freedom, use the Gamma distribution with $k = n/2$ and $\lambda = 1/2$ using the method of Sec. 37.4.6.

37.4.6. Gamma distribution :

All of the following algorithms are given for $\lambda = 1$. For $\lambda \neq 1$, divide the resulting random number x by λ .

- If $k = 1$ (the *exponential* distribution), accept $x = -\ln u$. (See also Sec. 37.4.1.)

- If $0 < k < 1$, initialize with $v_1 = (e + k)/e$ (with $e = 2.71828\dots$ being the natural log base). Generate u_1, u_2 . Define $v_2 = v_1 u_1$.

Case 1: $v_2 \leq 1$. Define $x = v_2^{1/k}$. If $u_2 \leq e^{-x}$, accept x and stop, else restart by generating new u_1, u_2 .

Case 2: $v_2 > 1$. Define $x = -\ln([v_1 - v_2]/k)$. If $u_2 \leq x^{k-1}$, accept x and stop, else restart by generating new u_1, u_2 . Note that, for $k < 1$, the probability density has a pole at $x = 0$, so that return values of zero due to underflow must be accepted or otherwise dealt with.

- Otherwise, if $k > 1$, initialize with $c = 3k - 0.75$. Generate u_1 and compute $v_1 = u_1(1 - u_1)$ and $v_2 = (u_1 - 0.5)\sqrt{c/v_1}$. If $x = k + v_2 - 1 \leq 0$, go back and generate new u_1 ; otherwise generate u_2 and compute $v_3 = 64v_1^3 u_2^2$. If $v_3 \leq 1 - 2v_2^2/x$ or if $\ln v_3 \leq 2\{[k-1] \ln[x/(k-1)] - v_2\}$, accept x and stop; otherwise go back and generate new u_1 .

37.4.7. Binomial distribution :

Begin with $k = 0$ and generate u uniform in $[0,1]$. Compute $P_k = (1-p)^n$ and store P_k into B . If $u \leq B$ accept $r_k = k$ and stop. Otherwise, increment k by one; compute the next P_k as $P_k \cdot (p/(1-p)) \cdot (n-k)/(k+1)$; add this to B . Again, if $u \leq B$, accept $r_k = k$ and stop, otherwise iterate until a value is accepted. If $p > 1/2$, it will be more efficient to generate r from $f(r; n, q)$, *i.e.*, with p and q interchanged, and then set $r_k = n - r$.

37.4.8. Poisson distribution :

Iterate until a successful choice is made: Begin with $k = 1$ and set $A = 1$ to start. Generate u . Replace A with uA ; if now $A < \exp(-\mu)$, where μ is the Poisson parameter, accept $n_k = k - 1$ and stop. Otherwise increment k by 1, generate a new u and repeat, always starting with the value of A left from the previous try.

Note that the Poisson generator used in ROOT's `TRandom` classes before version 5.12 (including the derived classes `TRandom1`, `TRandom2`, `TRandom3`) as well as the routine `RNPSSN` from CERNLIB, use a Gaussian approximation when μ exceeds a given threshold. This may be satisfactory (and much faster) for some applications. To do this, generate z from a Gaussian with zero mean and unit standard deviation; then use $x = \max(0, [\mu + z\sqrt{\mu} + 0.5])$ where $[\]$ signifies the greatest integer \leq the expression. The routines from Numerical Recipes [13] and CLHEP's routine `RandPoisson` do not make this approximation (see, *e.g.*, Ref. 11).

37.4.9. Student's t distribution :

Generate u_1 and u_2 uniform in $(0,1)$; then $t = \sin(2\pi u_1)[n(u_2^{-2/n} - 1)]^{1/2}$ follows the Student's t distribution for $n > 0$ degrees of freedom (n not necessarily an integer).

Alternatively, generate x from a Gaussian with mean 0 and $\sigma^2 = 1$ according to the method of 37.4.4. Next generate y , an independent gamma random variate, according to 37.4.6 with $\lambda = 1/2$ and $k = n/2$. Then $z = x/\sqrt{y/n}$ is distributed as a t with n degrees of freedom.

For the special case $n = 1$, the Breit-Wigner distribution, generate u_1 and u_2 ; set $v_1 = 2u_1 - 1$ and $v_2 = 2u_2 - 1$. If $v_1^2 + v_2^2 \leq 1$ accept $z = v_1/v_2$ as a Breit-Wigner distribution with unit area, center at 0.0, and FWHM 2.0. Otherwise start over. For center M_0 and FWHM Γ , use $W = z\Gamma/2 + M_0$.

37.4.10. Beta distribution :

The choice of an appropriate algorithm for generation of beta distributed random numbers depends on the values of the parameters α and β . For, e.g., $\alpha = 1$, one can use the transformation method to find $x = 1 - u^{1/\beta}$, and similarly if $\beta = 1$ one has $x = u^{1/\alpha}$. For more general cases see, e.g., Refs. [17,18] and references therein.

37.5. Markov Chain Monte Carlo

In applications involving generation of random numbers following a multivariate distribution with a high number of dimensions, the transformation method may not be possible and the acceptance-rejection technique may have too low of an efficiency to be practical. If it is not required to have independent random values, but only that they follow a certain distribution, then Markov Chain Monte Carlo (MCMC) methods can be used. In depth treatments of MCMC can be found, e.g., in the texts by Robert and Casella [19], Liu [20], and the review by Neal [21].

MCMC is particularly useful in connection with Bayesian statistics, where a p.d.f. $p(\boldsymbol{\theta})$ for an n -dimensional vector of parameters $\boldsymbol{\theta} = (\theta_1, \dots, \theta_n)$ is obtained, and one needs the marginal distribution of a subset of the components. Here one samples $\boldsymbol{\theta}$ from $p(\boldsymbol{\theta})$ and simply records the marginal distribution for the components of interest.

A simple and broadly applicable MCMC method is the Metropolis-Hastings algorithm, which allows one to generate multidimensional points $\boldsymbol{\theta}$ distributed according to a target p.d.f. that is proportional to a given function $p(\boldsymbol{\theta})$. It is not necessary to have $p(\boldsymbol{\theta})$ normalized to unit area, which is useful in Bayesian statistics, as posterior probability densities are often determined only up to an unknown normalization constant.

To generate points that follow $p(\boldsymbol{\theta})$, one first needs a proposal p.d.f. $q(\boldsymbol{\theta}; \boldsymbol{\theta}_0)$, which can be (almost) any p.d.f. from which independent random values $\boldsymbol{\theta}$ can be generated, and which contains a parameter another point in the same space $\boldsymbol{\theta}_0$. For example, a multivariate Gaussian centered about $\boldsymbol{\theta}_0$ can be used. Beginning at an arbitrary starting point $\boldsymbol{\theta}_0$, the Hastings algorithm iterates the following steps:

1. Generate a value $\boldsymbol{\theta}$ using the proposal density $q(\boldsymbol{\theta}; \boldsymbol{\theta}_0)$;
2. Form the Hastings test ratio, $\alpha = \min \left[1, \frac{p(\boldsymbol{\theta})q(\boldsymbol{\theta}_0; \boldsymbol{\theta})}{p(\boldsymbol{\theta}_0)q(\boldsymbol{\theta}; \boldsymbol{\theta}_0)} \right]$;
3. Generate a value u uniformly distributed in $[0, 1]$;
4. If $u \leq \alpha$, take $\boldsymbol{\theta}_1 = \boldsymbol{\theta}$. Otherwise, repeat the old point, i.e., $\boldsymbol{\theta}_1 = \boldsymbol{\theta}_0$.
5. Set $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_1$ and return to step 1.

If one takes the proposal density to be symmetric in $\boldsymbol{\theta}$ and $\boldsymbol{\theta}_0$, then this is the *Metropolis-Hastings* algorithm, and the test ratio becomes $\alpha = \min[1, p(\boldsymbol{\theta})/p(\boldsymbol{\theta}_0)]$. That is, if the proposed $\boldsymbol{\theta}$ is at a value of probability higher than $\boldsymbol{\theta}_0$, the step is taken. If the proposed step is rejected, the old point is repeated.

Methods for assessing and optimizing the performance of the algorithm are discussed in, e.g., Refs. [19–21]. One can, for example, examine the autocorrelation as a function of the lag k , i.e., the correlation of a sampled point with that k steps removed. This should decrease as quickly as possible for increasing k .

Generally one chooses the proposal density so as to optimize some quality measure such as the autocorrelation. For certain problems it has been shown that one achieves optimal performance when the acceptance fraction, that is, the fraction of points with $u \leq \alpha$, is around 40%. This can be adjusted by varying the width of the proposal density. For example, one can use for the proposal p.d.f. a multivariate Gaussian with the same covariance matrix as that of the target p.d.f., but scaled by a constant.

38. MONTE CARLO EVENT GENERATORS

Written January 2012 by P. Nason (INFN, Milan) and P.Z. Skands (CERN).

General-purpose Monte Carlo (GPMC) generators like HERWIG [1], HERWIG++ [2], PYTHIA 6 [3], PYTHIA 8 [4], and SHERPA [5], provide fully exclusive modeling of high-energy collisions. They play an essential role in QCD modeling (in particular for aspects beyond fixed-order perturbative QCD), in data analysis, where they are used together with detector simulation to provide a realistic estimate of the detector response to collision events, and in the planning of new experiments, where they are used to estimate signals and backgrounds in high-energy processes. They are built from several components, that describe the physics starting from very short distance scales, up to the typical scale of hadron formation and decay. Since QCD is weakly interacting at short distances (below a femtometer), the components of the GPMC dealing with short-distance physics are based upon perturbation theory. At larger distances, all soft hadronic phenomena, like hadronization and the formation of the underlying event, cannot be computed from first principles, and one must rely upon QCD-inspired models.

The purpose of this review is to illustrate the main components of these generators. It is divided into four sections. The first one deals with short-distance, perturbative phenomena. The basic concepts leading to the simulations of the dominant QCD processes are illustrated here. In the second section, hadronization phenomena are treated. The two most popular hadronization models for the formation of primary hadrons, the string and cluster models, are illustrated. The basics of the implementation of primary-hadron decays into stable ones is also illustrated here. In the third section, models for soft hadron physics are discussed. These include models for the underlying event, and for minimum-bias interactions. Issues of Bose-Einstein and color-reconnection effects are also discussed here. The fourth section briefly introduces the problem of MC tuning.

We use natural units throughout, such that $c = 1$ and $\hbar = 1$, with energy, momenta and masses measured in GeV, and time and distances measured in GeV^{-1} .

38.1. Short-distance physics in GPMC generators

The short-distance components of a GPMC generator deal with the computation of the primary process at hand, with decays of short-lived particles, and with the generation of QCD and QED radiation, on time scales below $1/\Lambda$, with Λ denoting a typical hadronic scale of a few hundred MeV, corresponding roughly to an inverse femtometer. In e^+e^- annihilation, for example, the short-distance physics describes the evolution of the system from the instant when the e^+e^- pair annihilates up to a time when the size of the produced system is just below a femtometer.

In the present discussion we take the momentum scale of the primary process to be $Q \gg \Lambda$, so that the corresponding time and distance scale $1/Q$ is small. Soft- and collinear-safe inclusive observables, such as total decay widths or inclusive cross sections, can be reliably computed in QCD perturbation theory (pQCD), with the perturbative expansion truncated at any fixed order n , and the remainder suppressed by $\alpha_S(Q)^{n+1}$.

Less inclusive observables, however, can receive large enhancements that destroy the convergence of the fixed-order expansion. This is due to the presence of collinear and infrared singularities in QCD. Thus, for example, a correction in which a parton from the primary interaction splits collinearly into two partons of comparable energy, is of order $\alpha_S(Q) \ln(Q/\Lambda)$, where the logarithm arises from an integral over a singularity regulated by the hadronic scale Λ . Since $\alpha_S(Q) \propto 1/\ln(Q/\Lambda)$, the corresponding cross section receives a correction of order unity. Two subsequent collinear splittings yield $\alpha_S^2(Q) \ln^2(Q/\Lambda)$, and so on. Thus, corrections of order unity arise at all orders in perturbation theory. The dominant region of phase space is the one where radiation is strongly ordered in a measure of hardness and/or angle. This means that, from a typical final-state configuration, by clustering together final-state parton pairs with, say, the smallest angle, recursively, we can reconstruct a branching tree, that may be viewed as the splitting history of the event. This history necessarily has some dependence on which measure is used to

order the clusterings. However, strong ordering in energy times angle, in virtuality or in transverse momenta are in fact equivalent in the dominant region. In fact, in the small-angle limit, the virtuality t of a parton of energy E , splitting into two on-shell partons is given by

$$t = E^2 z(1-z)(1-\cos\theta) \approx \frac{z(1-z)}{2} E^2 \theta^2, \quad (38.1)$$

where z and $1-z$ are the energy fractions carried by the produced partons, and θ is their relative angle. The transverse momentum of the final partons relative to the direction of the incoming one is given by

$$p_T^2 \approx z^2(1-z)^2 E^2 \theta^2. \quad (38.2)$$

Thus, significant differences between these measures only arise in regions with very small z or $1-z$ values. In QCD, because of soft divergences, these regions are in fact important, and the choice of the appropriate ordering variable is very relevant (see Sec. 38.3).

The so called KLN theorem [6,7] guarantees that large logarithmically divergent corrections, arising from final-state collinear splitting and from soft emissions, cancel against the virtual corrections in the total cross section, order by order in perturbation theory. Furthermore, the factorization theorem guarantees that initial-state collinear singularities can be factorized into the parton density functions (PDFs). Therefore, the cross section for the basic process remains accurate up to corrections of higher orders in $\alpha_S(Q)$, provided it is interpreted as an inclusive cross section, rather than as a bare partonic cross section. Thus, for example, the leading order (LO) cross section for $e^+e^- \rightarrow q\bar{q}$ is a good LO estimate of the e^+e^- cross section for the production of a pair of quarks accompanied by an arbitrary number of collinear and soft gluons, but is not a good estimate of the cross section for the production of a $q\bar{q}$ pair with no extra radiation.

Shower algorithms are used to compute the cross section for generic hard processes including all leading-logarithmic (LL) corrections. These algorithms begin with the generation of the kinematics of the basic process, performed with a probability proportional to its LO partonic cross section, which is interpreted physically as the inclusive cross section for the basic process, followed by an arbitrary sequence of small-angle splittings. A probability is then assigned to each splitting sequence. Thus, the initial LO cross section is partitioned into the cross sections for a multitude of final states of arbitrary multiplicity. The sum of all these partial cross sections equals that of the primary process. This property of the GPMCs reflects the KLN cancellation mentioned earlier, and it is often called “unitarity of the shower process”, a name that reminds us that the KLN cancellation itself is a consequence of unitarity. The fact that a quantum mechanical process can be described in terms of composition of probabilities, rather than amplitudes, follows from the LL approximation. In fact, in the dominant, strongly ordered region, subsequent splittings are separated by increasingly large times and distances, and this suppresses interference effects.

We now illustrate the basic parton-shower algorithm, as first introduced in Ref. 8. The purpose of this illustration is to give a schematic representation of how shower algorithms work, to introduce some concepts that will be referred to in the following, and to show the relationship between shower algorithms and Feynman-diagram results. For simplicity, we consider the example of e^+e^- annihilation into $q\bar{q}$ pairs. With each dominant (i.e. strongly ordered) final-state configuration one can associate a unique ordered tree diagram, by recursively clustering together final-state parton pairs with the smallest angle, and ending up with the hard production vertex (i.e. the $\gamma^* \rightarrow q\bar{q}$). The momenta of all intermediate lines of the tree diagram are then uniquely determined from the final-state momenta. Virtualities in the graph are also strongly ordered. One assigns to each splitting vertex a virtuality t , equal to the invariant mass of the pair of generated partons, the energy fractions z and $1-z$ of the two generated partons, and the azimuth ϕ of the splitting process with respect to the momentum of the incoming parton. For definiteness, we assume that z and ϕ are defined in the center-of-mass (CM) frame of the e^+e^- collision, although other definitions are possible that differ only beyond the LL approximation. The differential cross section for

a given final state is given by the product of the differential cross section for the initial $e^+e^- \rightarrow q\bar{q}$ process, multiplied by a factor

$$\Delta_i(t, t') \frac{\alpha_S(t)}{2\pi} P_{i,jk}(z) \frac{dt}{t} \frac{d\phi}{2\pi} \quad (38.3)$$

for each intermediate line ending in a splitting vertex. We have denoted with t' the maximal virtuality that is allowed for the line, with t its virtuality, and z and ϕ refer to the splitting process. $\Delta(t, t')$ is the so-called Sudakov form factor

$$\Delta_i(t, t') = \exp \left[- \int_t^{t'} \frac{dq^2}{q^2} \frac{\alpha_S(q^2)}{2\pi} \sum_{jk} P_{i,jk}(z) dz \frac{d\phi}{2\pi} \right]. \quad (38.4)$$

The suffixes i and jk represent the parton species of the incoming and final partons, respectively, and $P_{i,jk}(z)$ are the Altarelli-Parisi [9] splitting kernels. Final-state lines that do not undergo any further splitting are associated with a factor

$$\Delta_i(t_0, t'), \quad (38.5)$$

where t_0 is an infrared cutoff defined by the shower hadronization scale (at which the charges are screened by hadronization) or, for an unstable particle, its width (a source cannot emit radiation with a period exceeding its lifetime).

Notice that the definition of the Sudakov form factor is such that

$$\Delta_i(t_2, t_1) + \int_{t_2}^{t_1} \frac{dt}{t} dz \frac{d\phi}{2\pi} \sum_{jk} \Delta_i(t, t_1) \frac{\alpha_S(t)}{2\pi} P_{i,jk}(z) = 1. \quad (38.6)$$

This implies that the cross section for developing the shower up to a given stage does not depend on what happens next, since subsequent factors for further splitting or not splitting add up to one.

The shower cross section can then be formulated in a probabilistic way. The Sudakov form factor $\Delta_i(t_2, t_1)$ is interpreted as the probability for a splitting *not* to occur, for a parton of type i , starting from a branching vertex at the scale t_1 , down to a scale t_2 . Notice that $0 < \Delta_i(t_2, t_1) \leq 1$, where the upper extreme is reached for $t_2 = t_1$, and the lower extreme is approached for $t_2 = t_0$. From Eq. (38.4), it seems that the Sudakov form factor should vanish if $t_2 = 0$. However, because of the presence of the running coupling in the integrand, t_2 cannot be taken smaller than some cutoff scale of the order of Λ , so that at its lower extreme the Sudakov form factor is small, but not zero. Event generation then proceeds as follows. One gets a uniform random number $0 \leq r \leq 1$, and seeks a solution of the equation $r = \Delta_i(t_2, t_1)$ as a function of t_2 . If r is too small and no solution exists, no splitting is generated, and the line is interpreted as a final parton. If a solution t_2 exists, a branching is generated at the scale t_2 . Its z value and the final parton species jk are generated with a probability proportional to $P_{i,jk}(z)$. The azimuth is generated uniformly. This procedure is started with both the initial quark and the antiquark, and is applied recursively to all generated partons, thus producing two shower cascades. It may generate an arbitrary number of partons, and it stops when no final-state partons undergo further splitting.

We emphasize that the shower cross section described above can be derived from perturbative QCD by keeping only the collinear-dominant real and virtual contributions to the cross section. In particular, up to terms that vanish after azimuthal averaging, the product of the cross section for the basic process, times the factors

$$\frac{\alpha_S}{2\pi} \frac{dt}{t} dz \frac{d\phi}{2\pi} P_{i,jk}(z) \quad (38.7)$$

at each branching vertex, gives the leading collinear contribution to the tree-level cross section for the same process. The dominant virtual corrections in the same approximation are provided by the running coupling at each vertex and by the Sudakov form factors in the intermediate lines.

38.1.1. Angular correlations : In gluon splitting processes ($g \rightarrow q\bar{q}$, $g \rightarrow gg$) in the collinear approximation, the distribution of the split pair is not uniform in azimuth, and the Altarelli-Parisi splitting functions are recovered only after azimuthal averaging. This dependence is due to the interference of positive and negative helicity states for the gluon that undergoes splitting. Spin correlations propagate through the splitting process, and determine acausal correlations of the EPR kind [10]. A method to partially account for these effects was introduced in Ref. 11, in which the azimuthal correlation between two successive splittings is computed by averaging over polarizations. This can then be applied at each branching step. Acausal correlations are argued to be small, and are discarded with this method, that is still used in the PYTHIA code [139]. A method that fully includes spin correlation effects was later proposed by Collins [12], and has been implemented in the fortran HERWIG code [13].

38.1.2. Initial-state radiation : Initial-state radiation (ISR) arises because incoming charged particles can radiate before entering the hard-scattering process. In doing so, they acquire a non-vanishing transverse momentum, and their virtuality becomes negative (spacelike). The dominant logarithmic region is the collinear one, where virtualities become larger and larger in absolute value with each emission, up to a limit given by the hardness of the basic process itself. A shower that starts by considering the highest virtualities first would thus have to work backward in time for ISR. A corresponding backwards-evolution algorithm was formulated by Sjöstrand [14], and was basically adopted in all shower models.

The key point in backwards evolution is that the evolution probability depends on the amount of partons that could have given rise to the one being evolved. This is reflected by introducing the ratio of the PDF after the branching to the PDF before the branching in the definition of the backward-evolution Sudakov form factor,

$$\Delta_i^{\text{ISR}}(t, t') = \exp \left[- \int_{t'}^t \frac{dt''}{t''} \frac{\alpha_S(t'')}{2\pi} \int_x^1 \frac{dz}{z} \sum_{jk} P_{j,ik}(z) \frac{f_j(t'', x/z)}{f_i(t'', x)} \right]. \quad (38.8)$$

Notice that there are two uses of the PDFs: they are used to compute the cross section for the basic hard process, and they control ISR via backward evolution. Since the evolution is generated with leading-logarithmic accuracy, it is acceptable to use two different PDF sets for these two tasks, provided they agree at the LO level.

In the context of GPMC evolution, each ISR emission generates a finite amount of transverse momentum. Details on how the recoils generated by these transverse “kicks” are distributed among other partons in the event, in particular the ones involved in the hard process, constitute one of the main areas of difference between existing algorithms, see Ref. 15. An additional $\mathcal{O}(1 \text{ GeV})$ of “primordial k_T ” is typically added, to represent the sum of unresolved and/or non-perturbative motion below the shower cutoff scale.

38.1.3. Soft emissions and QCD coherence : In massless field theories like QCD, there are two sources of large logarithms of infrared origin. One has to do with collinear singularities, which arise when two final-state particles become collinear, or when a final-state particle becomes collinear to an initial-state one. The other has to do with the emission of soft gluons at arbitrary angles. Because of that, it turns out that in QCD perturbation theory two powers of large logarithms can arise for each power of α_S . The expansion in leading soft and collinear logarithms is often referred to as the double-logarithmic expansion.

Within the conventional parton-shower formalism, based on collinear factorization, it was shown in a sequel of publications (see Ref. 16 and references therein) that the double-logarithmic region can be correctly described by using the angle of the emissions as the ordering variable, rather than the virtuality, and that the argument of α_S at the splitting vertex should be the relative parton transverse momentum after the splitting. Physically, the ordering in angle approximates the coherent interference arising from large-angle soft emission from a bunch of collinear partons. Without this effect,

the particle multiplicity would grow too rapidly with energy, in conflict with e^+e^- data. For this reason, angular ordering is used as the evolution variable in both the HERWIG [16] and HERWIG++ [17] programs, and an angular veto is imposed on the virtuality-ordered evolution in PYTHIA 6 [18].

A radical alternative formulation of QCD cascades first proposed in Ref. 19 focuses upon soft emission, rather than collinear emission, as the basic splitting mechanism. It then becomes natural to consider a branching process where it is a parton pair (i.e. a dipole) rather than a single parton, that emits a soft parton. Adding a suitable correction for non-soft, collinear partons, one can achieve in this framework the correct logarithmic structure for both soft and collinear emissions in the limit of large number of colors N_c , without any explicit angular-ordering requirement. The ARIADNE [20] and VINCIA [21] programs are based on this approach. In SHERPA, the default shower [22] is also of a dipole type [23], while the p_\perp -ordered showers in PYTHIA 6 and 8 represent a hybrid, combining collinear splitting kernels with dipole kinematics [24].

38.1.4. Massive quarks : Quark masses act as cut-off on collinear singularities. If the mass of a quark is below, or of the order of Λ , its effect in the shower is small. For larger quark masses, like in c or b production, it is the mass, rather than the typical hadronic scale, that cuts off collinear radiation. For a quark with energy E and mass m_Q , the divergent behavior $d\theta/\theta$ of the collinear splitting process is regulated for $\theta \leq \theta_0 = m_Q/E$. We thus expect less collinear activity for heavy quarks than for light ones, which in turn is the reason why heavy quarks carry a larger fraction of the momentum acquired in the hard production process.

This feature can be implemented with different levels of sophistication. Using the fact that soft emission exhibits a zero at zero emission angle, older parton shower algorithms simply limited the shower emission to be not smaller than the angle θ_0 . More modern approaches are used in both PYTHIA, where mass effects are included using a kind of matrix-element correction method [25], and in HERWIG++ and SHERPA, where a generalization of the Altarelli-Parisi splitting kernel is used for massive quarks [26].

38.1.5. Color information : Shower MC generators track large- N_c color information during the development of the shower. In the large- N_c limit, a quark is represented by a color line, i.e. a line with an arrow in the direction of the shower development, an antiquark by an anticolor line, with the arrow in the opposite direction, and a gluon by a pair of color-anticolor lines. The rules for color propagation are:

(38.9)

At the end of the shower development, partons are connected by color lines. We can have a quark directly connected by a color line to an antiquark, or via an arbitrary number of intermediate gluons, as shown in Fig. 38.1.

Figure 38.1: Color development of a shower in e^+e^- annihilation. Systems of color-connected partons are indicated by the dashed lines.

It is also possible for a set of gluons to be connected cyclically in color, as e.g. in the decay $\Upsilon \rightarrow ggg$.

The color information is used in angular-ordered showers, where the angle of color-connected partons determines the initial angle for the shower development, and in dipole showers, where dipoles are always color-connected partons. It is also used in hadronization models, where the initial strings or clusters used for hadronization are formed by systems of color-connected partons.

38.1.6. Electromagnetic corrections : The physics of photon emission from light charged particles can also be treated with a shower MC algorithm. A high-energy electron, for example, is accompanied by bremsstrahlung photons, which considerably affect its dynamics. Also here, similarly to the QCD case, electromagnetic corrections are of order $\alpha_{em} \ln Q/m_e$, or even of order $\alpha_{em} \ln Q/m_e \ln E_\gamma/E$ in the region where soft photon emission is important, so that their inclusion in the simulation process is mandatory. This can be done with a Monte Carlo algorithm. In case of photons emitted by leptons, at variance with the QCD case, the shower can be continued down to values of the lepton virtuality that are arbitrarily close to its mass shell. In practice, photon radiation must be cut off below a certain energy, in order for the shower algorithm to terminate. Therefore, there is always a minimum energy for emitted photons that depends upon the implementations (and so does the MC truth for a charged lepton). In the case of electrons, this energy is typically of the order of its mass. Electromagnetic radiation below this scale is not enhanced by collinear singularities, and is thus bound to be soft, so that the electron momentum is not affected by it.

For photons emitted from quarks, we have instead the obvious limitation that the photon wavelength cannot exceed the typical hadronic size. Longer-wavelength photons are in fact emitted by hadrons, rather than quarks. This last effect is in practice never modeled by existing shower MC implementations. Thus, electromagnetic radiation from quarks is cut off at a typical hadronic scale.

38.1.7. Beyond-the-Standard-Model Physics : The inclusion of processes for physics beyond the Standard Model (BSM) in event generators is to some extent just a matter of implementing the relevant hard processes and (chains of) decays, with the level of difficulty depending on the complexity of the model and the degree of automation [27,28]. Notable exceptions are long-lived colored particles [29], particles in exotic color representations, and particles showering under new gauge symmetries, with a growing set of implementations documented in the individual GPMC manuals. Further complications that may be relevant are finite-width effects (discussed in Sec. 38.1.8) and the assumed threshold behavior.

In addition to code-specific implementations [15], there are a few commonly adopted standards that are useful for transferring information and events between codes. Currently, the most important of these is the Les Houches Event File (LHEF) standard [30], normally used to transfer parton-level events from a hard-process generator to a shower generator. Another important standard is the Supersymmetry Les Houches Accord (SLHA) format [31], originally used to transfer information on supersymmetric particle spectra and couplings, but by now extended to apply also to more general BSM frameworks and incorporated within the LHEF standard [32].

38.1.8. Decay Chains and Particle Widths : In most BSM processes and some SM ones, an important aspect of the event simulation is how decays of short-lived particles, such as top quarks, electroweak and Higgs bosons, and new BSM resonances, are handled. We here briefly summarize the spectrum of possibilities, but emphasize that there is no universal standard. Users are advised to check whether the treatment of a given code is adequate for the physics study at hand.

The appearance of an unstable resonance as a physical particle at some intermediate stage of the event generation implies that its production and decay processes are treated as being factorized. This is valid up to corrections of order Γ/m_0 , with Γ the width and m_0 the pole mass. States whose widths are a substantial fraction of their mass should not be treated as “physical particles,” but rather as intrinsically off-shell internal propagator lines.

For states treated as physical particles, two aspects are relevant: the mass distribution of the decaying particle itself and the distributions of its decay products. For the former, matrix-element generators often use a simple δ function at m_0 . The next level up, typically used in GPMCs, is to use a Breit-Wigner distribution (relativistic or non-relativistic), which formally resums higher-order virtual corrections to the mass distribution. Note, however, that this still only generates an

improved picture for *moderate* fluctuations away from m_0 . Similarly to above, particles that are significantly off-shell (in units of Γ) should not be treated as resonant, but rather as internal off-shell propagator lines. In most GPMCs, further refinements are included, for instance by letting Γ be a function of m (“running widths”) and by limiting the magnitude of the allowed fluctuations away from m_0 .

For the distributions of the decay products, the simplest treatment is again to assign them their respective m_0 values, with a uniform phase-space distribution. A more sophisticated treatment distributes the decay products according to the differential decay matrix elements, capturing at least the internal dynamics and helicity structure of the decay process, including EPR-like correlations. Further refinements include polarizations of the external states [33] and assigning the decay products their own Breit-Wigner distributions, the latter of which opens the possibility to include also intrinsically off-shell decay channels, like $H \rightarrow WW^*$.

During subsequent showering of the decay products, most parton-shower models will preserve their total invariant mass, so as not to skew the original resonance shape.

When computing partial widths and/or modifying decay tables, one should be aware of the danger of double-counting intermediate on-shell particles, see Sec. 38.2.3.

38.1.9. Matching with Matrix Elements : Shower algorithms are based upon a combination of the collinear (small-angle) and soft (small-energy) approximations and are thus inaccurate for hard, large-angle emissions. They also lack next-to-leading order (NLO) corrections to the basic process.

Traditional GPMCs, like HERWIG and PYTHIA, have included for a long time the so called Matrix Element Corrections (MEC), first formulated in Ref. 34 with later developments summarized in Ref. 15. They are available for processes involving two incoming and one outgoing or one incoming and two outgoing particles, like DIS, vector boson and Higgs production and decays, and top decays. The MEC corrects the emission of the hardest jets at large angles, so that it becomes exact at leading order.

In the past decade, considerable progress has taken place in order to improve the parton shower description of hard collisions, in two different directions: the so called Matrix Elements and Parton Shower matching (ME+PS from now on), and the matching of NLO calculations and Parton Showers (NLO+PS).

The ME+PS method allows one to use tree-level matrix elements for hard, large-angle emissions. It was first formulated in the so-called CKKW paper [35], and several variants have appeared, including the CKKW-L, MLM, and pseudoshower methods, see Refs. 36, 15 for summaries. Truncated showers are required [37] in order to maintain color coherence when interfacing matrix-element calculations to angular-ordered parton showers using these methods. It is also important to ensure consistent α_S choices between the real (ME-driven) and virtual (PS-driven) corrections [38].

In the ME+PS method one typically starts by generating exact matrix elements for the production of the basic process plus a certain number $\leq n$ of other partons. A minimum separation is imposed on the produced partons, requiring, for example, that the relative transverse momentum in any pair of partons is above a given cut Q_{cut} . One then reweights these amplitudes in such a way that, in the strongly ordered region, the virtual effects that are included in the shower algorithm (i.e. running couplings and Sudakov form factors) are also accounted for. At this stage the generated configurations are tree-level accurate at large angle, and at small angle they match the results of the shower algorithm, except that there are no emissions below the scale Q_{cut} , and no final states with more than n partons. These kinematic configurations are thus fed into a GPMC, that must generate all splittings with relative transverse momentum below the scale Q_{cut} , for initial events with less than n partons, or below the scale of the smallest pair transverse momentum, for events with exactly n partons. The matching parameter Q_{cut} must be chosen to be large enough for fixed-order perturbation theory to hold, but small enough so that the shower is accurate for emissions below it. Notice that the accuracy achieved with MEC is equivalent to that of ME+PS

with $n = 1$, where MEC has the advantage of not having a matching parameter Q_{cut} .

The popularity of the ME+PS method is due to the fact that processes with many jets appear often as background of new physics searches. These jets are typically required to be well separated, and to have large transverse momenta. These kinematical configurations, away from the small-angle region, are precisely those where GPMCs fail to be accurate, and it is thus mandatory to describe them using exact tree-level matrix element calculations.

The NLO+PS methods extend the accuracy of the generation of the basic process at the NLO level in QCD. They must thus include the radiation of an extra parton with full tree-level accuracy, since this radiation constitutes a NLO correction to the basic process. They must also include NLO virtual corrections. They can be viewed as an extension of the MEC method with the inclusion of NLO virtual corrections. They are however more general, since they are applicable to processes of arbitrary complexity. Two of these methods are now widely used: MC@NLO [39] and POWHEG [37,40], with several alternative methods now also being pursued, see Ref. 15 and references therein.

NLO+PS generators should produce NLO accurate distributions for inclusive quantities, and should generate the hardest jet with tree-level accuracy even at large angle. It should be recalled, though, that in $2 \rightarrow 1$ processes like Z/W production, GPMCs including MEC and weighted by a constant K factor may perform nearly as well, and, if suitably tuned, may even yield a better description of data. It may thus be wise to consider tuning also the NLO+PS generators for these processes.

ME+PS generators should be preferred over NLO+PS ones when one needs an accurate description of hard, large-angle emissions, beyond the hardest jet. Attempts to merge ME+PS and NLO+PS, in order to get event samples that have the advantage of both methods have appeared, see Refs. 41, 15, and references therein.

Several ME+PS implementations use existing LO generators, like ALPGEN [42], MADGRAPH [43], and others summarized in Ref. 36, for the calculation of the matrix element, and feed the partonic events to a GPMC like PYTHIA or HERWIG using the Les Houches Interface for User Processes (LHI/LHEF) [44,30]. SHERPA and HERWIG++ also include their own matrix-element generators and matching algorithms.

Several NLO+PS processes are implemented in the MC@NLO program [39], together with the new AMC@NLO development [45], and in the POWHEG BOX framework [40]. Again, SHERPA and HERWIG++, also include their own POWHEG implementation, suitably adapted with the inclusion of vetoed and truncated showers, for several processes.

38.2. Hadronization Models

In the context of event generators, *hadronization* denotes the process by which a set of colored partons (*after* showering) is transformed into a set of color-singlet *primary* hadrons, which may then subsequently decay further. This non-perturbative transition takes place at the *hadronization scale* Q_{had} , which by construction is identical to the infrared cutoff of the parton shower. In the absence of a first-principles solution to the relevant dynamics, event generators use QCD-inspired phenomenological models to describe this transition.

A key difference between MC hadronization models and the fragmentation-function (FF) formalism used to describe inclusive hadron spectra in perturbative QCD (see Chap. 9 of PDG book) is that the former is always defined at the hadronization scale, while the latter can be defined at an arbitrary perturbative scale Q . They can therefore only be compared directly if the perturbative evolution between Q and Q_{had} is taken into account. FFs are calculable in pQCD, given a non-perturbative initial condition obtained by fits to hadron spectra. In the MC context, one can prove that the correct QCD evolution of the FFs arises from the shower formalism, with the hadronization model providing an explicit parametrization of the non-perturbative component. It should be kept in mind, however, that the MC modeling of shower and hadronization includes much more information on the final state since it is fully exclusive (i.e., it addresses all particles in the final state explicitly), while FFs only describe inclusive spectra. This exclusivity also enables MC models to

make use of the color-flow information coming from the perturbative shower evolution (see Sec. 38.1.5) to determine between which partons the confining potentials should arise.

If one had an exact hadronization model, its dependence upon the hadronization scale Q_{had} would be compensated by the corresponding scale dependence of the shower algorithm, which stops generating branchings at the scale Q_{had} . However, due to their complicated and fully exclusive nature, it is generally not possible to enforce this compensation automatically in MC models of hadronization. One must therefore be aware that the model must be “retuned” by hand if changes are made to the perturbative evolution, in particular if the infrared cutoff is modified. Tuning is discussed briefly in Sec. 38.4.

An important result in “quenched” lattice QCD (see Chap. 17 of PDG book) is that the potential of the color-dipole field between a charge and an anticharge appears to grow linearly with the separation of the charges, at distances greater than about a femtometer. This is known as “linear confinement”, and it forms the starting point for the *string model of hadronization*, discussed below in Sec. 38.2.1. Alternatively, a property of perturbative QCD called “preconfinement” is the basis of the *cluster model of hadronization*, discussed in Sec. 38.2.2.

Finally, it should be emphasized that the so-called “parton level” that can be obtained by switching off hadronization in a GPMC, is not a universal concept, since each model defines the hadronization scale differently (e.g. by a cutoff in p_{\perp} , invariant mass, etc., with different tunes using different values for the cutoff). Comparisons to distributions at this level may therefore be used to provide an idea of the overall impact of hadronization corrections within a given model, but should be avoided in the context of physical observables.

38.2.1. The String Model: Starting from early concepts [46], several hadronization models based on strings have been proposed [15]. Of these, the most widely used today is the so-called Lund model [47,48], implemented in PYTHIA [139,140]. We concentrate on that particular model here, though many of the overall concepts would be shared by any string-inspired method.

Consider a color-connected quark-antiquark pair with no intermediate gluons emerging from the parton shower (like the $\bar{q}q$ pair in the center of Fig. 38.1), e.g. a red q and an antired \bar{q} . As the charges move apart, linear confinement implies that a potential $V(r) = \kappa r$ is reached for large distances r . (At short distances, there is a Coulomb term $\propto 1/r$ as well, but this is neglected in the Lund string.) This potential describes a string with tension $\kappa \sim 1 \text{ GeV/fm} \sim 0.2 \text{ GeV}^2$. The physical picture is that of a color flux tube being stretched between the q and the \bar{q} .

Figure 38.2: Illustration of string breaking by quark pair-creation in the string field.

As the string grows, the non-perturbative creation of quark-antiquark pairs can break the string, via the process $(q\bar{q}) \rightarrow (q\bar{q}') + (q'\bar{q})$, illustrated in Fig. 38.2. More complicated color-connected quark-antiquark configurations involving intermediate gluons (like the $\bar{q}gggq$ and $\bar{q}gq$ systems on the left and right part of Fig. 38.1) are treated by representing gluons as transverse “kinks.” Thus soft gluons effectively build up a transverse structure in the originally one-dimensional object, with infinitely soft ones smoothly absorbed into the string. For strings with finite-energy kinks, the space-time evolution is slightly more involved [48], but the main point is that there are no separate free parameters for gluon jets. Differences with respect to quark fragmentation arise simply because quarks are only connected to a single string piece, while gluons have one on either side, increasing their relative energy loss (per unit

invariant time) by a factor of 2, similar to the ratio of color Casimirs $C_A/C_F = 2.25$.

Since the string breaks are causally disconnected (as can be realized from space-time diagrams [48]), they do not have to be considered in any specific time-ordered sequence. In the Lund model, the string breaks are generated starting with the leading (“outermost”) hadrons, containing the endpoint quarks, and iterating inwards towards the center of the string, alternating randomly between the left and right sides. One can thereby split off a single on-shell hadron in each step, making it straightforward to ensure that only states consistent with known hadron states are produced.

For each breakup vertex, quantum mechanical tunneling is assumed to control the masses and p_{\perp} kicks that can be produced, leading to a Gaussian suppression

$$\text{Prob}(m_q^2, p_{\perp q}^2) \propto \exp\left(\frac{-\pi m_q^2}{\kappa}\right) \exp\left(\frac{-\pi p_{\perp q}^2}{\kappa}\right), \quad (38.10)$$

where m_q is the mass of the produced quark flavor and p_{\perp} is the non-perturbative transverse momentum imparted to it by the breakup process (the antiquark has the same mass and opposite p_{\perp}), with a universal average value of $\langle p_{\perp q}^2 \rangle = \kappa/\pi \sim (250 \text{ MeV})^2$. The charm and bottom masses are sufficiently heavy that they are not produced at all in the soft fragmentation. The transverse direction is defined with respect to the string axis, so the p_{\perp} in a frame where the string is moving will be modified by a Lorentz boost. Note that the effective amount of “non-perturbative” p_{\perp} , in a Monte Carlo model with a fixed shower cutoff Q_{had} , may be larger than the purely non-perturbative κ/π above, to account for effects of additional unresolved soft-gluon radiation below Q_{had} . In principle, the magnitude of this additional component should scale with the cutoff, but in practice it is up to the user to enforce this by retuning the relevant parameter when changing the hadronization scale.

Since quark masses are difficult to define for light quarks, the value of the strangeness suppression is determined from experimental observables, such as the K/π and K^*/ρ ratios. The parton-shower evolution generates a small amount of strangeness as well, through perturbative $g \rightarrow s\bar{s}$ splittings. The optimal value for the non-perturbative $2s/(u+d)$ ratio should therefore exhibit a mild anticorrelation with the amount of quarks produced in the perturbative stage.

Baryon production can also be incorporated, by allowing string breaks to produce pairs of *diquarks*, loosely bound states of two quarks in an overall $\bar{3}$ representation. Again, since diquark masses are difficult to define, the relative rate of diquark to quark production is extracted, e.g. from the p/π ratio, and since the perturbative shower splittings do not produce diquarks, the effective value for this parameter is mildly correlated with the amount of $g \rightarrow q\bar{q}$ splittings occurring on the shower side. More advanced scenarios for baryon production have also been proposed, see Ref. 48. Within the PYTHIA framework, a fragmentation model including baryon string junctions [49] is also available.

The next step of the algorithm is the assignment of the produced quarks within hadron multiplets. Using a nonrelativistic classification of spin states, the fragmenting q may combine with the \bar{q}' from a newly created breakup to produce a meson — or baryon, if diquarks are involved — of a given valence quark spin S and angular momentum L . The lowest-lying pseudoscalar and vector meson multiplets, and spin-1/2 and -3/2 baryons, are assumed to dominate in a string framework¹, but individual rates are not predicted by the model. This is therefore the sector that contains the largest amount of free parameters.

¹ The PYTHIA implementation includes the lightest pseudoscalar and vector mesons, with the four $L = 1$ multiplets (scalar, tensor, and 2 pseudovectors) available but disabled by default, largely because several states are poorly known and thus may result in a worse overall description when included. For baryons, the lightest spin-1/2 and -3/2 multiplets are included.

From spin counting, the ratio V/P of vectors to pseudoscalars is expected to be 3, but in practice this is only approximately true for B mesons. For lighter flavors, the difference in phase space caused by the V - P mass splittings implies a suppression of vector production. When extracting the corresponding parameters from data, it is advisable to begin with the heaviest states, since so-called feed-down from the decays of higher-lying hadron states complicates the extraction for lighter particles, see Sec. 38.2.3. For diquarks, separate parameters control the relative rates of spin-1 diquarks vs. spin-0 ones and, likewise, have to be extracted from data.

With p_{\perp}^2 and m^2 now fixed, the final step is to select the fraction, z , of the fragmenting endpoint quark's longitudinal momentum that is carried by the created hadron, an aspect for which the string model is highly predictive. The requirement that the fragmentation be independent of the sequence in which breakups are considered (causality) imposes a "left-right symmetry" on the possible form of the fragmentation function, $f(z)$, with the solution

$$f(z) \propto \frac{1}{z} (1-z)^a \exp\left(-\frac{b(m_h^2 + p_{\perp h}^2)}{z}\right), \quad (38.11)$$

which is known as the Lund symmetric fragmentation function (normalized to unit integral). The dimensionless parameter a dampens the hard tail of the fragmentation function, towards $z \rightarrow 1$, and may in principle be flavor-dependent, while b , with dimension GeV^{-2} , is a universal constant related to the string tension [48] which determines the behavior in the soft limit, $z \rightarrow 0$. Note that the explicit mass dependence in $f(z)$ implies a harder fragmentation function for heavier hadrons (in the rest frame of the string).

As a by-product, the probability distribution in invariant time τ of $q'\bar{q}$ breakup vertices, or equivalently $\Gamma = (\kappa\tau)^2$, is also obtained, with $dP/d\Gamma \propto \Gamma^a \exp(-b\Gamma)$ implying an area law for the color flux, and the average breakup time lying along a hyperbola of constant invariant time $\tau_0 \sim 10^{-23}\text{s}$ [48].

For massive endpoints (e.g. c and b quarks, or hypothetical hadronizing new-physics particles), which do not move along straight lightcone sections, the exponential suppression with string area leads to modifications of the form $f(z) \rightarrow f(z)/z^{bm_Q^2}$, with m_Q the mass of the heavy quark [50]. Although different forms can also be used to describe inclusive heavy-meson spectra (see Sec 19.9 of PDG book), such choices are not consistent with causality in the string framework and hence are theoretically disfavored in this context, one well-known example being the Peterson formula [51],

$$f(z) \propto \frac{1}{z} \left(1 - \frac{1}{z} - \frac{\epsilon_Q}{1-z}\right)^{-2}, \quad (38.12)$$

with ϵ_Q a free parameter expected to scale $\propto 1/m_Q^2$.

38.2.2. The Cluster Model: The cluster hadronization model is based on *preconfinement*, i.e., on the observation [52,53] that the color structure of a perturbative QCD shower evolution at any scale Q_0 is such that color-singlet subsystems of partons (labeled "clusters") occur with a universal invariant mass distribution that only depends on Q_0 and on Λ_{QCD} , not on the starting scale Q , for $Q \gg Q_0 \gg \Lambda_{\text{QCD}}$. Further, this mass distribution is power-suppressed at large masses.

Following early models based on this universality [8,54], the cluster model developed by Webber [55] has for many years been a hallmark of the HERWIG and HERWIG++ generators, with an alternative implementation [56] now available in the SHERPA generator. The key idea, in addition to preconfinement, is to force "by hand" all gluons to split into quark-antiquark pairs at the end of the parton shower. Compared with the string description, this effectively amounts to viewing gluons as "seeds" for string breaks, rather than as kinks in a continuous object. After the splittings, a new set of low-mass color-singlet clusters is obtained, formed only by quark-antiquark pairs. These can be decayed to on-shell hadrons in a simple manner.

The algorithm starts by generating the forced $g \rightarrow q\bar{q}$ breakups, and by assigning flavors and momenta to the produced quark pairs. For a typical shower cutoff corresponding to a gluon virtuality

of $Q_{\text{had}} \sim 1\text{GeV}$, the p_{\perp} generated by the splittings can be neglected. The constituent light-quark masses, $m_{u,d} \sim 300\text{MeV}$ and $m_s \sim 450\text{MeV}$, imply a suppression (typically even an absence) of strangeness production. In principle, the model also allows for diquarks to be produced at this stage, but due to the larger constituent masses this would only become relevant for shower cutoffs larger than 1GeV .

If a cluster formed in this way has an invariant mass above some cutoff value, typically 3–4 GeV, it is forced to undergo sequential $1 \rightarrow 2$ cluster breakups, along an axis defined by the constituent partons of the original cluster, until all sub-cluster masses fall below the cutoff value. Due to the preservation of the original axis in these breakups, this treatment has some resemblance to the string-like picture.

Next, on the low-mass side of the spectrum, some clusters are allowed to decay directly to a single hadron, with nearby clusters absorbing any excess momentum. This improves the description of the high- z part of the fragmentation spectrum — where the hadron carries almost all the momentum of its parent jet — at the cost of introducing one additional parameter, controlling the probability for single-hadron cluster decay.

Having obtained a final distribution of small-mass clusters, now with a strict cutoff at 3–4 GeV and with the component destined to decay to single hadrons already removed, the remaining clusters are interpreted as a smoothed-out spectrum of excited mesons, each of which decays isotropically to two hadrons, with relative probabilities proportional to the available phase space for each possible two-hadron combination that is consistent with the cluster's internal flavors, including spin degeneracy. It is important that all the light members (containing only uds) of each hadron multiplet be included, as the absence of members can lead to unphysical isospin or SU(3) flavor violation. Typically, the lightest pseudoscalar, vector, scalar, even and odd charge conjugation pseudovector, and tensor multiplets of light mesons are included. In addition, some excited vector multiplets of light mesons may be available. For baryons, usually only the lightest octet, decuplet and singlet baryons are present, although both the HERWIG++ and SHERPA implementations now include some heavier baryon multiplets as well.

Contrary to the case in the string model, the mechanism of phase-space suppression employed here leads to a natural enhancement of the lighter pseudoscalars, and no parameters beyond the spectrum of hadron masses need to be introduced at this point. The phase space also limits the transverse momenta of the produced hadrons relative to the jet axis.

Note that, since the masses and decays of excited heavy-flavor hadrons in particular are not well known, there is some freedom in the model to adjust these, which in turn will affect their relative phase-space populations.

38.2.3. Hadron and τ Decays: Of the so-called primary hadrons, originating directly from string breaks and/or cluster decays (see above), many are unstable and so decay further, until a set of particles is obtained that can be considered stable on time scales relevant to the given measurement². The decay modeling can therefore have a significant impact on final particle yields and spectra, especially for the lowest-lying hadronic states, which receive the largest relative contributions from decays (feed-down). Note that the interplay between primary production and feed-down implies that the hadronization parameters should be retuned if significant changes to the decay treatment are made.

Particle summary tables, such as those given elsewhere in this *Review*, represent a condensed summary of the available experimental measurements and hence may be incomplete and/or exhibit inconsistencies within the experimental precision. In an MC decay package, on the other hand, all information must be quantified and consistent, with all branching ratios summing to unity.

² E.g., a typical hadron-collider definition of a "stable particle" is $c\tau \geq 10\text{mm}$, which includes the weakly-decaying strange hadrons (K , Λ , Σ^{\pm} , $\bar{\Sigma}^{\pm}$, Ξ , Ω).

When adapting particle summary information for use in a decay package, a number of choices must therefore be made. The amount of ambiguity increases as more excited hadron multiplets are added to the simulation, about which less and less is known from experiment, with each GPMC making its own choices.

A related choice is how to distribute the decay products differentially in phase space, in particular which matrix elements to use. Historically, MC generators contained matrix elements only for selected (generator-specific) classes of hadron and τ decays, coupled with a Breit-Wigner smearing of the masses, truncated at the edges of the physical decay phase space (the treatment of decay thresholds can be important for certain modes [15]). A more sophisticated treatment can then be obtained by reweighting the generated events using the obtained particle four-momenta and/or by using specialized external packages such as EVTGEN [57] for hadron decays and TAUOLA [58] for τ decays.

More recently, HERWIG++ and SHERPA include helicity-dependence in τ decays [59,60], with a more limited treatment available in PYTHIA 8 [140]. The HERWIG++ and SHERPA generators have also included significantly improved internal simulations of hadronic decays, which include spin correlations between those decays for which matrix elements are used.

HERWIG++ and PYTHIA include the probability for B mesons to oscillate into \bar{B} ones before decay. SHERPA and EVTGEN also include CP-violating effects and, for common decay modes of the neutral meson and its antiparticle, the interference between the direct decay and oscillation followed by decay.

We end on a note of warning on double counting. This may occur if a particle can decay via an intermediate on-shell resonance. An example is $a_1 \rightarrow \pi\pi\pi$ which may proceed via $a_1 \rightarrow \rho\pi$, $\rho \rightarrow \pi\pi$. If these decay channels of the a_1 are both included, each with their full partial width, a double counting of the on-shell $a_1 \rightarrow \rho\pi$ contribution would result. Such cases are normally dealt with consistently in the default MC generator packages, so this warning is mostly relevant for users that wish to edit decay tables on their own.

38.3. Models for Soft Hadron-Hadron Physics

38.3.1. Minimum-Bias and Diffraction: The term “minimum bias” (MB) originates from the experimental requirement of a minimal number of tracks (or hits) in a given instrumented region. In order to make MC predictions for such observables, all possible contributions to the relevant phase-space region must be accounted for. There are essentially four types of physics processes, which together make up the total hadron-hadron (hh) cross section: 1) elastic scattering³: $hh \rightarrow hh$, 2) single diffractive dissociation: $hh \rightarrow h + \text{gap} + X$, with X denoting anything that is not the original beam particle, and “gap” denoting a rapidity region devoid of observed activity; 3) double diffractive dissociation: $hh \rightarrow X + \text{gap} + X$, and 4) inelastic non-diffractive scattering: everything else. A fifth class may also be defined, called central diffraction ($hh \rightarrow h + \text{gap} + X + \text{gap} + h$). Some differences exist between theoretical and experimental terminology [61]. In the experimental setting, diffraction is defined by an observable gap, of some minimal size in rapidity. In the MC context, each diffractive physics process typically produces a whole spectrum of gaps, with small ones suppressed but not excluded.

The inelastic non-diffractive part of the cross section is typically modeled either by smoothly regulating and extending the perturbative QCD scattering cross sections all the way to zero p_\perp [62] (PYTHIA 6, PYTHIA 8, and SHERPA), or by regulating the QCD cross sections with a sharp cutoff [63] (HERWIG+JIMMY) and adding a separate class of intrinsically soft scatterings below that scale [64] (HERWIG++). See also Sec. 38.3.2. In all cases, the three most important ingredients are: 1) the IR regularization of the perturbative scattering cross sections, including their PDF dependence, 2) the assumed matter distribution of the colliding hadrons, possibly including multi-parton correlations [49] and/or x dependence [65], and 3) additional soft-QCD effects

such as color reconnections and/or other collective effects, discussed in Sec. 38.3.3.

Currently, there are essentially three methods for simulating diffraction in the main MC models: 1) in PYTHIA 6, one picks a diffractive mass according to parametrized cross sections $\propto dM^2/M^2$ [66]. This mass is represented as a string, which is fragmented as described in Sec. 38.2.1, though differences in the effective scale of the hadronization may necessitate a (re)tuning of the fragmentation parameters for diffraction; 2) in PYTHIA 8, the high-mass tail beyond $M \sim 10$ GeV is augmented by a partonic description in terms of pomeron PDFs [67], allowing diffractive jet production including showers and underlying event [68]; 3) the PHOJET and DPMJET programs also include central diffraction and rely directly on a formulation in terms of pomerons (color-singlet multi-gluon states) [69–71]. Cut pomerons correspond to exchanges of soft gluons while uncut ones give elastic and diffractive topologies as well as virtual corrections that help preserve unitarity. So-called “hard pomerons” provide a transition to the perturbative regime. Fragmentation is still handled using the Lund string model, so there is some overlap with the above models at the hadronization stage. In addition, a pomeron-based package exists for HERWIG [72], and an effort is underway to construct an MC implementation of the “KMR” model [73] within the SHERPA generator. Color reconnections (Sec. 38.3.3) may also play a role in creating rapidity gaps and the underlying event (Sec. 38.3.2) in destroying them.

38.3.2. Underlying Event and Jet Pedestals: In the event-generator context, the term underlying event (UE) denotes any additional activity *beyond* the basic process and its associated ISR and FSR activity. The dominant contribution to this is believed to come from additional color exchanges between the beam particles, which can be represented either as multiple parton-parton interactions (MPI) or as so-called cut pomerons (Sec. 38.3.1). The experimentally observed fact that the UE is more active than MB events at the same CM energy is called the “jet pedestal” effect.

The most easily identifiable consequence of MPI is arguably the possibility of observing several hard parton-parton interactions in one and the same hadron-hadron event. This tends to produce largely uncorrelated back-to-back jet pairs, with each pair having a small value of $\text{sum}(\vec{p}_\perp)$. For comparison, jets from bremsstrahlung tend to be aligned with the direction of their parent initial- or final-state partons. The fraction of MPI that give rise to additional reconstructible jets is, however, quite small. Soft interactions that do not give rise to observable jets are much more plentiful, and can give significant corrections to the color flow and total scattered energy of the event. This affects the final-state activity in a more global way, increasing multiplicity and summed E_T distributions, and contributing to the break-up of the beam remnants in the forward direction.

The first detailed Monte Carlo model for perturbative MPI was proposed in Ref. 62, and with some variation this still forms the basis for most modern implementations. Some useful additional references can be found in Ref. 15. The first crucial observation is that the t -channel propagators appearing in perturbative QCD $2 \rightarrow 2$ scattering almost go on shell at low p_\perp , causing the differential cross sections to become very large, behaving roughly as

$$d\sigma_{2 \rightarrow 2} \propto \frac{dt}{t^2} \sim \frac{dp_\perp^2}{p_\perp^4}. \quad (38.13)$$

This cross section is an inclusive number. Thus, if a single hadron-hadron event contains two parton-parton interactions, it will “count” twice in $\sigma_{2 \rightarrow 2}$ but only once in σ_{tot} , and so on. In the limit that all the interactions are independent and equivalent, one would have

$$\sigma_{2 \rightarrow 2}(p_{\perp \text{min}}) = \langle n \rangle (p_{\perp \text{min}}) \sigma_{\text{tot}}, \quad (38.14)$$

with $\langle n \rangle (p_{\perp \text{min}})$ giving the average of a Poisson distribution in the number of parton-parton interactions above $p_{\perp \text{min}}$ per hadron-hadron collision,

$$\mathcal{P}_n(p_{\perp \text{min}}) = \frac{\langle n \rangle (p_{\perp \text{min}})^n \exp(-\langle n \rangle (p_{\perp \text{min}}))}{n!}. \quad (38.15)$$

³ The QED elastic-scattering cross section diverges and is normally a non-default option in MC models.

This simple argument in fact expresses unitarity; instead of the total interaction cross section diverging as $p_{\perp\min} \rightarrow 0$ (which would violate unitarity), we have restated the problem so that it is now the *number of MPI per collision* that diverges, with the total cross section remaining finite. At LHC energies, the $2 \rightarrow 2$ scattering cross sections computed using the full LO QCD cross section folded with modern PDFs becomes larger than the total pp one for p_{\perp} values of order 4–5 GeV [74]. One therefore expects the average number of perturbative MPI to exceed unity at around that scale.

Two important ingredients remain to fully regulate the remaining divergence. Firstly, the interactions cannot use up more momentum than is available in the parent hadron. This suppresses the large- n tail of the estimate above. In PYTHIA-based models, the MPI are ordered in p_{\perp} , and the parton densities for each successive interaction are explicitly constructed so that the sum of x fractions can never be greater than unity. In the HERWIG models, instead the uncorrelated estimate of $\langle n \rangle$ above is used as an initial guess, but the generation of actual MPI is stopped once the energy-momentum conservation limit is reached.

The second ingredient invoked to suppress the number of interactions, at low p_{\perp} and x , is color screening; if the wavelength $\sim 1/p_{\perp}$ of an exchanged colored parton becomes larger than a typical color-anticolor separation distance, it will only see an *average* color charge that vanishes in the limit $p_{\perp} \rightarrow 0$, hence leading to suppressed interactions. This provides an infrared cutoff for MPI similar to that provided by the hadronization scale for parton showers. A first estimate of the color-screening cutoff would be the proton size, $p_{\perp\min} \approx \hbar/r_p \approx 0.3 \text{ GeV} \approx \Lambda_{\text{QCD}}$, but empirically this appears to be far too low. In current models, one replaces the proton radius r_p in the above formula by a “typical color screening distance,” i.e., an average size of a region within which the net compensation of a given color charge occurs. This number is not known from first principles [73] and is perceived of simply as an effective cutoff parameter. The simplest choice is to introduce a step function $\Theta(p_{\perp} - p_{\perp\min})$. Alternatively, one may note that the jet cross section is divergent like $\alpha_s^2(p_{\perp}^2)/p_{\perp}^4$, cf. Eq. (38.13), and that therefore a factor

$$\frac{\alpha_s^2(p_{\perp 0}^2 + p_{\perp 1}^2)}{\alpha_s^2(p_{\perp 1}^2)} \frac{p_{\perp 1}^4}{(p_{\perp 0}^2 + p_{\perp 1}^2)^2} \quad (38.16)$$

would smoothly regulate the divergences, now with $p_{\perp 0}$ as the free parameter. Regardless of whether it is imposed as a smooth (PYTHIA and SHERPA) or steep (HERWIG++) function, this is effectively the main “tuning” parameter in such models.

Note that the numerical value obtained for the cross section depends upon the PDF set used, and therefore the optimal value to use for the cutoff will also depend on this choice. Note also that the cutoff does not have to be energy-independent. Higher energies imply that parton densities can be probed at smaller x values, where the number of partons rapidly increases. Partons then become closer packed and the color screening distance d decreases. The uncertainty on the energy and/or x scaling of the cutoff is a major concern when extrapolating between different collider energies [75].

We now turn to the origin of the observational fact that hard jets appear to sit on top of a higher “pedestal” of underlying activity than events with no hard jets. This is interpreted as a consequence of impact-parameter-dependence: in peripheral collisions, only a small fraction of events contain any high- p_{\perp} activity, whereas central collisions are more likely to contain at least one hard scattering; a high- p_{\perp} triggered sample will therefore be biased towards small impact parameters, b . The ability of a model to describe the shape of the pedestal (e.g. to describe both MB and UE distributions simultaneously) therefore depends upon its modeling of the b -dependence, and correspondingly the impact-parameter shape constitutes another main tuning parameter.

For each impact parameter b , the number of interactions $\tilde{n}(b)$ can then still be assumed to be distributed according to Eq. (38.15), again modulo momentum conservation, but now with the mean value of the Poisson distribution depending on impact parameter, $\langle \tilde{n}(b) \rangle$. This causes the final n -distribution (integrated over b) to be wider than a Poissonian.

Finally, there are two perturbative modeling aspects which go beyond the introduction of MPI themselves: 1) parton showers off the MPI, and 2) perturbative parton-rescattering effects. Without showers, MPI models would generate very sharp peaks for back-to-back MPI jets, caused by unshowered partons passed directly to the hadronization model. However, with the exception of the oldest PYTHIA6 model, all GPMC models do include such showers [15], and hence should exhibit more realistic (i.e., broader and more decorrelated) MPI jets. On the initial-state side, the main questions are whether and how correlated multi-parton densities are taken into account and, as discussed previously, how the showers are regulated at low p_{\perp} and/or low x . Although none of the MC models currently impose a rigorous correlated multi-parton evolution, all of them include some elementary aspects. The most significant for parton-level results is arguably momentum conservation, which is enforced explicitly in all the models. The so-called “interleaved” models [24] attempt to go a step further, generating an explicitly correlated multi-parton evolution in which flavor sum rules are imposed to conserve, e.g. the total numbers of valence and sea quarks [49].

Perturbative rescattering in the final state can occur if partons are allowed to undergo several distinct interactions, with showering activity possibly taking place in-between. This has so far not been studied extensively, but a first exploratory model is available [76]. In the initial state, parton rescattering/recombination effects have so far not been included in any of the GPMC models.

38.3.3. Bose-Einstein and Color-Reconnection Effects : In the context of e^+e^- collisions, Bose-Einstein (BE) correlations have mostly been discussed as a source of uncertainty on high-precision W mass determinations at LEP [77]. In hadron-hadron (and nucleus-nucleus) collisions, however, BE correlations are used extensively to study the space-time structure of hadronizing matter (“femtoscopy”).

In MC models of hadronization, each string break and/or particle/cluster decay is normally factorized from all other ones. This reduces the number of variables that must be considered simultaneously, but also makes the introduction of correlations among particles from different breaks/decays intrinsically difficult to address. In the context of GPMCs, a few semi-classical models are available within the PYTHIA 6 and 8 generators [78], in which the BE effect is mimicked by an attractive interaction between pairs of identical particles in the final state, with no higher correlations included. This “force” acts after the decays of very short-lived particles, like ρ , but before decays of longer-lived ones, like π^0 . The main differences between the variants of this model is the assumed shape of the correlation function and how overall momentum conservation is handled.

As discussed in Sec. 38.2, leading-color (“planar”) color flows are used to set up the hadronizing systems (clusters or strings) at the hadronization stage. If the systems do not overlap significantly in space and time, subleading-color ambiguities and/or non-perturbative reconnections are expected to be small. However, if the density of displaced color charges is sufficiently high that several systems can overlap significantly, full-color and/or reconnection effects should become progressively larger.

In the specific context of MPI, a crucial question is how color is neutralized *between* different MPI systems, including the remnants. The large rapidity differences involved imply large invariant masses (though normally low p_{\perp}), and hence large amounts of (soft) particle production. Indeed, in the context of soft-inclusive physics, it is these “inter-system” strings/clusters that furnish the dominant particle-production mechanism, and hence their modeling is an essential part of the soft-physics description, affecting topics such as MB/UE multiplicity and p_{\perp} distributions, rapidity gaps, and precision mass measurements. A more comprehensive review of color-reconnection effects can be found in Ref. 15.

38.4. Parameters and Tuning

The achievable accuracy in GPMC models depends both on the inclusiveness of the chosen observable and on the sophistication of the simulation. An important driver for the latter is obviously the development of improved theoretical models, discussed in the preceding sections; but it also depends crucially on the available constraints on the remaining free parameters. Using existing data to constrain these is referred to as generator tuning.

Although MC models may appear to have a bewildering array of adjustable parameters, most of them only control relatively small (exclusive) details of the event generation. The majority of the (inclusive) physics is determined by only a few, very important ones, such as the value of α_s , in the perturbative domain, and the properties of the non-perturbative fragmentation functions, in the non-perturbative one. One may therefore take a factorized approach, first constraining the perturbative parameters and thereafter the non-perturbative ones, each ordered in a measure of their relative significance to the overall modeling.

At LO \times LL, perturbation theory is doing well if it agrees with an IR safe measurement within 10%. It would therefore not make much sense to tune a GPMC beyond roughly 5% (it might even be dangerous, due to overfitting). The advent of NLO Monte Carlos may reduce this number slightly, but only for quantities for which one expects NLO precision. For LO Monte Carlos, distributions should be normalized to unity, since the NLO normalization is not tunable. For quantities governed by non-perturbative physics, uncertainties are larger. For some quantities, e.g. ones for which the underlying modeling is known to be poor, an order-of-magnitude agreement or worse may have to be accepted.

In the context of LO \times LL GPMC tuning, subleading aspects of coupling-constant and PDF choices are relevant. In particular, one should be aware that the choice of QCD Λ parameter $\Lambda_{MC} = 1.569\Lambda_{\overline{MS}}$ (for 5 active flavors) improves the predictions of coherent shower algorithms at the NLL level [79], and hence this scheme is typically considered the baseline for shower tuning. The question of LO vs. NLO PDFs is more involved [15], but it should be emphasized that the low- x gluon in particular is important for determining the level of the underlying event in MPI models (Sec. 38.3.2), and hence the MB/UE tuning (and energy scaling [75]) is linked to the choice of PDF in such models. Further issues and an example of a specific recipe that could be followed in a realistic set-up can be found in Ref. 80.

Recent years have seen the emergence of automated tools that attempt to reduce the amount of both computer and manpower required for tuning [81]. Automating the human expert input is more difficult. In the tools currently on the market, this question is addressed by a combination of input solicited from the generator authors (e.g., which parameters and ranges to consider, which observables constitute a complete set, etc) and a set of weights determining the relative priority given to each bin in each distribution. The field is still burgeoning, however, and future sophistications are to be expected. Nevertheless, the overall quality of the automated tunes appear to at least be competitive with the manual ones.

39. MONTE CARLO PARTICLE NUMBERING SCHEME

Revised April 2012 by J.-F. Arguin (LBNL, U. Montreal), L. Garren (Fermilab), F. Krauss (Durham U.), C.-J. Lin (LBNL), S. Navas (U. Granada), P. Richardson (Durham U.), and T. Sjöstrand (Lund U.).

The Monte Carlo particle numbering scheme presented here is intended to facilitate interfacing between event generators, detector simulators, and analysis packages used in particle physics. The numbering scheme was introduced in 1988 [1] and a revised version [2,3] was adopted in 1998 in order to allow systematic inclusion of quark model states which are as yet undiscovered and hypothetical particles such as SUSY particles. The numbering scheme is used in several event generators, *e.g.* HERWIG, PYTHIA, and SHERPA, and interfaces, *e.g.* /HEPEVT/ and HepMC.

The general form is a 7-digit number:

$$\pm n n_r n_L n_{q_1} n_{q_2} n_{q_3} n_J .$$

This encodes information about the particle's spin, flavor content, and internal quantum numbers. The details are as follows:

1. Particles are given positive numbers, antiparticles negative numbers. The PDG convention for mesons is used, so that K^+ and B^+ are particles.
2. Quarks and leptons are numbered consecutively starting from 1 and 11 respectively; to do this they are first ordered by family and within families by weak isospin.
3. In composite quark systems (diquarks, mesons, and baryons) $n_{q_{1-3}}$ are quark numbers used to specify the quark content, while the rightmost digit $n_J = 2J + 1$ gives the system's spin (except for the K_S^0 and K_L^0). The scheme does not cover particles of spin $J > 4$.
4. Diquarks have 4-digit numbers with $n_{q_1} \geq n_{q_2}$ and $n_{q_3} = 0$.
5. The numbering of mesons is guided by the nonrelativistic (L - S decoupled) quark model, as listed in Tables 14.2 and 14.3.
 - a. The numbers specifying the meson's quark content conform to the convention $n_{q_1} = 0$ and $n_{q_2} \geq n_{q_3}$. The special case K_L^0 is the sole exception to this rule.
 - b. The quark numbers of flavorless, light (u, d, s) mesons are: 11 for the member of the isotriplet (π^0, ρ^0, \dots), 22 for the lighter isosinglet (η, ω, \dots), and 33 for the heavier isosinglet (η', ϕ, \dots). Since isosinglet mesons are often large mixtures of $u\bar{u} + d\bar{d}$ and $s\bar{s}$ states, 22 and 33 are assigned by mass and do not necessarily specify the dominant quark composition.
 - c. The special numbers 310 and 130 are given to the K_S^0 and K_L^0 respectively.
 - d. The fifth digit n_L is reserved to distinguish mesons of the same total (J) but different spin (S) and orbital (L) angular momentum quantum numbers. For $J > 0$ the numbers are: (L, S) = ($J - 1, 1$) $n_L = 0$, ($J, 0$) $n_L = 1$, ($J, 1$) $n_L = 2$ and ($J + 1, 1$) $n_L = 3$. For the exceptional case $J = 0$ the numbers are ($0, 0$) $n_L = 0$ and ($1, 1$) $n_L = 1$ (*i.e.* $n_L = L$). See Table 39.1.

Table 39.1: Meson numbering logic. Here qq stands for $n_{q_2} n_{q_3}$.

	$L = J - 1, S = 1$	$L = J, S = 0$	$L = J, S = 1$	$L = J + 1, S = 1$
J	code $J^{PC} L$	code $J^{PC} L$	code $J^{PC} L$	code $J^{PC} L$
0	— — —	00qq1 0 ⁺⁺ 0	— — —	10qq1 0 ⁺⁺ 1
1	00qq3 1 ⁺⁻ 0	10qq3 1 ⁺⁻ 1	20qq3 1 ⁺⁺ 1	30qq3 1 ⁺⁻ 2
2	00qq5 2 ⁺⁺ 1	10qq5 2 ⁺⁻ 2	20qq5 2 ⁺⁻ 2	30qq5 2 ⁺⁺ 3
3	00qq7 3 ⁺⁻ 2	10qq7 3 ⁺⁻ 3	20qq7 3 ⁺⁺ 3	30qq7 3 ⁺⁻ 4
4	00qq9 4 ⁺⁺ 3	10qq9 4 ⁺⁻ 4	20qq9 4 ⁺⁻ 4	30qq9 4 ⁺⁺ 5

- e. If a set of physical mesons correspond to a (non-negligible) mixture of basis states, differing in their internal quantum numbers, then the lightest physical state gets the smallest basis state number. For example the $K_1(1270)$ is numbered 10313 ($1^1 P_1 K_{1B}$) and the $K_1(1400)$ is numbered 20313 ($1^3 P_1 K_{1A}$).

- f. The sixth digit n_r is used to label mesons radially excited above the ground state.
- g. Numbers have been assigned for complete $n_r = 0$ S - and P -wave multiplets, even where states remain to be identified.
- h. In some instances assignments within the $q\bar{q}$ meson model are only tentative; here best guess assignments are made.
- i. Many states appearing in the Meson Listings are not yet assigned within the $q\bar{q}$ model. Here $n_{q_{2-3}}$ and n_J are assigned according to the state's likely flavors and spin; all such unassigned light isoscalar states are given the flavor code 22. Within these groups $n_L = 0, 1, 2, \dots$ is used to distinguish states of increasing mass. These states are flagged using $n = 9$. It is to be expected that these numbers will evolve as the nature of the states are elucidated. Codes are assigned to all mesons which are listed in the one-page table at the end of the Meson Summary Table as long as they have a preferred or established spin. Additional heavy meson states expected from heavy quark spectroscopy are also assigned codes.

6. The numbering of baryons is again guided by the nonrelativistic quark model, see Table 14.6. This numbering scheme is illustrated through a few examples in Table 39.2.
 - a. The numbers specifying a baryon's quark content are such that in general $n_{q_1} \geq n_{q_2} \geq n_{q_3}$.
 - b. Two states exist for $J = 1/2$ baryons containing 3 different types of quarks. In the lighter baryon ($\Lambda, \Xi, \Omega, \dots$) the light quarks are in an antisymmetric ($J = 0$) state while for the heavier baryon ($\Sigma^0, \Xi', \Omega', \dots$) they are in a symmetric ($J = 1$) state. In this situation n_{q_2} and n_{q_3} are reversed for the lighter state, so that the smaller number corresponds to the lighter baryon.
 - c. For excited baryons a scheme is adopted, where the n_r label is used to denote the excitation bands in the harmonic oscillator model, see Sec. 14.4. Using the notation employed there, n_r is given by the N -index of the D_N band identifier.
 - d. Further degeneracies of excited hadron multiplets with the same excitation number n_r and spin J are lifted by labelling such multiplets with the n_L index according to their mass, as given by its N or Δ -equivalent.
 - e. In such excited multiplets extra singlets may occur, the $\Lambda(1520)$ being a prominent example. In such cases the ordering is reversed such that the heaviest quark label is pushed to the last position: $n_{q_3} > n_{q_1} > n_{q_2}$.
 - f. For pentaquark states $n = 9$, $n_r n_L n_{q_1} n_{q_2}$ gives the four quark numbers in order $n_r \geq n_L \geq n_{q_1} \geq n_{q_2}$, n_{q_3} gives the antiquark number, and $n_J = 2J + 1$, with the assumption that $J = 1/2$ for the states currently reported.
7. The gluon, when considered as a gauge boson, has official number 21. In codes for glueballs, however, 9 is used to allow a notation in close analogy with that of hadrons.
8. The pomeron and odderon trajectories and a generic reggeon trajectory of states in QCD are assigned codes 990, 9990, and 110 respectively, where the final 0 indicates the indeterminate nature of the spin, and the other digits reflect the expected "valence" flavor content. We do not attempt a complete classification of all reggeon trajectories, since there is currently no need to distinguish a specific such trajectory from its lowest-lying member.
9. Two-digit numbers in the range 21–30 are provided for the Standard Model gauge bosons and Higgs.
10. Codes 81–100 are reserved for generator-specific pseudoparticles and concepts.
11. The search for physics beyond the Standard Model is an active area, so these codes are also standardized as far as possible.
 - a. A standard fourth generation of fermions is included by analogy with the first three.
 - b. The graviton and the boson content of a two-Higgs-doublet scenario and of additional $SU(2) \times U(1)$ groups are found in the range 31–40.
 - c. "One-of-a-kind" exotic particles are assigned numbers in the range 41–80.
 - d. Fundamental supersymmetric particles are identified by adding a nonzero n to the particle number. The superpartner of a boson or a left-handed fermion has $n = 1$ while the

Table 39.2: Some examples of octet (top) and decuplet (bottom) members for the numbering scheme for excited baryons. Here qqq stands for $n_{q_1}n_{q_2}n_{q_3}$. See the text for the definition of the notation. The numbers in parenthesis correspond to the mass of the baryons. The states marked as (?) are not experimentally confirmed.

- superpartner of a right-handed fermion has $n = 2$. When mixing occurs, such as between the winos and charged Higgsinos to give charginos, or between left and right sfermions, the lighter physical state is given the smaller basis state number.
- Technicolor states have $n = 3$, with technifermions treated like ordinary fermions. States which are ordinary color singlets have $n_r = 0$. Color octets have $n_r = 1$. If a state has non-trivial quantum numbers under the topcolor groups $SU(3)_1 \times SU(3)_2$, the quantum numbers are specified by tech, i, j , where i and j are 1 or 2. n_L is then $2i + j$. The colon, V_8 , is a heavy gluon color octet and thus is 3100021.
 - Excited (composite) quarks and leptons are identified by setting $n = 4$ and $n_r = 0$.
 - Within several scenarios of new physics, it is possible to have colored particles sufficiently long-lived for color-singlet hadronic states to form around them. In the context of supersymmetric scenarios, these states are called R -hadrons, since they carry odd R -parity. R -hadron codes, defined here, should be viewed as templates for corresponding codes also in other scenarios, for any long-lived particle that is either an unflavored color octet or a flavored color triplet. The R -hadron code is obtained by combining the SUSY particle code with a code for the light degrees of freedom, with as many intermediate zeros removed from the former as required to make place for the latter at the end. (To exemplify, a sparticle $n0000n_{\tilde{q}}$ combined with quarks q_1 and q_2 obtains code $n00n_{\tilde{q}}n_{q_1}n_{q_2}n_J$.) Specifically, the new-particle spin decouples in the limit of large masses, so that the final n_J digit is defined by the spin state of the light-quark system alone. An appropriate number of n_q digits is used to define the ordinary-quark content. As usual, 9 rather than 21 is used to denote a gluon/gluino in composite states. The sign of the hadron agrees with that of the constituent new particle (a color triplet) where there is a distinct new antiparticle, and else is defined as for normal hadrons. Particle names are R with the flavor content as lower index.
 - A black hole in models with extra dimensions has code 5000040. Kaluza-Klein excitations in models with extra dimensions have $n = 5$ or $n = 6$, to distinguish excitations of left- or right-handed fermions or, in case of mixing, the lighter or heavier state (cf. 11d). The nonzero n_r digit gives the radial excitation number, in scenarios where the level spacing allow these to be distinguished. Should the model also contain supersymmetry, excited SUSY states would be denoted by an $n_r > 0$, with $n = 1$ or 2 as usual. Should some colored states be long-lived enough that hadrons would form around them, the coding strategy of 11g applies, with the initial two nn_r digits preserved in the combined code.

- Magnetic monopoles and dyons are assumed to have one unit of Dirac monopole charge and a variable integer number $n_{q_1}n_{q_2}n_{q_3}$ units of electric charge. Codes $411n_{q_1}n_{q_2}n_{q_3}0$ are then used when the magnetic and electrical charge sign agree and $412n_{q_1}n_{q_2}n_{q_3}0$ when they disagree, with the overall sign of the particle set by the magnetic charge. For now no spin information is provided.

- Occasionally program authors add their own states. To avoid confusion, these should be flagged by setting $nn_r = 99$.
- Concerning the non-99 numbers, it may be noted that only quarks, excited quarks, squarks, and diquarks have $n_{q_3} = 0$; only diquarks, baryons (including pentaquarks), and the odderon have $n_{q_1} \neq 0$; and only mesons, the reggeon, and the pomeron have $n_{q_1} = 0$ and $n_{q_2} \neq 0$. Concerning mesons (not antimessons), if n_{q_1} is odd then it labels a quark and an antiquark if even.
- Nuclear codes are given as 10-digit numbers $\pm 10LZZZAAAI$. For a (hyper)nucleus consisting of n_p protons, n_n neutrons and n_Λ Λ 's, $A = n_p + n_n + n_\Lambda$ gives the total baryon number, $Z = n_p$ the total charge and $L = n_\Lambda$ the total number of strange quarks. I gives the isomer level, with $I = 0$ corresponding to the ground state and $I > 0$ to excitations, see [4], where states denoted m, n, p, q translate to $I = 1 - 4$. As examples, the deuteron is 1000010020 and ^{235}U is 1000922350. To avoid ambiguities, nuclear codes should not be applied to a single hadron, like p , n or Λ^0 , where quark-contents-based codes already exist.

This text and full lists of particle numbers, including excited baryons particles from physics beyond the standard model, can be found on the WWW [5]. The StdHep Monte Carlo standardization project [6] maintains the list of PDG particle numbers, as well as numbering schemes from most event generators and software to convert between the different schemes.

Footnotes to the Tables:

- a) Particularity in the third generation, the left and right sfermion states may mix, as shown. The lighter mixed state is given the smaller number.
- b) The physical $\tilde{\chi}$ states are admixtures of the pure $\tilde{\gamma}$, \tilde{Z}^0 , \tilde{W}^+ , \tilde{H}_1^0 , \tilde{H}_2^0 , and \tilde{H}^+ states.
- c) Σ^* and Ξ^* are alternate names for $\Sigma(1385)$ and $\Xi(1530)$.

40. CLEBSCH-GORDAN COEFFICIENTS, SPHERICAL HARMONICS, AND d FUNCTIONS

Note: A square-root sign is to be understood over every coefficient, e.g., for $-8/15$ read $-\sqrt{8/15}$.

$d_{1,-1}^1 = \frac{1-\cos\theta}{2} (2\cos\theta + 1)$

$d_{0,0}^2 = \left(\frac{3}{2} \cos^2 \theta - \frac{1}{2} \right)$

Figure 40.1: The sign convention is that of Wigner (*Group Theory*, Academic Press, New York, 1959), also used by Condon and Shortley (*The Theory of Atomic Spectra*, Cambridge Univ. Press, New York, 1953), Rose (*Elementary Theory of Angular Momentum*, Wiley, New York, 1957), and Cohen (*Tables of the Clebsch-Gordan Coefficients*, North American Rockwell Science Center, Thousand Oaks, Calif., 1974).

41. SU(3) ISOSCALAR FACTORS AND REPRESENTATION MATRICES

Written by R.L. Kelly (LBNL).

The most commonly used SU(3) isoscalar factors, corresponding to the singlet, octet, and decuplet content of $8 \otimes 8$ and $10 \otimes 8$, are shown at the right. The notation uses particle names to identify the coefficients, so that the pattern of relative couplings may be seen at a glance. We illustrate the use of the coefficients below. See J.J de Swart, Rev. Mod. Phys. **35**, 916 (1963) for detailed explanations and phase conventions.

A $\sqrt{\quad}$ is to be understood over every integer in the matrices; the exponent 1/2 on each matrix is a reminder of this. For example, the $\Xi \rightarrow \Omega K$ element of the $10 \rightarrow 10 \otimes 8$ matrix is $-\sqrt{6}/\sqrt{24} = -1/2$.

Intramultiplet relative decay strengths may be read directly from the matrices. For example, in decuplet \rightarrow octet + octet decays, the ratio of $\Omega^* \rightarrow \Xi \bar{K}$ and $\Delta \rightarrow N\pi$ partial widths is, from the $10 \rightarrow 8 \times 8$ matrix,

$$\frac{\Gamma(\Omega^* \rightarrow \Xi \bar{K})}{\Gamma(\Delta \rightarrow N\pi)} = \frac{12}{6} \times (\text{phase space factors}). \quad (41.1)$$

Including isospin Clebsch-Gordan coefficients, we obtain, e.g.,

$$\frac{\Gamma(\Omega^{*-} \rightarrow \Xi^0 K^-)}{\Gamma(\Delta^+ \rightarrow p \pi^0)} = \frac{1/2}{2/3} \times \frac{12}{6} \times p.s.f. = \frac{3}{2} \times p.s.f. \quad (41.2)$$

Partial widths for $8 \rightarrow 8 \otimes 8$ involve a linear superposition of 8_1 (symmetric) and 8_2 (antisymmetric) couplings. For example,

$$\Gamma(\Xi^* \rightarrow \Xi \pi) \sim \left(-\sqrt{\frac{9}{20}} g_1 + \sqrt{\frac{3}{12}} g_2 \right)^2. \quad (41.3)$$

The relations between g_1 and g_2 (with de Swart's normalization) and the standard D and F couplings that appear in the interaction Lagrangian,

$$\mathcal{L} = -\sqrt{2} D \text{Tr}(\{\bar{B}, B\}M) + \sqrt{2} F \text{Tr}([\bar{B}, B]M), \quad (41.4)$$

where $[\bar{B}, B] \equiv \bar{B}B - B\bar{B}$ and $\{\bar{B}, B\} \equiv \bar{B}B + B\bar{B}$, are

$$D = \frac{\sqrt{30}}{40} g_1, \quad F = \frac{\sqrt{6}}{24} g_2. \quad (41.5)$$

Thus, for example,

$$\Gamma(\Xi^* \rightarrow \Xi \pi) \sim (F - D)^2 \sim (1 - 2\alpha)^2, \quad (41.6)$$

where $\alpha \equiv F/(D + F)$. (This definition of α is de Swart's. The alternative $D/(D + F)$, due to Gell-Mann, is also used.)

The generators of SU(3) transformations, λ_a ($a = 1, 8$), are 3×3 matrices that obey the following commutation and anticommutation relationships:

$$[\lambda_a, \lambda_b] \equiv \lambda_a \lambda_b - \lambda_b \lambda_a = 2i f_{abc} \lambda_c \quad (41.7)$$

$$\{\lambda_a, \lambda_b\} \equiv \lambda_a \lambda_b + \lambda_b \lambda_a = \frac{4}{3} \delta_{ab} I + 2d_{abc} \lambda_c, \quad (41.8)$$

where I is the 3×3 identity matrix, and δ_{ab} is the Kronecker delta symbol. The f_{abc} are odd under the permutation of any pair of indices, while the d_{abc} are even. The nonzero values are

$1 \rightarrow 8 \otimes 8$

$$(\Lambda) \rightarrow (N \bar{K} \ \Sigma \pi \ \Lambda \eta \ \Xi K) = \frac{1}{\sqrt{8}} (2 \ 3 \ -1 \ -2)^{1/2}$$

$8_1 \rightarrow 8 \otimes 8$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \rightarrow \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\bar{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ N\bar{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ \Sigma\bar{K} & \Lambda\bar{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{20}} \begin{pmatrix} 9 & -1 & -9 & -1 \\ -6 & 0 & 4 & 4 & -6 \\ 2 & -12 & -4 & -2 \\ 9 & -1 & -9 & -1 \end{pmatrix}^{1/2}$$

$8_2 \rightarrow 8 \otimes 8$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \rightarrow \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\bar{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ N\bar{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ \Sigma\bar{K} & \Lambda\bar{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{12}} \begin{pmatrix} 3 & 3 & 3 & -3 \\ 2 & 8 & 0 & 0 & -2 \\ 6 & 0 & 0 & 6 \\ 3 & 3 & 3 & -3 \end{pmatrix}^{1/2}$$

$10 \rightarrow 8 \otimes 8$

$$\begin{pmatrix} \Delta \\ \Sigma \\ \Xi \\ \Omega \end{pmatrix} \rightarrow \begin{pmatrix} N\pi & \Sigma K \\ N\bar{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ \Sigma\bar{K} & \Lambda\bar{K} & \Xi\pi & \Xi\eta \\ \Xi\bar{K} \end{pmatrix} = \frac{1}{\sqrt{12}} \begin{pmatrix} -6 & 6 \\ -2 & 2 & -3 & 3 & 2 \\ 3 & -3 & 3 & 3 \\ 12 \end{pmatrix}^{1/2}$$

$8 \rightarrow 10 \otimes 8$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \rightarrow \begin{pmatrix} \Delta\pi & \Sigma K \\ \Delta\bar{K} & \Sigma\pi & \Sigma\eta & \Xi K \\ \Sigma\bar{K} & \Sigma\pi & \Xi K \\ \Xi\bar{K} & \Xi\pi & \Xi\eta & \Omega K \end{pmatrix} = \frac{1}{\sqrt{15}} \begin{pmatrix} -12 & 3 \\ 8 & -2 & -3 & 2 \\ -9 & 6 \\ 3 & -3 & -3 & 6 \end{pmatrix}^{1/2}$$

$10 \rightarrow 10 \otimes 8$

$$\begin{pmatrix} \Delta \\ \Sigma \\ \Xi \\ \Omega \end{pmatrix} \rightarrow \begin{pmatrix} \Delta\pi & \Delta\eta & \Sigma K \\ \Delta\bar{K} & \Sigma\pi & \Sigma\eta & \Xi K \\ \Sigma\bar{K} & \Xi\pi & \Xi\eta & \Omega K \\ \Xi\bar{K} & \Omega\eta \end{pmatrix} = \frac{1}{\sqrt{24}} \begin{pmatrix} 15 & 3 & -6 \\ 8 & 8 & 0 & -8 \\ 12 & 3 & -3 & -6 \\ 12 & -12 \end{pmatrix}^{1/2}$$

abc	f_{abc}	abc	d_{abc}	abc	d_{abc}
123	1	118	$1/\sqrt{3}$	355	1/2
147	1/2	146	1/2	366	-1/2
156	-1/2	157	1/2	377	-1/2
246	1/2	228	$1/\sqrt{3}$	448	$-1/(2\sqrt{3})$
257	1/2	247	-1/2	558	$-1/(2\sqrt{3})$
345	1/2	256	1/2	668	$-1/(2\sqrt{3})$
367	-1/2	338	$1/\sqrt{3}$	778	$-1/(2\sqrt{3})$
458	$\sqrt{3}/2$	344	1/2	888	$-1/\sqrt{3}$
678	$\sqrt{3}/2$				

The λ_a 's are

$$\lambda_1 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_2 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

$$\lambda_4 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} \quad \lambda_5 = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix} \quad \lambda_6 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$

$$\lambda_7 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix} \quad \lambda_8 = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}$$

Equation (41.7) defines the Lie algebra of SU(3). A general d -dimensional representation is given by a set of $d \times d$ matrices satisfying Eq. (41.7) with the f_{abc} given above. Equation (41.8) is specific to the defining 3-dimensional representation.

42. SU(n) MULTIPLETS AND YOUNG DIAGRAMMS

Written by C.G. Wohl (LBNL).

This note tells (1) how SU(n) particle multiplets are identified or labeled, (2) how to find the number of particles in a multiplet from its label, (3) how to draw the Young diagram for a multiplet, and (4) how to use Young diagrams to determine the overall multiplet structure of a composite system, such as a 3-quark or a meson-baryon system.

In much of the literature, the word “representation” is used where we use “multiplet,” and “tableau” is used where we use “diagram.”

42.1. Multiplet labels

An SU(n) multiplet is uniquely identified by a string of (n-1) nonnegative integers: (α, β, γ, ...). Any such set of integers specifies a multiplet. For an SU(2) multiplet such as an isospin multiplet, the single integer α is the number of steps from one end of the multiplet to the other (i.e., it is one fewer than the number of particles in the multiplet). In SU(3), the two integers α and β are the numbers of steps across the top and bottom levels of the multiplet diagram. Thus the labels for the SU(3) octet and decuplet

are (1,1) and (3,0). For larger n, the interpretation of the integers in terms of the geometry of the multiplets, which exist in an (n-1)-dimensional space, is not so readily apparent.

The label for the SU(n) singlet is (0, 0, ..., 0). In a flavor SU(n), the n quarks together form a (1, 0, ..., 0) multiplet, and the n antiquarks belong to a (0, ..., 0, 1) multiplet. These two multiplets are conjugate to one another, which means their labels are related by (α, β, ...) ↔ (... , β, α).

42.2. Number of particles

The number of particles in a multiplet, N = N(α, β, ...), is given as follows (note the pattern of the equations).

In SU(2), N = N(α) is

$$N = \frac{(\alpha + 1)}{1} \tag{42.1}$$

In SU(3), N = N(α, β) is

$$N = \frac{(\alpha + 1)}{1} \cdot \frac{(\beta + 1)}{1} \cdot \frac{(\alpha + \beta + 2)}{2} \tag{42.2}$$

In SU(4), N = N(α, β, γ) is

$$N = \frac{(\alpha + 1)}{1} \cdot \frac{(\beta + 1)}{1} \cdot \frac{(\gamma + 1)}{1} \cdot \frac{(\alpha + \beta + 2)}{2} \cdot \frac{(\beta + \gamma + 2)}{2} \cdot \frac{(\alpha + \beta + \gamma + 3)}{3} \tag{42.3}$$

Note that in Eq. (42.3) there is no factor with (α + γ + 2): only a consecutive sequence of the label integers appears in any factor. One more example should make the pattern clear for any SU(n). In SU(5), N = N(α, β, γ, δ) is

$$N = \frac{(\alpha + 1)}{1} \cdot \frac{(\beta + 1)}{1} \cdot \frac{(\gamma + 1)}{1} \cdot \frac{(\delta + 1)}{1} \cdot \frac{(\alpha + \beta + 2)}{2} \cdot \frac{(\beta + \gamma + 2)}{2} \cdot \frac{(\gamma + \delta + 2)}{2} \cdot \frac{(\alpha + \beta + \gamma + 3)}{3} \cdot \frac{(\beta + \gamma + \delta + 3)}{3} \cdot \frac{(\alpha + \beta + \gamma + \delta + 4)}{4} \tag{42.4}$$

From the symmetry of these equations, it is clear that multiplets that are conjugate to one another have the same number of particles, but so can other multiplets. For example, the SU(4) multiplets (3,0,0) and (1,1,0) each have 20 particles. Try the equations and see.

42.3. Young diagrams

A Young diagram consists of an array of boxes (or some other symbol) arranged in one or more left-justified rows, with each row being at least as long as the row beneath. The correspondence between a diagram and a multiplet label is: The top row juts out α boxes to the right past the end of the second row, the second row juts out β boxes to the right past the end of the third row, etc. A diagram in SU(n) has at most n rows. There can be any number of “completed” columns of n boxes buttressing the left of a diagram; these don’t affect the label. Thus in SU(3) the diagrams

represent the multiplets (1,0), (0,1), (0,0), (1,1), and (3,0). In any SU(n), the quark multiplet is represented by a single box, the antiquark multiplet by a column of (n-1) boxes, and a singlet by a completed column of n boxes.

42.4. Coupling multiplets together

The following recipe tells how to find the multiplets that occur in coupling two multiplets together. To couple together more than two multiplets, first couple two, then couple a third with each of the multiplets obtained from the first two, etc.

First a definition: A sequence of the letters a, b, c, ... is admissible if at any point in the sequence at least as many a’s have occurred as b’s, at least as many b’s have occurred as c’s, etc. Thus abcd and aabcb are admissible sequences and abb and acb are not. Now the recipe:

(a) Draw the Young diagrams for the two multiplets, but in one of the diagrams replace the boxes in the first row with a’s, the boxes in the second row with b’s, etc. Thus, to couple two SU(3) octets (such as the π-meson octet and the baryon octet), we start with and

. The unlettered diagram forms the upper left-hand corner of all the enlarged diagrams constructed below.

(b) Add the a’s from the lettered diagram to the right-hand ends of the rows of the unlettered diagram to form all possible legitimate Young diagrams that have no more than one a per column. In general, there will be several distinct diagrams, and all the a’s appear in each diagram. At this stage, for the coupling of the two SU(3) octets, we have:

(c) Use the b’s to further enlarge the diagrams already obtained, subject to the same rules. Then throw away any diagram in which the full sequence of letters formed by reading right to left in the first row, then the second row, etc., is not admissible.

(d) Proceed as in (c) with the c’s (if any), etc.

The final result of the coupling of the two SU(3) octets is:

Here only the diagrams with admissible sequences of a’s and b’s and with fewer than four rows (since n = 3) have been kept. In terms of multiplet labels, the above may be written

$$(1, 1) \otimes (1, 1) = (2, 2) \oplus (3, 0) \oplus (0, 3) \oplus (1, 1) \oplus (1, 1) \oplus (0, 0) .$$

In terms of numbers of particles, it may be written

$$8 \otimes 8 = 27 \oplus 10 \oplus \overline{10} \oplus 8 \oplus 8 \oplus 1 .$$

The product of the numbers on the left here is equal to the sum on the right, a useful check. (See also Sec. 14 on the Quark Model.)

43. KINEMATICS

Revised January 2000 by J.D. Jackson (LBNL) and June 2008 by D.R. Tovey (Sheffield).

Throughout this section units are used in which $\hbar = c = 1$. The following conversions are useful: $\hbar c = 197.3$ MeV fm, $(\hbar c)^2 = 0.3894$ (GeV)² mb.

43.1. Lorentz transformations

The energy E and 3-momentum \mathbf{p} of a particle of mass m form a 4-vector $p = (E, \mathbf{p})$ whose square $p^2 \equiv E^2 - |\mathbf{p}|^2 = m^2$. The velocity of the particle is $\boldsymbol{\beta} = \mathbf{p}/E$. The energy and momentum (E^*, \mathbf{p}^*) viewed from a frame moving with velocity $\boldsymbol{\beta}_f$ are given by

$$\begin{pmatrix} E^* \\ p_{\parallel}^* \end{pmatrix} = \begin{pmatrix} \gamma_f & -\gamma_f \boldsymbol{\beta}_f \\ -\gamma_f \boldsymbol{\beta}_f & \gamma_f \end{pmatrix} \begin{pmatrix} E \\ p_{\parallel} \end{pmatrix}, \quad p_T^* = p_T, \quad (43.1)$$

where $\gamma_f = (1 - \beta_f^2)^{-1/2}$ and p_T (p_{\parallel}) are the components of \mathbf{p} perpendicular (parallel) to $\boldsymbol{\beta}_f$. Other 4-vectors, such as the space-time coordinates of events, of course transform in the same way. The scalar product of two 4-momenta $p_1 \cdot p_2 = E_1 E_2 - \mathbf{p}_1 \cdot \mathbf{p}_2$ is invariant (frame independent).

43.2. Center-of-mass energy and momentum

In the collision of two particles of masses m_1 and m_2 the total center-of-mass energy can be expressed in the Lorentz-invariant form

$$\begin{aligned} E_{\text{cm}} &= \left[(E_1 + E_2)^2 - (\mathbf{p}_1 + \mathbf{p}_2)^2 \right]^{1/2}, \\ &= \left[m_1^2 + m_2^2 + 2E_1 E_2 (1 - \beta_1 \beta_2 \cos \theta) \right]^{1/2}, \end{aligned} \quad (43.2)$$

where θ is the angle between the particles. In the frame where one particle (of mass m_2) is at rest (lab frame),

$$E_{\text{cm}} = (m_1^2 + m_2^2 + 2E_{1\text{lab}} m_2)^{1/2}. \quad (43.3)$$

The velocity of the center-of-mass in the lab frame is

$$\boldsymbol{\beta}_{\text{cm}} = \mathbf{p}_{\text{lab}} / (E_{1\text{lab}} + m_2), \quad (43.4)$$

where $\mathbf{p}_{\text{lab}} \equiv \mathbf{p}_{1\text{lab}}$ and

$$\gamma_{\text{cm}} = (E_{1\text{lab}} + m_2) / E_{\text{cm}}. \quad (43.5)$$

The c.m. momenta of particles 1 and 2 are of magnitude

$$p_{\text{cm}} = p_{\text{lab}} \frac{m_2}{E_{\text{cm}}}. \quad (43.6)$$

For example, if a 0.80 GeV/c kaon beam is incident on a proton target, the center of mass energy is 1.699 GeV and the center of mass momentum of either particle is 0.442 GeV/c. It is also useful to note that

$$E_{\text{cm}} dE_{\text{cm}} = m_2 dE_{1\text{lab}} = m_2 \beta_{1\text{lab}} dp_{\text{lab}}. \quad (43.7)$$

43.3. Lorentz-invariant amplitudes

The matrix elements for a scattering or decay process are written in terms of an invariant amplitude $-i\mathcal{M}$. As an example, the S -matrix for $2 \rightarrow 2$ scattering is related to \mathcal{M} by

$$\begin{aligned} \langle p'_1 p'_2 | S | p_1 p_2 \rangle &= I - i(2\pi)^4 \delta^4(p_1 + p_2 - p'_1 - p'_2) \\ &\times \frac{\mathcal{M}(p_1, p_2; p'_1, p'_2)}{(2E_1)^{1/2} (2E_2)^{1/2} (2E'_1)^{1/2} (2E'_2)^{1/2}}. \end{aligned} \quad (43.8)$$

The state normalization is such that

$$\langle p' | p \rangle = (2\pi)^3 \delta^3(\mathbf{p} - \mathbf{p}'). \quad (43.9)$$

43.4. Particle decays

The partial decay rate of a particle of mass M into n bodies in its rest frame is given in terms of the Lorentz-invariant matrix element \mathcal{M} by

$$d\Gamma = \frac{(2\pi)^4}{2M} |\mathcal{M}|^2 d\Phi_n(P; p_1, \dots, p_n), \quad (43.10)$$

where $d\Phi_n$ is an element of n -body phase space given by

$$d\Phi_n(P; p_1, \dots, p_n) = \delta^4(P - \sum_{i=1}^n p_i) \prod_{i=1}^n \frac{d^3 p_i}{(2\pi)^3 2E_i}. \quad (43.11)$$

This phase space can be generated recursively, viz.

$$\begin{aligned} d\Phi_n(P; p_1, \dots, p_n) &= d\Phi_j(q; p_1, \dots, p_j) \\ &\times d\Phi_{n-j+1}(P; q, p_{j+1}, \dots, p_n) (2\pi)^3 dq^2, \end{aligned} \quad (43.12)$$

where $q^2 = (\sum_{i=1}^j E_i)^2 - |\sum_{i=1}^j \mathbf{p}_i|^2$. This form is particularly useful in the case where a particle decays into another particle that subsequently decays.

43.4.1. Survival probability: If a particle of mass M has mean proper lifetime τ ($= 1/\Gamma$) and has momentum (E, \mathbf{p}) , then the probability that it lives for a time t_0 or greater before decaying is given by

$$P(t_0) = e^{-t_0 \Gamma / \gamma} = e^{-M t_0 \Gamma / E}, \quad (43.13)$$

and the probability that it travels a distance x_0 or greater is

$$P(x_0) = e^{-M x_0 \Gamma / |\mathbf{p}|}. \quad (43.14)$$

43.4.2. Two-body decays:

Figure 43.1: Definitions of variables for two-body decays.

In the rest frame of a particle of mass M , decaying into 2 particles labeled 1 and 2,

$$E_1 = \frac{M^2 - m_2^2 + m_1^2}{2M}, \quad (43.15)$$

$$|\mathbf{p}_1| = |\mathbf{p}_2|$$

$$= \frac{[(M^2 - (m_1 + m_2)^2)(M^2 - (m_1 - m_2)^2)]^{1/2}}{2M}, \quad (43.16)$$

and

$$d\Gamma = \frac{1}{32\pi^2} |\mathcal{M}|^2 \frac{|\mathbf{p}_1|}{M^2} d\Omega, \quad (43.17)$$

where $d\Omega = d\phi_1 d(\cos \theta_1)$ is the solid angle of particle 1. The invariant mass M can be determined from the energies and momenta using Eq. (43.2) with $M = E_{\text{cm}}$.

43.4.3. Three-body decays:

Figure 43.2: Definitions of variables for three-body decays.

Defining $p_{ij} = p_i + p_j$ and $m_{ij}^2 = p_{ij}^2$, then $m_{12}^2 + m_{23}^2 + m_{13}^2 = M^2 + m_1^2 + m_2^2 + m_3^2$ and $m_{12}^2 = (P - p_3)^2 = M^2 + m_3^2 - 2ME_3$, where E_3 is the energy of particle 3 in the rest frame of M . In that frame, the momenta of the three decay particles lie in a plane. The relative orientation of these three momenta is fixed if their energies are known. The momenta can therefore be specified in space by giving three Euler angles (α, β, γ) that specify the orientation of the final system relative to the initial particle [1]. Then

$$d\Gamma = \frac{1}{(2\pi)^5} \frac{1}{16M} |\mathcal{M}|^2 dE_1 dE_2 d\alpha d(\cos\beta) d\gamma. \quad (43.18)$$

Alternatively

$$d\Gamma = \frac{1}{(2\pi)^5} \frac{1}{16M^2} |\mathcal{M}|^2 |\mathbf{p}_1^*| |\mathbf{p}_3| dm_{12} d\Omega_1^* d\Omega_3, \quad (43.19)$$

where $(|\mathbf{p}_1^*|, \Omega_1^*)$ is the momentum of particle 1 in the rest frame of 1 and 2, and Ω_3 is the angle of particle 3 in the rest frame of the decaying particle. $|\mathbf{p}_1^*|$ and $|\mathbf{p}_3|$ are given by

$$|\mathbf{p}_1^*| = \frac{[(m_{12}^2 - (m_1 + m_2)^2)(m_{12}^2 - (m_1 - m_2)^2)]^{1/2}}{2m_{12}}, \quad (43.20a)$$

and

$$|\mathbf{p}_3| = \frac{[(M^2 - (m_{12} + m_3)^2)(M^2 - (m_{12} - m_3)^2)]^{1/2}}{2M}. \quad (43.20b)$$

[Compare with Eq. (43.16).]

If the decaying particle is a scalar or we average over its spin states, then integration over the angles in Eq. (43.18) gives

$$\begin{aligned} d\Gamma &= \frac{1}{(2\pi)^3} \frac{1}{8M} |\overline{\mathcal{M}}|^2 dE_1 dE_2 \\ &= \frac{1}{(2\pi)^3} \frac{1}{32M^3} |\overline{\mathcal{M}}|^2 dm_{12}^2 dm_{23}^2. \end{aligned} \quad (43.21)$$

This is the standard form for the Dalitz plot.

43.4.3.1. Dalitz plot: For a given value of m_{12}^2 , the range of m_{23}^2 is determined by its values when \mathbf{p}_2 is parallel or antiparallel to \mathbf{p}_3 :

$$(m_{23}^2)_{\max} = (E_2^* + E_3^*)^2 - \left(\sqrt{E_2^{*2} - m_2^2} - \sqrt{E_3^{*2} - m_3^2} \right)^2, \quad (43.22a)$$

$$(m_{23}^2)_{\min} = (E_2^* + E_3^*)^2 - \left(\sqrt{E_2^{*2} - m_2^2} + \sqrt{E_3^{*2} - m_3^2} \right)^2. \quad (43.22b)$$

Here $E_2^* = (m_{12}^2 - m_1^2 + m_2^2)/2m_{12}$ and $E_3^* = (M^2 - m_{12}^2 - m_3^2)/2m_{12}$ are the energies of particles 2 and 3 in the m_{12} rest frame. The scatter plot in m_{12}^2 and m_{23}^2 is called a Dalitz plot. If $|\overline{\mathcal{M}}|^2$ is constant, the allowed region of the plot will be uniformly populated with events [see Eq. (43.21)]. A nonuniformity in the plot gives immediate information on $|\overline{\mathcal{M}}|^2$. For example, in the case of $D \rightarrow K\pi\pi$, bands appear when $m_{(K\pi)} = m_{K^*(892)}$, reflecting the appearance of the decay chain $D \rightarrow K^*(892)\pi \rightarrow K\pi\pi$.

43.4.4. Kinematic limits :

43.4.4.1. Three-body decays: In a three-body decay (Fig. 43.2) the maximum of $|\mathbf{p}_3|$, [given by Eq. (43.20)], is achieved when $m_{12} = m_1 + m_2$, *i.e.*, particles 1 and 2 have the same vector velocity in the rest frame of the decaying particle. If, in addition, $m_3 > m_1, m_2$, then $|\mathbf{p}_3|_{\max} > |\mathbf{p}_1|_{\max}, |\mathbf{p}_2|_{\max}$. The distribution of m_{12} values possesses an end-point or maximum value at $m_{12} = M - m_3$. This can be used to constrain the mass difference of a parent particle and one invisible decay product.

Figure 43.3: Dalitz plot for a three-body final state. In this example, the state is π^+K^0p at 3 GeV. Four-momentum conservation restricts events to the shaded region.

43.4.4.2. Sequential two-body decays:

Figure 43.4: Particles participating in sequential two-body decay chain. Particles labeled 1 and 2 are visible while the particle terminating the chain (a) is invisible.

When a heavy particle initiates a sequential chain of two-body decays terminating in an invisible particle, constraints on the masses of the states participating in the chain can be obtained from end-points and thresholds in invariant mass distributions of the aggregated decay products. For the two-step decay chain depicted in Fig. 43.4 the invariant mass distribution of the two visible particles possesses an end-point given by:

$$(m_{12}^{\max})^2 = \frac{(m_c^2 - m_b^2)(m_b^2 - m_a^2)}{m_b^2}, \quad (43.23)$$

provided particles 1 and 2 are massless. If visible particle 1 has non-zero mass m_1 then Eq. (43.23) is replaced by

$$(m_{12}^{\max})^2 = m_1^2 + \frac{(m_c^2 - m_b^2)}{2m_b^2} \times \left(m_1^2 + m_b^2 - m_a^2 + \sqrt{(-m_1^2 + m_b^2 - m_a^2)^2 - 4m_1^2 m_a^2} \right). \quad (43.24)$$

See Refs. 2 and 3 for other cases.

43.4.5. Multibody decays : The above results may be generalized to final states containing any number of particles by combining some of the particles into “effective particles” and treating the final states as 2 or 3 “effective particle” states. Thus, if $p_{ijk\dots} = p_i + p_j + p_k + \dots$, then

$$m_{ijk\dots} = \sqrt{p_{ijk\dots}^2}, \quad (43.25)$$

and $m_{ijk\dots}$ may be used in place of *e.g.*, m_{12} in the relations in Sec. 43.4.3 or Sec. 43.4.4 above.

43.5. Cross sections

Figure 43.5: Definitions of variables for production of an n -body final state.

The differential cross section is given by

$$d\sigma = \frac{(2\pi)^4 |\mathcal{M}|^2}{4\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}} \times d\Phi_n(p_1 + p_2; p_3, \dots, p_{n+2}). \quad (43.26)$$

[See Eq. (43.11).] In the rest frame of m_2 (lab),

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = m_2 p_{1\text{lab}}; \quad (43.27a)$$

while in the center-of-mass frame

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = p_{1\text{cm}} \sqrt{s}. \quad (43.27b)$$

43.5.1. Two-body reactions :

Figure 43.6: Definitions of variables for a two-body final state.

Two particles of momenta p_1 and p_2 and masses m_1 and m_2 scatter to particles of momenta p_3 and p_4 and masses m_3 and m_4 ; the Lorentz-invariant Mandelstam variables are defined by

$$s = (p_1 + p_2)^2 = (p_3 + p_4)^2 = m_1^2 + 2E_1 E_2 - 2\mathbf{p}_1 \cdot \mathbf{p}_2 + m_2^2, \quad (43.28)$$

$$t = (p_1 - p_3)^2 = (p_2 - p_4)^2 = m_1^2 - 2E_1 E_3 + 2\mathbf{p}_1 \cdot \mathbf{p}_3 + m_3^2, \quad (43.29)$$

$$u = (p_1 - p_4)^2 = (p_2 - p_3)^2 = m_1^2 - 2E_1 E_4 + 2\mathbf{p}_1 \cdot \mathbf{p}_4 + m_4^2, \quad (43.30)$$

and they satisfy

$$s + t + u = m_1^2 + m_2^2 + m_3^2 + m_4^2. \quad (43.31)$$

The two-body cross section may be written as

$$\frac{d\sigma}{dt} = \frac{1}{64\pi s} \frac{1}{|\mathbf{p}_{1\text{cm}}|^2} |\mathcal{M}|^2. \quad (43.32)$$

In the center-of-mass frame

$$t = (E_{1\text{cm}} - E_{3\text{cm}})^2 - (p_{1\text{cm}} - p_{3\text{cm}})^2 - 4p_{1\text{cm}} p_{3\text{cm}} \sin^2(\theta_{\text{cm}}/2) = t_0 - 4p_{1\text{cm}} p_{3\text{cm}} \sin^2(\theta_{\text{cm}}/2), \quad (43.33)$$

where θ_{cm} is the angle between particle 1 and 3. The limiting values t_0 ($\theta_{\text{cm}} = 0$) and t_1 ($\theta_{\text{cm}} = \pi$) for $2 \rightarrow 2$ scattering are

$$t_0(t_1) = \left[\frac{m_1^2 - m_3^2 - m_2^2 + m_4^2}{2\sqrt{s}} \right]^2 - (p_{1\text{cm}} \mp p_{3\text{cm}})^2. \quad (43.34)$$

In the literature the notation t_{min} (t_{max}) for t_0 (t_1) is sometimes used, which should be discouraged since $t_0 > t_1$. The center-of-mass energies and momenta of the incoming particles are

$$E_{1\text{cm}} = \frac{s + m_1^2 - m_2^2}{2\sqrt{s}}, \quad E_{2\text{cm}} = \frac{s + m_2^2 - m_1^2}{2\sqrt{s}}, \quad (43.35)$$

For $E_{3\text{cm}}$ and $E_{4\text{cm}}$, change m_1 to m_3 and m_2 to m_4 . Then

$$p_{i\text{cm}} = \sqrt{E_{i\text{cm}}^2 - m_i^2} \text{ and } p_{1\text{cm}} = \frac{p_{1\text{lab}} m_2}{\sqrt{s}}. \quad (43.36)$$

Here the subscript lab refers to the frame where particle 2 is at rest. [For other relations see Eqs. (43.2)–(43.4).]

43.5.2. Inclusive reactions : Choose some direction (usually the beam direction) for the z -axis; then the energy and momentum of a particle can be written as

$$E = m_T \cosh y, \quad p_x, p_y, p_z = m_T \sinh y, \quad (43.37)$$

where m_T , conventionally called the ‘transverse mass’, is given by

$$m_T^2 = m^2 + p_x^2 + p_y^2. \quad (43.38)$$

and the rapidity y is defined by

$$y = \frac{1}{2} \ln \left(\frac{E + p_z}{E - p_z} \right)$$

$$= \ln \left(\frac{E + p_z}{m_T} \right) = \tanh^{-1} \left(\frac{p_z}{E} \right). \quad (43.39)$$

Note that the definition of the transverse mass in Eq. (43.38) differs from that used by experimentalists at hadron colliders (see Sec. 43.6.1 below). Under a boost in the z -direction to a frame with velocity β , $y \rightarrow y - \tanh^{-1} \beta$. Hence the shape of the rapidity distribution dN/dy is invariant, as are differences in rapidity. The invariant cross section may also be rewritten

$$E \frac{d^3\sigma}{d^3p} = \frac{d^3\sigma}{d\phi dy p_T dp_T} \Rightarrow \frac{d^2\sigma}{\pi dy d(p_T^2)}. \quad (43.40)$$

The second form is obtained using the identity $dy/dp_z = 1/E$, and the third form represents the average over ϕ .

Feynman’s x variable is given by

$$x = \frac{p_z}{p_{z\text{max}}} \approx \frac{E + p_z}{(E + p_z)_{\text{max}}} \quad (p_T \ll |p_z|). \quad (43.41)$$

In the c.m. frame,

$$x \approx \frac{2p_{z\text{cm}}}{\sqrt{s}} = \frac{2m_T \sinh y_{\text{cm}}}{\sqrt{s}} \quad (43.42)$$

and

$$= (y_{\text{cm}})_{\text{max}} = \ln(\sqrt{s}/m). \quad (43.43)$$

The invariant mass M of the two-particle system described in Sec. 43.4.2 can be written in terms of these variables as

$$M^2 = m_1^2 + m_2^2 + 2[E_T(1)E_T(2) \cosh \Delta y - \mathbf{p}_T(1) \cdot \mathbf{p}_T(2)], \quad (43.44)$$

where

$$E_T(i) = \sqrt{|\mathbf{p}_T(i)|^2 + m_i^2}, \quad (43.45)$$

and $\mathbf{p}_T(i)$ denotes the transverse momentum vector of particle i .

For $p \gg m$, the rapidity [Eq. (43.39)] may be expanded to obtain

$$y = \frac{1}{2} \ln \frac{\cos^2(\theta/2) + m^2/4p^2 + \dots}{\sin^2(\theta/2) + m^2/4p^2 + \dots} \approx -\ln \tan(\theta/2) \equiv \eta \quad (43.46)$$

where $\cos \theta = p_z/p$. The pseudorapidity η defined by the second line is approximately equal to the rapidity y for $p \gg m$ and $\theta \gg 1/\gamma$, and in any case can be measured when the mass and momentum of the particle are unknown. From the definition one can obtain the identities

$$\sinh \eta = \cot \theta, \quad \cosh \eta = 1/\sin \theta, \quad \tanh \eta = \cos \theta. \quad (43.47)$$

43.5.3. Partial waves : The amplitude in the center of mass for elastic scattering of spinless particles may be expanded in Legendre polynomials

$$f(k, \theta) = \frac{1}{k} \sum_{\ell} (2\ell + 1) a_{\ell} P_{\ell}(\cos \theta), \quad (43.48)$$

where k is the c.m. momentum, θ is the c.m. scattering angle, $a_{\ell} = (\eta_{\ell} e^{2i\delta_{\ell}} - 1)/2i$, $0 \leq \eta_{\ell} \leq 1$, and δ_{ℓ} is the phase shift of the ℓ^{th} partial wave. For purely elastic scattering, $\eta_{\ell} = 1$. The differential cross section is

$$\frac{d\sigma}{d\Omega} = |f(k, \theta)|^2. \quad (43.49)$$

The optical theorem states that

$$\sigma_{\text{tot}} = \frac{4\pi}{k} \text{Im} f(k, 0), \quad (43.50)$$

and the cross section in the ℓ^{th} partial wave is therefore bounded:

$$\sigma_{\ell} = \frac{4\pi}{k^2} (2\ell + 1) |a_{\ell}|^2 \leq \frac{4\pi(2\ell + 1)}{k^2}. \quad (43.51)$$

The evolution with energy of a partial-wave amplitude a_{ℓ} can be displayed as a trajectory in an Argand plot, as shown in Fig. 43.7.

Figure 43.7: Argand plot showing a partial-wave amplitude a_{ℓ} as a function of energy. The amplitude leaves the unitary circle where inelasticity sets in ($\eta_{\ell} < 1$).

The usual Lorentz-invariant matrix element \mathcal{M} (see Sec. 43.3 above) for the elastic process is related to $f(k, \theta)$ by

$$\mathcal{M} = -8\pi\sqrt{s} f(k, \theta), \quad (43.52)$$

so

$$\sigma_{\text{tot}} = -\frac{1}{2p_{\text{lab}} m_2} \text{Im} \mathcal{M}(t = 0), \quad (43.53)$$

where s and t are the center-of-mass energy squared and momentum transfer squared, respectively (see Sec. 43.4.1).

43.5.3.1. Resonances: The Breit-Wigner (nonrelativistic) form for an elastic amplitude a_{ℓ} with a resonance at c.m. energy E_R , elastic width Γ_{el} , and total width Γ_{tot} is

$$a_{\ell} = \frac{\Gamma_{\text{el}}/2}{E_R - E - i\Gamma_{\text{tot}}/2}, \quad (43.54)$$

where E is the c.m. energy. As shown in Fig. 43.8, in the absence of background the elastic amplitude traces a counterclockwise circle with center $ix_{\text{el}}/2$ and radius $x_{\text{el}}/2$, where the elasticity $x_{\text{el}} = \Gamma_{\text{el}}/\Gamma_{\text{tot}}$. The amplitude has a pole at $E = E_R - i\Gamma_{\text{tot}}/2$.

The spin-averaged Breit-Wigner cross section for a spin- J resonance produced in the collision of particles of spin S_1 and S_2 is

$$\sigma_{BW}(E) = \frac{(2J+1)}{(2S_1+1)(2S_2+1)} \frac{\pi}{k^2} \frac{B_{\text{in}} B_{\text{out}} \Gamma_{\text{tot}}^2}{(E - E_R)^2 + \Gamma_{\text{tot}}^2/4}, \quad (43.55)$$

where k is the c.m. momentum, E is the c.m. energy, and B_{in} and B_{out} are the branching fractions of the resonance into the entrance and exit channels. The $2S+1$ factors are the multiplicities of the incident spin states, and are replaced by 2 for photons. This expression is valid only for an isolated state. If the width is not small, Γ_{tot} cannot be treated as a constant independent of E . There are many other forms for σ_{BW} , all of which are equivalent to the one given here in the narrow-width case. Some of these forms may be more appropriate if the resonance is broad.

Figure 43.8: Argand plot for a resonance.

The relativistic Breit-Wigner form corresponding to Eq. (43.54) is:

$$a_{\ell} = \frac{-m\Gamma_{\text{el}}}{s - m^2 + im\Gamma_{\text{tot}}}. \quad (43.56)$$

A better form incorporates the known kinematic dependences, replacing $m\Gamma_{\text{tot}}$ by $\sqrt{s}\Gamma_{\text{tot}}(s)$, where $\Gamma_{\text{tot}}(s)$ is the width the resonance particle would have if its mass were \sqrt{s} , and correspondingly $m\Gamma_{\text{el}}$ by $\sqrt{s}\Gamma_{\text{el}}(s)$ where $\Gamma_{\text{el}}(s)$ is the partial width in the incident channel for a mass \sqrt{s} :

$$a_{\ell} = \frac{-\sqrt{s}\Gamma_{\text{el}}(s)}{s - m^2 + i\sqrt{s}\Gamma_{\text{tot}}(s)}. \quad (43.57)$$

For the Z boson, all the decays are to particles whose masses are small enough to be ignored, so on dimensional grounds $\Gamma_{\text{tot}}(s) = \sqrt{s}\Gamma_0/m_Z$, where Γ_0 defines the width of the Z , and $\Gamma_{\text{el}}(s)/\Gamma_{\text{tot}}(s)$ is constant. A full treatment of the line shape requires consideration of dynamics, not just kinematics. For the Z this is done by calculating the radiative corrections in the Standard Model.

43.6. Transverse variables

At hadron colliders, a significant and unknown proportion of the energy of the incoming hadrons in each event escapes down the beam-pipe. Consequently if invisible particles are created in the final state, their net momentum can only be constrained in the plane transverse to the beam direction. Defining the z -axis as the beam direction, this net momentum is equal to the missing transverse energy vector

$$\mathbf{E}_T^{\text{miss}} = -\sum_i \mathbf{p}_T(i), \quad (43.58)$$

where the sum runs over the transverse momenta of all visible final state particles.

43.6.1. Single production with semi-invisible final state :

Consider a single heavy particle of mass M produced in association with visible particles which decays as in Fig. 43.1 to two particles, of which one (labeled particle 1) is invisible. The mass of the parent particle can be constrained with the quantity M_T defined by

$$M_T^2 \equiv [E_T(1) + E_T(2)]^2 - [\mathbf{p}_T(1) + \mathbf{p}_T(2)]^2 = m_1^2 + m_2^2 + 2[E_T(1)E_T(2) - \mathbf{p}_T(1) \cdot \mathbf{p}_T(2)], \quad (43.59)$$

where

$$\mathbf{p}_T(1) = \mathbf{E}_T^{\text{miss}}. \quad (43.60)$$

This quantity is called the ‘transverse mass’ by hadron collider experimentalists but it should be noted that it is quite different from that used in the description of inclusive reactions [Eq. (43.38)]. The distribution of event M_T values possesses an end-point at $M_T^{\text{max}} = M$. If $m_1 = m_2 = 0$ then

$$M_T^2 = 2|\mathbf{p}_T(1)||\mathbf{p}_T(2)|(1 - \cos \phi_{12}), \quad (43.61)$$

where ϕ_{ij} is defined as the angle between particles i and j in the transverse plane.

43.6.2. Pair production with semi-invisible final states :

Figure 43.9: Definitions of variables for pair production of semi-invisible final states. Particles 1 and 3 are invisible while particles 2 and 4 are visible.

Consider two identical heavy particles of mass M produced such that their combined center-of-mass is at rest in the transverse plane (Fig. 43.9). Each particle decays to a final state consisting of an invisible particle of fixed mass m_1 together with an additional visible particle. M and m_1 can be constrained with the variables M_{T2} and M_{CT} which are defined in Refs. [4] and [5].

44. CROSS-SECTION FORMULAE FOR SPECIFIC PROCESSES

Revised October 2009 by H. Baer (University of Oklahoma) and R.N. Cahn (LBNL).

PART I: STANDARD MODEL PROCESSES

Setting aside leptoproduction (for which, see Sec. 16 of this *Review*), the cross sections of primary interest are those with light incident particles, e^+e^- , $\gamma\gamma$, $q\bar{q}$, gq , gg , etc., where g and q represent gluons and light quarks. The produced particles include both light particles and heavy ones - t , W , Z , and the Higgs boson H . We provide the production cross sections calculated within the Standard Model for several such processes.

44.1. Resonance Formation

Resonant cross sections are generally described by the Breit-Wigner formula (Sec. 18 of this *Review*).

$$\sigma(E) = \frac{2J+1}{(2S_1+1)(2S_2+1)} \frac{4\pi}{k^2} \left[\frac{\Gamma^2/4}{(E-E_0)^2 + \Gamma^2/4} \right] B_{in} B_{out}, \quad (44.1)$$

where E is the c.m. energy, J is the spin of the resonance, and the number of polarization states of the two incident particles are $2S_1+1$ and $2S_2+1$. The c.m. momentum in the initial state is k , E_0 is the c.m. energy at the resonance, and Γ is the full width at half maximum height of the resonance. The branching fraction for the resonance into the initial-state channel is B_{in} and into the final-state channel is B_{out} . For a narrow resonance, the factor in square brackets may be replaced by $\pi\Gamma\delta(E-E_0)/2$.

44.2. Production of light particles

The production of point-like, spin-1/2 fermions in e^+e^- annihilation through a virtual photon, $e^+e^- \rightarrow \gamma^* \rightarrow ff$, at c.m. energy squared s is given by

$$\frac{d\sigma}{d\Omega} = N_c \frac{\alpha^2}{4s} \beta [1 + \cos^2\theta + (1-\beta^2)\sin^2\theta] Q_f^2, \quad (44.2)$$

where β is v/c for the produced fermions in the c.m., θ is the c.m. scattering angle, and Q_f is the charge of the fermion. The factor N_c is 1 for charged leptons and 3 for quarks. In the ultrarelativistic limit, $\beta \rightarrow 1$,

$$\sigma = N_c Q_f^2 \frac{4\pi\alpha^2}{3s} = N_c Q_f^2 \frac{86.8 \text{ nb}}{s(\text{GeV}^2)}. \quad (44.3)$$

The cross section for the annihilation of a $q\bar{q}$ pair into a distinct pair $q'\bar{q}'$ through a gluon is completely analogous up to color factors, with the replacement $\alpha \rightarrow \alpha_s$. Treating all quarks as massless, averaging over the colors of the initial quarks and defining $t = -s\sin^2(\theta/2)$, $u = -s\cos^2(\theta/2)$, one finds [1]

$$\frac{d\sigma}{d\Omega}(q\bar{q} \rightarrow q'\bar{q}') = \frac{\alpha_s^2}{9s} \frac{t^2 + u^2}{s^2}. \quad (44.4)$$

Crossing symmetry gives

$$\frac{d\sigma}{d\Omega}(qq' \rightarrow qq') = \frac{\alpha_s^2}{9s} \frac{s^2 + u^2}{t^2}. \quad (44.5)$$

If the quarks q and q' are identical, we have

$$\frac{d\sigma}{d\Omega}(q\bar{q} \rightarrow q\bar{q}) = \frac{\alpha_s^2}{9s} \left[\frac{t^2 + u^2}{s^2} + \frac{s^2 + u^2}{t^2} - \frac{2u^2}{3st} \right], \quad (44.6)$$

and by crossing

$$\frac{d\sigma}{d\Omega}(qq \rightarrow qq) = \frac{\alpha_s^2}{9s} \left[\frac{t^2 + s^2}{u^2} + \frac{s^2 + u^2}{t^2} - \frac{2s^2}{3ut} \right]. \quad (44.7)$$

Annihilation of e^+e^- into $\gamma\gamma$ has the cross section

$$\frac{d\sigma}{d\Omega}(e^+e^- \rightarrow \gamma\gamma) = \frac{\alpha^2}{2s} \frac{u^2 + t^2}{tu}. \quad (44.8)$$

The related QCD process also has a triple-gluon coupling. The cross section is

$$\frac{d\sigma}{d\Omega}(q\bar{q} \rightarrow gg) = \frac{8\alpha_s^2}{27s} (t^2 + u^2) \left(\frac{1}{tu} - \frac{9}{4s^2} \right). \quad (44.9)$$

The crossed reactions are

$$\frac{d\sigma}{d\Omega}(gq \rightarrow gq) = \frac{\alpha_s^2}{9s} (s^2 + u^2) \left(-\frac{1}{su} + \frac{9}{4t^2} \right) \quad (44.10)$$

and

$$\frac{d\sigma}{d\Omega}(gg \rightarrow q\bar{q}) = \frac{\alpha_s^2}{24s} (t^2 + u^2) \left(\frac{1}{tu} - \frac{9}{4s^2} \right). \quad (44.11)$$

Finally,

$$\frac{d\sigma}{d\Omega}(gg \rightarrow gg) = \frac{9\alpha_s^2}{8s} \left(3 - \frac{ut}{s^2} - \frac{su}{t^2} - \frac{st}{u^2} \right). \quad (44.12)$$

Lepton-quark scattering is analogous (neglecting Z exchange)

$$\frac{d\sigma}{d\Omega}(e_q q \rightarrow e_q q) = \frac{\alpha^2}{2s} e_q^2 \frac{s^2 + u^2}{t^2}. \quad (44.13)$$

where e_q is the charge of the quark. For neutrino scattering with the four-Fermi interaction

$$\frac{d\sigma}{d\Omega}(\nu d \rightarrow \ell^- u) = \frac{G_F^2 s}{4\pi^2}, \quad (44.14)$$

where the Cabibbo angle suppression is ignored. Similarly

$$\frac{d\sigma}{d\Omega}(\nu \bar{u} \rightarrow \ell^+ \bar{d}) = \frac{G_F^2 s}{4\pi^2} \frac{(1 + \cos\theta)^2}{4}. \quad (44.15)$$

To obtain the formulae for deep inelastic scattering (presented in more detail in Section 16) we consider quarks of type i carrying a fraction $x = Q^2/(2M\nu)$ of the nucleon's energy, where $\nu = E - E'$ is the energy lost by the lepton in the nucleon rest frame. With $y = \nu/E$ we have the correspondences

$$\begin{aligned} 1 + \cos\theta &\rightarrow 2(1-y), \\ d\Omega_{cm} &\rightarrow 4\pi f_i(x) dx dy, \end{aligned} \quad (44.16)$$

where the latter incorporates the quark distribution, $f_i(x)$. In this way we find

$$\begin{aligned} \frac{d\sigma}{dx dy}(eN \rightarrow eX) &= \frac{4\pi\alpha^2 xs}{Q^4} \frac{1}{2} \left[1 + (1-y)^2 \right] \\ &\times \left[\frac{4}{9}(u(x) + \bar{u}(x) + \dots) + \frac{1}{9}(d(x) + \bar{d}(x) + \dots) \right] \end{aligned} \quad (44.17)$$

where now $s = 2ME$ is the cm energy squared for the electron-nucleon collision and we have suppressed contributions from higher mass quarks.

Similarly,

$$\frac{d\sigma}{dx dy}(\nu N \rightarrow \ell^- X) = \frac{G_F^2 xs}{\pi} [(d(x) + \dots) + (1-y)^2(\bar{u}(x) + \dots)] \quad (44.18)$$

and

$$\frac{d\sigma}{dx dy}(\bar{\nu} N \rightarrow \ell^+ X) = \frac{G_F^2 xs}{\pi} [\bar{d}(x) + \dots + (1-y)^2(u(x) + \dots)]. \quad (44.19)$$

Quasi-elastic neutrino scattering ($\nu_\mu n \rightarrow \mu^- p$, $\bar{\nu}_\mu p \rightarrow \mu^+ n$) is directly related to the crossed reaction, neutron decay. The formula for the differential cross section is presented, for example, in N.J. Baker *et al.*, Phys. Rev. **D23**, 2499 (1981).

44.3. Hadroproduction of heavy quarks

For hadroproduction of heavy quarks $Q = c, b, t$, it is important to include mass effects in the formulae. For $q\bar{q} \rightarrow Q\bar{Q}$, one has

$$\frac{d\sigma}{d\Omega}(q\bar{q} \rightarrow Q\bar{Q}) = \frac{\alpha_s^2}{9s^3} \left[(m_Q^2 - t)^2 + (m_Q^2 - u)^2 + 2m_Q^2 s \right], \quad (44.20)$$

while for $gg \rightarrow Q\bar{Q}$ one has

$$\begin{aligned} \frac{d\sigma}{d\Omega}(gg \rightarrow Q\bar{Q}) &= \frac{\alpha_s^2}{32s} \left[\frac{6}{s^2} (m_Q^2 - t)(m_Q^2 - u) - \frac{m_Q^2(s - 4m_Q^2)}{3(m_Q^2 - t)(m_Q^2 - u)} + \right. \\ &\quad \frac{4}{3} \frac{(m_Q^2 - t)(m_Q^2 - u) - 2m_Q^2(m_Q^2 + t)}{(m_Q^2 - t)^2} \\ &\quad + \frac{4}{3} \frac{(m_Q^2 - t)(m_Q^2 - u) - 2m_Q^2(m_Q^2 + u)}{(m_Q^2 - u)^2} \\ &\quad - \left[3 \frac{(m_Q^2 - t)(m_Q^2 - u) + m_Q^2(u - t)}{s(m_Q^2 - t)} \right. \\ &\quad \left. \left. - 3 \frac{(m_Q^2 - t)(m_Q^2 - u) + m_Q^2(t - u)}{s(m_Q^2 - u)} \right] \right]. \quad (44.21) \end{aligned}$$

44.4. Production of Weak Gauge Bosons

44.4.1. W and Z resonant production :

Resonant production of a single W or Z is governed by the partial widths

$$\Gamma(W \rightarrow \ell_i \bar{\nu}_i) = \frac{\sqrt{2} G_F m_W^3}{12\pi} \quad (44.22)$$

$$\Gamma(W \rightarrow q_i \bar{q}_j) = 3 \frac{\sqrt{2} G_F |V_{ij}|^2 m_W^3}{12\pi} \quad (44.23)$$

$$\begin{aligned} \Gamma(Z \rightarrow f\bar{f}) &= N_c \frac{\sqrt{2} G_F m_Z^3}{6\pi} \\ &\quad \times \left[(T_3 - Q_f \sin^2 \theta_W)^2 + (Q_f \sin \theta_W)^2 \right]. \quad (44.24) \end{aligned}$$

The weak mixing angle is θ_W . The CKM matrix elements are indicated by V_{ij} and N_c is 3 for $q\bar{q}$ final states and 1 for leptonic final states.

The full differential cross section for $f_i \bar{f}_j \rightarrow (W, Z) \rightarrow f'_i \bar{f}'_j$ is given by

$$\begin{aligned} \frac{d\sigma}{d\Omega} &= \frac{N_c^f}{N_c^i} \cdot \frac{1}{256\pi^2 s} \cdot \frac{s^2}{(s - M^2)^2 + s\Gamma^2} \\ &\quad \times \left[(L^2 + R^2)(L'^2 + R'^2)(1 + \cos^2 \theta) \right. \\ &\quad \left. + (L^2 - R^2)(L'^2 - R'^2) 2 \cos \theta \right] \quad (44.25) \end{aligned}$$

where M is the mass of the W or Z . The couplings for the W are $L = (8G_F m_W^2 / \sqrt{2})^{1/2} V_{ij} / \sqrt{2}$; $R = 0$ where V_{ij} is the corresponding CKM matrix element, with an analogous expression for L' and R' . For Z , the couplings are $L = (8G_F m_Z^2 / \sqrt{2})^{1/2} (T_3 - \sin^2 \theta_W Q)$; $R = -(8G_F m_Z^2 / \sqrt{2})^{1/2} \sin^2 \theta_W Q$, where T_3 is the weak isospin of the initial left-handed fermion and Q is the initial fermion's electric charge. The expressions for L' and R' are analogous. The color factors $N_c^{i,f}$ are 3 for initial or final quarks and 1 for initial or final leptons.

44.4.2. Production of pairs of weak gauge bosons :

The cross section for $f\bar{f} \rightarrow W^+ W^-$ is given in term of the couplings of the left-handed and right-handed fermion f , $\ell = 2(T_3 - Qx_W)$, $r = -2Qx_W$, where T_3 is the third component of weak isospin for the left-handed f , Q is its electric charge (in units of the proton charge), and $x_W = \sin^2 \theta_W$:

$$\begin{aligned} \frac{d\sigma}{dt} &= \frac{2\pi\alpha^2}{N_c s^2} \left\{ \left[\left(Q + \frac{\ell + r}{4x_W} \frac{s}{s - m_Z^2} \right)^2 + \left(\frac{\ell - r}{4x_W} \frac{s}{s - m_Z^2} \right)^2 \right] A(s, t, u) \right. \\ &\quad + \frac{1}{2x_W} \left(Q + \frac{\ell}{2x_W} \frac{s}{s - m_Z^2} \right) (\Theta(-Q)I(s, t, u) - \Theta(Q)I(s, u, t)) \\ &\quad \left. + \frac{1}{8x_W^2} (\Theta(-Q)E(s, t, u) + \Theta(Q)E(s, u, t)) \right\}, \quad (44.26) \end{aligned}$$

where $\Theta(x)$ is 1 for $x > 0$ and 0 for $x < 0$, and where

$$\begin{aligned} A(s, t, u) &= \left(\frac{tu}{m_W^4} - 1 \right) \left(\frac{1}{4} - \frac{m_W^2}{s} + 3 \frac{m_W^4}{s^2} \right) + \frac{s}{m_W^2} - 4, \\ I(s, t, u) &= \left(\frac{tu}{m_W^4} - 1 \right) \left(\frac{1}{4} - \frac{m_W^2}{2s} - \frac{m_W^4}{st} \right) + \frac{s}{m_W^2} - 2 + 2 \frac{m_W^2}{t}, \\ E(s, t, u) &= \left(\frac{tu}{m_W^4} - 1 \right) \left(\frac{1}{4} + \frac{m_W^4}{t^2} \right) + \frac{s}{m_W^2}, \quad (44.27) \end{aligned}$$

and s, t, u are the usual Mandelstam variables with $s = (p_f + p_{\bar{f}})^2$, $t = (p_f - p_{W^-})^2$, $u = (p_f - p_{W^+})^2$. The factor N_c is 3 for quarks and 1 for leptons.

The analogous cross-section for $q_i \bar{q}_j \rightarrow W^\pm Z^0$ is

$$\begin{aligned} \frac{d\sigma}{dt} &= \frac{\pi\alpha^2 |V_{ij}|^2}{6s^2 x_W^2} \left\{ \left(\frac{1}{s - m_W^2} \right)^2 \left[\left(\frac{9 - 8x_W}{4} \right) (ut - m_W^2 m_Z^2) \right. \right. \\ &\quad \left. \left. + (8x_W - 6) s (m_W^2 + m_Z^2) \right] \right. \\ &\quad + \left[\frac{ut - m_W^2 m_Z^2 - s(m_W^2 + m_Z^2)}{s - m_W^2} \right] \left[\frac{\ell_j}{t} - \frac{\ell_i}{u} \right] \\ &\quad \left. + \frac{ut - m_W^2 m_Z^2}{4(1 - x_W)} \left[\frac{\ell_j^2}{t^2} + \frac{\ell_i^2}{u^2} \right] + \frac{s(m_W^2 + m_Z^2)}{2(1 - x_W)} \frac{\ell_i \ell_j}{tu} \right\}, \quad (44.28) \end{aligned}$$

where ℓ_i and ℓ_j are the couplings of the left-handed q_i and q_j as defined above. The CKM matrix element between q_i and q_j is V_{ij} .

The cross section for $q_i \bar{q}_i \rightarrow Z^0 Z^0$ is

$$\frac{d\sigma}{dt} = \frac{\pi\alpha^2}{96} \frac{\ell_i^4 + r_i^4}{x_W^2 (1 - x_W^2)^2 s^2} \left[\frac{t}{u} + \frac{u}{t} + \frac{4m_Z^2 s}{tu} - m_Z^4 \left(\frac{1}{t^2} + \frac{1}{u^2} \right) \right]. \quad (44.29)$$

44.5. Production of Higgs Bosons

44.5.1. Resonant Production :

The Higgs boson of the Standard Model can be produced resonantly in the collisions of quarks, leptons, W or Z bosons, gluons, or photons. The production cross section is thus controlled by the partial width of the Higgs boson into the entrance channel and its total width. The branching fractions for the Standard Model Higgs boson are shown in Fig. 1 of the ‘‘Searches for Higgs bosons’’ review in the Particle Listings section, as a function of the Higgs boson mass. The partial widths are given by the relations

$$\Gamma(H \rightarrow f\bar{f}) = \frac{G_F m_f^2 m_H N_c}{4\pi\sqrt{2}} \left(1 - 4m_f^2/m_H^2 \right)^{3/2}, \quad (44.30)$$

$$\Gamma(H \rightarrow W^+ W^-) = \frac{G_F m_H^3 \beta_W}{32\pi\sqrt{2}} \left(4 - 4a_W + 3a_W^2 \right), \quad (44.31)$$

$$\Gamma(H \rightarrow ZZ) = \frac{G_F m_H^3 \beta_Z}{64\pi\sqrt{2}} \left(4 - 4a_Z + 3a_Z^2 \right), \quad (44.32)$$

where N_c is 3 for quarks and 1 for leptons and where $a_W = 1 - \beta_W^2 = 4m_W^2/m_H^2$ and $a_Z = 1 - \beta_Z^2 = 4m_Z^2/m_H^2$. The decay to two gluons proceeds through quark loops, with the t quark dominating [2]. Explicitly,

$$\Gamma(H \rightarrow gg) = \frac{\alpha_s^2 G_F m_H^3}{36\pi^3 \sqrt{2}} \left| \sum_q I(m_q^2/m_H^2) \right|^2, \quad (44.33)$$

where $I(z)$ is complex for $z < 1/4$. For $z < 2 \times 10^{-3}$, $|I(z)|$ is small so the light quarks contribute negligibly. For $m_H < 2m_t$, $z > 1/4$ and

$$I(z) = 3 \left[2z + 2z(1-4z) \left(\sin^{-1} \frac{1}{2\sqrt{z}} \right)^2 \right], \quad (44.34)$$

which has the limit $I(z) \rightarrow 1$ as $z \rightarrow \infty$.

44.5.2. Higgs Boson Production in W^* and Z^* decay :

The Standard Model Higgs boson can be produced in the decay of a virtual W or Z ("Higgsstrahlung") [3,4]: In particular, if k is the c.m. momentum of the Higgs boson,

$$\sigma(q_i \bar{q}_j \rightarrow WH) = \frac{\pi \alpha^2 |V_{ij}|^2}{36 \sin^4 \theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_W^2}{(s - m_W^2)^2} \quad (44.35)$$

$$\sigma(f \bar{f} \rightarrow ZH) = \frac{2\pi \alpha^2 (\ell_f^2 + r_f^2)}{48 N_c \sin^4 \theta_W \cos^4 \theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_Z^2}{(s - m_Z^2)^2}, \quad (44.36)$$

where ℓ and r are defined as above.

44.5.3. W and Z Fusion :

Just as high-energy electrons can be regarded as sources of virtual photon beams, at very high energies they are sources of virtual W and Z beams. For Higgs boson production, it is the longitudinal components of the W s and Z s that are important [5]. The distribution of longitudinal W s carrying a fraction y of the electron's energy is [6]

$$f(y) = \frac{g^2}{16\pi^2} \frac{1-y}{y}, \quad (44.37)$$

where $g = e/\sin \theta_W$. In the limit $s \gg m_H \gg m_W$, the partial decay rate is $\Gamma(H \rightarrow W_L W_L) = (g^2/64\pi)(m_H^3/m_W^2)$ and in the equivalent W approximation [7]

$$\sigma(e^+ e^- \rightarrow \bar{\nu}_e \nu_e H) = \frac{1}{16m_W^2} \left(\frac{\alpha}{\sin^2 \theta_W} \right)^3 \times \left[\left(1 + \frac{m_H^2}{s} \right) \log \frac{s}{m_H^2} - 2 + 2 \frac{m_H^2}{s} \right]. \quad (44.38)$$

There are significant corrections to this relation when m_H is not large compared to m_W [8]. For $m_H = 150$ GeV, the estimate is too high by 51% for $\sqrt{s} = 1000$ GeV, 32% too high at $\sqrt{s} = 2000$ GeV, and 22% too high at $\sqrt{s} = 4000$ GeV. Fusion of ZZ to make a Higgs boson can be treated similarly. Identical formulae apply for Higgs production in the collisions of quarks whose charges permit the emission of a W^+ and a W^- , except that QCD corrections and CKM matrix elements are required. Even in the absence of QCD corrections, the fine-structure constant ought to be evaluated at the scale of the collision, say m_W . All quarks contribute to the ZZ fusion process.

44.6. Inclusive hadronic reactions

One-particle inclusive cross sections $E d^3\sigma/d^3p$ for the production of a particle of momentum p are conveniently expressed in terms of rapidity y (see above) and the momentum p_T transverse to the beam direction (in the c.m.):

$$E \frac{d^3\sigma}{d^3p} = \frac{d^3\sigma}{d\phi dy p_T dp_T^2}. \quad (44.39)$$

In appropriate circumstances, the cross section may be decomposed as a partonic cross section multiplied by the probabilities of finding partons of the prescribed momenta:

$$\sigma_{\text{hadronic}} = \sum_{ij} \int dx_1 dx_2 f_i(x_1) f_j(x_2) d\hat{\sigma}_{\text{partonic}}, \quad (44.40)$$

The probability that a parton of type i carries a fraction of the incident particle's that lies between x_1 and $x_1 + dx_1$ is $f_i(x_1)dx_1$ and similarly for partons in the other incident particle. The partonic collision is specified by its c.m. energy squared $\hat{s} = x_1 x_2 s$ and the momentum transfer squared \hat{t} . The final hadronic state is more conveniently specified by the rapidities y_1, y_2 of the two jets resulting from the collision and the transverse momentum p_T . The connection between the differentials is

$$dx_1 dx_2 d\hat{t} = dy_1 dy_2 \frac{\hat{s}}{s} dp_T^2, \quad (44.41)$$

so that

$$\frac{d^3\sigma}{dy_1 dy_2 dp_T^2} = \frac{\hat{s}}{s} \left[f_i(x_1) f_j(x_2) \frac{d\hat{\sigma}}{d\hat{t}}(\hat{s}, \hat{t}, \hat{u}) + f_i(x_2) f_j(x_1) \frac{d\hat{\sigma}}{d\hat{t}}(\hat{s}, \hat{u}, \hat{t}) \right], \quad (44.42)$$

where we have taken into account the possibility that the incident parton types might arise from either incident particle. The second term should be dropped if the types are identical: $i = j$.

44.7. Two-photon processes

In the Weizsäcker-Williams picture, a high-energy electron beam is accompanied by a spectrum of virtual photons of energies ω and invariant-mass squared $q^2 = -Q^2$, for which the photon number density is

$$dn = \frac{\alpha}{\pi} \left[1 - \frac{\omega}{E} + \frac{\omega^2}{E^2} - \frac{m_e^2 \omega^2}{Q^2 E^2} \right] \frac{d\omega dQ^2}{\omega Q^2}, \quad (44.43)$$

where E is the energy of the electron beam. The cross section for $e^+ e^- \rightarrow e^+ e^- X$ is then [9]

$$d\sigma_{e^+ e^- \rightarrow e^+ e^- X}(s) = dn_1 dn_2 d\sigma_{\gamma\gamma \rightarrow X}(W^2), \quad (44.44)$$

where $W^2 = m_X^2$. Integrating from the lower limit $Q^2 =$

$m_e^2 \frac{\omega_i^2}{E_i(E_i - \omega_i)}$ to a maximum Q^2 gives

$$\sigma_{e^+ e^- \rightarrow e^+ e^- X}(s) = \frac{\alpha^2}{\pi^2} \int_{z_{th}}^1 \frac{dz}{z} \times \left[\left(\ln \frac{Q_{max}^2}{z m_e^2} - 1 \right)^2 f(z) + \frac{1}{3} (\ln z)^3 \right] \sigma_{\gamma\gamma \rightarrow X}(zs), \quad (44.45)$$

where

$$f(z) = \left(1 + \frac{1}{2} z \right)^2 \ln(1/z) - \frac{1}{2} (1-z)(3+z). \quad (44.46)$$

The appropriate value of Q_{max}^2 depends on the properties of the produced system X . For production of hadronic systems, $Q_{max}^2 \approx m_\rho^2$, while for lepton-pair production, $Q^2 \approx W^2$. For production of a resonance with spin $J \neq 1$, we have

$$\sigma_{e^+e^- \rightarrow e^+e^-R}(s) = (2J+1) \frac{8\alpha^2 \Gamma_{R \rightarrow \gamma\gamma}}{m_R^3} \times \left[f(m_R^2/s) \left(\ln \frac{m_V^2 s}{m_e^2 m_R^2} - 1 \right)^2 - \frac{1}{3} \left(\ln \frac{s}{M_R^2} \right)^3 \right], \quad (44.47)$$

where m_V is the mass that enters into the form factor for the $\gamma\gamma \rightarrow R$ transition, typically m_ρ .

PART II: PROCESSES BEYOND THE STANDARD MODEL

44.8. Production of supersymmetric particles

In supersymmetric (SUSY) theories (see Supersymmetric Particle Searches in this *Review*), every boson has a fermionic superpartner, and every fermion has a bosonic superpartner. The minimal supersymmetric Standard Model (MSSM) is a direct supersymmetrization of the Standard Model (SM), although a second Higgs doublet is needed to avoid triangle anomalies [10]. Under soft SUSY breaking, superpartner masses are lifted above the SM particle masses. In weak scale SUSY, the superpartners are invoked to stabilize the weak scale under radiative corrections, so the superpartners are expected to have masses of order the TeV scale.

44.8.1. Gluino and squark production :

The superpartners of gluons are the color octet, spin- $\frac{1}{2}$ gluinos (\tilde{g}), while each helicity component of quark flavor has a spin-0 squark partner, e.g. \tilde{q}_L and \tilde{q}_R . Third generation left- and right- squarks are expected to have large mixing, resulting in mass eigenstates \tilde{q}_1 and \tilde{q}_2 , with $m_{\tilde{q}_1} < m_{\tilde{q}_2}$ (here, q denotes any of the SM flavors of quarks and \tilde{q}_i the corresponding flavor and type ($i = L, R$ or $1, 2$) of squark). Gluino pair production ($\tilde{g}\tilde{g}$) takes place via either glue-gluon or quark-antiquark annihilation [11].

The subprocess cross sections are usually presented as differential distributions in the Mandelstam variables s , t and u . Note that for a $2 \rightarrow 2$ scattering subprocess $ab \rightarrow cd$, the Mandelstam variable $s = (p_a + p_b)^2 = (p_c + p_d)^2$, where p_a is the 4-momentum of particle a , and so forth. The variable $t = (p_c - p_a)^2$, where c and a are taken conventionally to be the most similar particles in the subprocess. The variable u would then be equal to $(p_d - p_a)^2$. Note that since s , t and u are squares of 4-vectors, they are invariants in any inertial reference frame.

Gluino pair production at hadron colliders is described by:

$$\begin{aligned} \frac{d\sigma}{dt}(gg \rightarrow \tilde{g}\tilde{g}) &= \frac{9\pi\alpha_s^2}{4s^2} \left\{ \frac{2(m_g^2 - t)(m_g^2 - u)}{s^2} \right. \\ &+ \frac{(m_g^2 - t)(m_g^2 - u) - 2m_g^2(m_g^2 + t)}{(m_g^2 - t)^2} \\ &+ \frac{(m_g^2 - t)(m_g^2 - u) - 2m_g^2(m_g^2 + u)}{(m_g^2 - u)^2} + \frac{m_g^2(s - 4m_g^2)}{(m_g^2 - t)(m_g^2 - u)} \\ &\left. - \frac{(m_g^2 - t)(m_g^2 - u) + m_g^2(u - t)}{s(m_g^2 - t)} - \frac{(m_g^2 - t)(m_g^2 - u) + m_g^2(t - u)}{s(m_g^2 - u)} \right\}, \quad (44.48) \end{aligned}$$

where α_s is the strong fine structure constant. Also,

$$\begin{aligned} \frac{d\sigma}{dt}(q\bar{q} \rightarrow \tilde{g}\tilde{g}) &= \frac{8\pi\alpha_s^2}{9s^2} \left\{ \frac{4}{3} \left(\frac{m_g^2 - t}{m_q^2 - t} \right)^2 + \frac{4}{3} \left(\frac{m_g^2 - u}{m_q^2 - u} \right)^2 \right. \\ &+ \frac{3}{s^2} \left[(m_g^2 - t)^2 + (m_g^2 - u)^2 + 2m_g^2 s \right] - 3 \frac{(m_g^2 - t)^2 + m_g^2 s}{s(m_q^2 - t)} \\ &\left. - 3 \frac{(m_g^2 - u)^2 + m_g^2 s}{s(m_q^2 - u)} + \frac{1}{3} \frac{m_g^2 s}{(m_q^2 - t)(m_q^2 - u)} \right\}. \quad (44.49) \end{aligned}$$

Gluinos can also be produced in association with squarks: $\tilde{g}\tilde{q}_i$ production, where \tilde{q}_i represents any of the various types (left-, right- or mixed) and flavors of squarks. The subprocess cross section is independent of whether the squark is the right-, left- or mixed type:

$$\begin{aligned} \frac{d\sigma}{dt}(gq \rightarrow \tilde{g}\tilde{q}_i) &= \frac{\pi\alpha_s^2}{24s^2} \left[\frac{16}{3}(s^2 + (m_{\tilde{q}_i}^2 - u)^2) + \frac{4}{3}s(m_{\tilde{q}_i}^2 - u) \right] \\ &\times \left((m_g^2 - u)^2 + (m_{\tilde{q}_i}^2 - m_g^2)^2 + \frac{2sm_g^2(m_{\tilde{q}_i}^2 - m_g^2)}{(m_g^2 - t)} \right). \quad (44.50) \end{aligned}$$

There are many different subprocesses for production of squark pairs. Since left- and right- squarks generally have different masses and different decay patterns, we present the differential cross section for each subprocess of \tilde{q}_i ($i = L, R$ or $1, 2$) separately. (In early literature, the following formulae were often combined into a single equation which didn't differentiate the various squark types.) The result for $gg \rightarrow \tilde{q}_i\tilde{q}_i$ is:

$$\begin{aligned} \frac{d\sigma}{dt}(gg \rightarrow \tilde{q}_i\tilde{q}_i) &= \frac{\pi\alpha_s^2}{4s^2} \left\{ \frac{1}{3} \left(\frac{m_q^2 + t}{m_q^2 - t} \right)^2 + \frac{1}{3} \left(\frac{m_q^2 + u}{m_q^2 - u} \right)^2 \right. \\ &+ \frac{3}{32s^2} \left(8s(4m_q^2 - s) + 4(u - t)^2 \right) + \frac{7}{12} \\ &- \frac{1}{48} \frac{(4m_q^2 - s)^2}{(m_q^2 - t)(m_q^2 - u)} \\ &+ \frac{3}{32} \frac{[(t - u)(4m_q^2 + 4t - s) - 2(m_q^2 - u)(6m_q^2 + 2t - s)]}{s(m_q^2 - t)} \\ &+ \frac{3}{32} \frac{[(u - t)(4m_q^2 + 4u - s) - 2(m_q^2 - t)(6m_q^2 + 2u - s)]}{s(m_q^2 - u)} \\ &\left. + \frac{7}{96} \frac{[4m_q^2 + 4t - s]}{m_q^2 - t} + \frac{7}{96} \frac{[4m_q^2 + 4u - s]}{m_q^2 - u} \right\}, \quad (44.51) \end{aligned}$$

which has an obvious $u \leftrightarrow t$ symmetry.

For $q\bar{q} \rightarrow \tilde{q}_i\tilde{q}_i$ with the same initial and final state flavors, we have

$$\begin{aligned} \frac{d\sigma}{dt}(q\bar{q} \rightarrow \tilde{q}_i\tilde{q}_i) &= \frac{2\pi\alpha_s^2}{9s^2} \left\{ \frac{1}{(t - m_q^2)^2} + \frac{2}{s^2} - \frac{2/3}{s(t - m_q^2)} \right\} \\ &\times \left[-st - (t - m_{\tilde{q}_i}^2)^2 \right], \quad (44.52) \end{aligned}$$

while if initial and final state flavors are different ($q\bar{q} \rightarrow \tilde{q}_i\tilde{q}_j$) we instead have

$$\frac{d\sigma}{dt}(q\bar{q} \rightarrow \tilde{q}_i\tilde{q}_j) = \frac{4\pi\alpha_s^2}{9s^4} \left[-st - (t - m_{\tilde{q}_i}^2)^2 \right]. \quad (44.53)$$

If the two initial state quarks are of different flavors, then we have

$$\frac{d\sigma}{dt}(q\bar{q}' \rightarrow \tilde{q}_i\tilde{q}_j) = \frac{2\pi\alpha_s^2 - st - (t - m_{\tilde{q}_i}^2)^2}{9s^2 (t - m_q^2)^2}. \quad (44.54)$$

If the initial quarks are of different flavor and final state squarks are of different type ($i \neq j$) then

$$\frac{d\sigma}{dt}(q\bar{q}' \rightarrow \tilde{q}_i\tilde{q}_j) = \frac{2\pi\alpha_s^2}{9s^2} \frac{m_g^2 s}{(t - m_q^2)^2}. \quad (44.55)$$

For same-flavor initial state quarks, but final state unlike-type squarks, we also have

$$\frac{d\sigma}{dt}(q\bar{q} \rightarrow \tilde{q}_i\tilde{q}_j) = \frac{2\pi\alpha_s^2}{9s^2} \frac{m_g^2 s}{(t - m_q^2)^2}. \quad (44.56)$$

There also exist cross sections for quark-quark annihilation to squark pairs. For same flavor quark-quark annihilation to same flavor/same type final state squarks,

$$\begin{aligned} \frac{d\sigma}{dt}(qq \rightarrow \tilde{q}_i \tilde{q}_i) &= \\ &= \frac{\pi\alpha_s^2 m_g^2 s}{9s^2} \left\{ \frac{1}{(t-m_g^2)^2} + \frac{1}{(u-m_g^2)^2} - \frac{2/3}{(t-m_g^2)(u-m_g^2)} \right\}, \end{aligned} \quad (44.57)$$

while if the final type squarks are different ($i \neq j$), we have

$$\begin{aligned} \frac{d\sigma}{dt}(qq \rightarrow \tilde{q}_i \tilde{q}_j) &= \\ \frac{2\pi\alpha_s^2}{9s^2} \left\{ \frac{[-st - (t-m_{\tilde{q}_i}^2)(t-m_{\tilde{q}_j}^2)]}{(t-m_g^2)} + \frac{[-su - (u-m_{\tilde{q}_i}^2)(u-m_{\tilde{q}_j}^2)]}{(u-m_g^2)} \right\}. \end{aligned} \quad (44.58)$$

If initial/final state flavors are different, but final state squark types are the same, then

$$\frac{d\sigma}{dt}(qq' \rightarrow \tilde{q}_i \tilde{q}_i) = \frac{2\pi\alpha_s^2 m_g^2 s}{9s^2 (t-m_g^2)^2}. \quad (44.59)$$

If initial quark flavors are different and final squark types are different, then

$$\frac{d\sigma}{dt}(qq' \rightarrow \tilde{q}_i \tilde{q}_j) = \frac{2\pi\alpha_s^2 (-st - (t-m_{\tilde{q}_i}^2)(t-m_{\tilde{q}_j}^2))}{9s^2 (t-m_g^2)^2}. \quad (44.60)$$

44.8.2. Gluino and squark associated production :

In the MSSM, the charged spin- $\frac{1}{2}$ winos and higgsinos mix to make chargino states $\chi_{1,2}^{\pm}$, with $m_{\chi_1^{\pm}} < m_{\chi_2^{\pm}}$. The spin- $\frac{1}{2}$ neutral bino, wino and higgsino fields mix to give four neutralino mass eigenstates $\chi_{1,2,3,4}^0$ ordered according to mass. We sometimes denote the charginos and neutralinos collectively as -inos for notational simplicity

For gluino and squark production in association with charginos and neutralinos [12], the quark-squark-neutralino couplings* are defined by the interaction Lagrangian terms $\mathcal{L}_{f\tilde{f}\tilde{\chi}_i^0} = \left[iA_{\tilde{\chi}_i^0}^f \tilde{f}_L^\dagger \tilde{\chi}_i^0 P_L f + iB_{\tilde{\chi}_i^0}^f \tilde{f}_R^\dagger \tilde{\chi}_i^0 P_R f + \text{h.c.} \right]$, where $A_{\tilde{\chi}_i^0}^f$ and $B_{\tilde{\chi}_i^0}^f$ are coupling constants involving gauge couplings, neutralino mixing elements and in the case of third generation fermions, Yukawa couplings. Their form depends on the conventions used for setting up the MSSM Lagrangian, and can be found in various reviews [13] and textbooks [14,15]. P_L and P_R are the usual left- and right-spinor projection operators and f denotes any of the SM fermions u, d, e, ν_e, \dots . The fermion-sfermion- chargino couplings have the form $\mathcal{L} = \left[iA_{\tilde{\chi}_i^{\pm}}^d \tilde{u}_L^\dagger \tilde{\chi}_i^{\pm} P_L d + iA_{\tilde{\chi}_i^{\pm}}^u \tilde{d}_L^\dagger \tilde{\chi}_i^{\pm} P_L u + \text{h.c.} \right]$ for u and d quarks, where the $A_{\tilde{\chi}_i^{\pm}}^d$ and $A_{\tilde{\chi}_i^{\pm}}^u$ couplings are again convention-dependent, and can be found in textbooks. The superscript c denotes ‘‘charge conjugate spinor’’, defined by $\psi^c \equiv C\bar{\psi}^T$.

The subprocess cross sections for chargino-squark associated production occur via squark exchange and are given by

$$\frac{d\sigma}{dt}(\bar{u}g \rightarrow \tilde{\chi}_i^- \tilde{d}_L) = \frac{\alpha_s}{24s^2} |A_{\tilde{\chi}_i^-}^u|^2 \psi(m_{\tilde{d}_L}, m_{\tilde{\chi}_i^-}, t), \quad (44.61)$$

$$\frac{d\sigma}{dt}(dg \rightarrow \tilde{\chi}_i^- \tilde{u}_L) = \frac{\alpha_s}{24s^2} |A_{\tilde{\chi}_i^-}^d|^2 \psi(m_{\tilde{u}_L}, m_{\tilde{\chi}_i^-}, t), \quad (44.62)$$

* The couplings $A_{\tilde{\chi}_i^0}^f$ and $B_{\tilde{\chi}_i^0}^f$ are given explicitly in Ref. 15 in Eq. (8.87). Also, the couplings $A_{\tilde{\chi}_i^{\pm}}^d$ and $A_{\tilde{\chi}_i^{\pm}}^u$ are given in Eq. (8.93). The couplings X_i^j and Y_i^j are given by Eq. (8.103), while the x_i and y_i couplings are given in Eq. (8.100). Finally, the couplings W_{ij} are given in Eq. (8.101).

while neutralino-squark production is given by

$$\frac{d\sigma}{dt}(qg \rightarrow \tilde{\chi}_i^0 \tilde{q}) = \frac{\alpha_s}{24s^2} \left(|A_{\tilde{\chi}_i^0}^q|^2 + |B_{\tilde{\chi}_i^0}^q|^2 \right) \psi(m_{\tilde{q}}, m_{\tilde{\chi}_i^0}, t), \quad (44.63)$$

where

$$\begin{aligned} \psi(m_1, m_2, t) &= \frac{s+t-m_1^2}{2s} - \frac{m_1^2(m_2^2-t)}{(m_1^2-t)^2} \\ &+ \frac{t(m_2^2-m_1^2) + m_2^2(s-m_2^2+m_1^2)}{s(m_1^2-t)}. \end{aligned} \quad (44.64)$$

Here, the variable t is given by the square of ‘‘squark-minus-quark’’ four-momentum. The neutralino-gluino associated production cross section also occurs via squark exchange and is given by

$$\begin{aligned} \frac{d\sigma}{dt}(q\bar{q} \rightarrow \tilde{\chi}_i^0 \tilde{g}) &= \frac{\alpha_s}{18s^2} \left(|A_{\tilde{\chi}_i^0}^q|^2 + |B_{\tilde{\chi}_i^0}^q|^2 \right) \left[\frac{(m_{\tilde{\chi}_i^0}^2-t)(m_g^2-t)}{(m_g^2-t)^2} \right. \\ &+ \left. \frac{(m_{\tilde{\chi}_i^0}^2-u)(m_g^2-u)}{(m_g^2-u)^2} - \frac{2\eta_i \eta_{\tilde{g}} m_{\tilde{g}} m_{\tilde{\chi}_i^0} s}{(m_g^2-t)(m_g^2-u)} \right], \end{aligned} \quad (44.65)$$

where η_i is the sign of the neutralino mass eigenvalue and $\eta_{\tilde{g}}$ is the sign of the gluino mass eigenvalue. We also have chargino-gluino associated production:

$$\begin{aligned} \frac{d\sigma}{dt}(\bar{u}d \rightarrow \tilde{\chi}_i^- \tilde{g}) &= \frac{\alpha_s}{18s^2} \left[|A_{\tilde{\chi}_i^-}^u|^2 \frac{(m_{\tilde{\chi}_i^-}^2-t)(m_g^2-t)}{(m_{\tilde{d}_L}^2-t)^2} \right. \\ &+ |A_{\tilde{\chi}_i^-}^d|^2 \frac{(m_{\tilde{\chi}_i^-}^2-u)(m_g^2-u)}{(m_{\tilde{u}_L}^2-u)^2} + \left. \frac{2\eta_{\tilde{g}} \text{Re}(A_{\tilde{\chi}_i^-}^u A_{\tilde{\chi}_i^-}^d) m_{\tilde{g}} m_{\tilde{\chi}_i^-} s}{(m_{\tilde{d}_L}^2-t)(m_{\tilde{u}_L}^2-u)} \right], \end{aligned} \quad (44.66)$$

where $\hat{t} = (\tilde{g} - d)^2$ and in the third term one must take the real part of the in general complex coupling constant product.

44.8.3. Slepton and sneutrino production :

The subprocess cross section for $\tilde{\ell}_L \tilde{\nu}_{\ell L}$ production ($\ell = e$ or μ) occurs via s -channel W exchange and is given by

$$\frac{d\sigma}{dt}(d\bar{u} \rightarrow \tilde{\ell}_L \tilde{\nu}_{\ell L}) = \frac{g^4 |D_W(s)|^2}{192\pi s^2} \left(tu - m_{\tilde{\ell}_L}^2 m_{\tilde{\nu}_{\ell L}}^2 \right), \quad (44.67)$$

where $D_W(s) = 1/(s - M_W^2 + iM_W\Gamma_W)$ is the W -boson propagator denominator. The production of $\tilde{\tau}_1 \tilde{\nu}_{\tau}$ is given as above, but replacing $m_{\tilde{\ell}_L} \rightarrow m_{\tilde{\tau}_1}$, $m_{\tilde{\nu}_{\ell L}} \rightarrow m_{\tilde{\nu}_{\tau}}$ and multiplying by an overall factor of $\cos^2 \theta_{\tau}$ (where θ_{τ} is the tau-slepton mixing angle). Similar substitutions hold for $\tilde{\tau}_2 \tilde{\nu}_{\tau}$ production, except the overall factor is $\sin^2 \theta_{\tau}$.

Table 44.1: The constants α_f and β_f that appear in in the SM neutral current Lagrangian. Here $t \equiv \tan \theta_W$ and $c \equiv \cot \theta_W$.

f	q_f	α_f	β_f
ℓ	-1	$\frac{1}{4}(3t-c)$	$\frac{1}{4}(t+c)$
ν_{ℓ}	0	$\frac{1}{4}(t+c)$	$-\frac{1}{4}(t+c)$
u	$\frac{2}{3}$	$-\frac{5}{12}t + \frac{1}{4}c$	$-\frac{1}{4}(t+c)$
d	$-\frac{1}{3}$	$\frac{1}{12}t - \frac{1}{4}c$	$\frac{1}{4}(t+c)$

The subprocess cross section for $\tilde{\ell}_L \bar{\ell}_L$ production occurs via s -channel γ and Z exchange, and depends on the neutral current interaction, with fermion couplings to γ and Z^0 given by $\mathcal{L}_{\text{neutral}} = -e q_f \bar{f} \gamma^\mu f A_\mu + e \bar{f} \gamma^\mu (\alpha_f + \beta_f \gamma_5) f Z_\mu$ (with values of q_f , α_f , and β_f given in Table 44.1.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(q\bar{q} \rightarrow \tilde{\ell}_L \bar{\ell}_L) = \frac{e^4}{24\pi s^2} (tu - m_{\tilde{\ell}_L}^4) \times \left\{ \frac{q_\ell^2 q_q^2}{s^2} + (\alpha_\ell - \beta_\ell)^2 (\alpha_q^2 + \beta_q^2) |D_Z(s)|^2 + \frac{2q_\ell q_q \alpha_q (\alpha_\ell - \beta_\ell) (s - M_Z^2)}{s} |D_Z(s)|^2 \right\}, \quad (44.68)$$

where $D_Z(s) = 1/(s - M_Z^2 + iM_Z\Gamma_Z)$. The cross section for sneutrino production is given by the same formula, but with α_ℓ , β_ℓ , q_ℓ and $m_{\tilde{\ell}_L}$ replaced by α_ν , β_ν , 0 and $m_{\tilde{\nu}_L}$, respectively. The cross section for $\tilde{\tau}_1 \bar{\tau}_1$ production is obtained by replacing $m_{\tilde{\ell}_L} \rightarrow m_{\tilde{\tau}_1}$ and $\beta_\ell \rightarrow \beta_\ell \cos 2\theta_\tau$.

The cross section for $\tilde{\ell}_R \bar{\ell}_R$ production is given by substituting $\alpha_\ell - \beta_\ell \rightarrow \alpha_\ell + \beta_\ell$ and $m_{\tilde{\ell}_L} \rightarrow m_{\tilde{\ell}_R}$ in the equation above. The cross section for $\tilde{\tau}_2 \bar{\tau}_2$ production is obtained from the formula for $\tilde{\ell}_R \bar{\ell}_R$ production by replacing $m_{\tilde{\ell}_R} \rightarrow m_{\tilde{\tau}_2}$ and $\beta_\ell \rightarrow \beta_\ell \cos 2\theta_\tau$.

Finally, the cross section for $\tilde{\tau}_1 \bar{\tau}_2$ production occurs only via Z exchange, and is given by

$$\frac{d\sigma}{dt}(q\bar{q} \rightarrow \tilde{\tau}_1 \bar{\tau}_2) = \frac{d\sigma}{dt}(q\bar{q} \rightarrow \tilde{\tau}_1 \bar{\tau}_2) = \frac{e^4}{24\pi s^2} (\alpha_q^2 + \beta_q^2) \beta_\ell^2 \sin^2 2\theta_\tau |D_Z(s)|^2 (ut - m_{\tilde{\tau}_1}^2 m_{\tilde{\tau}_2}^2). \quad (44.69)$$

44.8.4. Chargino and neutralino pair production :

44.8.4.1. $\tilde{\chi}_i^- \tilde{\chi}_j^0$ production:

The subprocess cross section for $d\bar{u} \rightarrow \tilde{\chi}_i^- \tilde{\chi}_j^0$ depends on Lagrangian couplings $\mathcal{L}_{W\bar{u}d} = -\frac{g}{\sqrt{2}} \bar{u} \gamma_\mu P_L d W^{+\mu} + \text{h.c.}$, $\mathcal{L}_{W\tilde{\chi}_i^- \tilde{\chi}_j^0} = -g(-i)^{\theta_j} \bar{\tilde{\chi}}_i^- [X_i^j + Y_i^j \gamma_5] \gamma_\mu \tilde{\chi}_j^0 W^{-\mu} + \text{h.c.}$, $\mathcal{L}_{q\bar{q}\tilde{\chi}_i^-} = iA_{\tilde{\chi}_i^-}^d \bar{u} \tilde{\chi}_i^- P_L d + iA_{\tilde{\chi}_i^-}^u \bar{d} \tilde{\chi}_i^- P_L u + \text{h.c.}$ and $\mathcal{L}_{q\bar{q}\tilde{\chi}_j^0} = iA_{\tilde{\chi}_j^0}^q \bar{q} \tilde{\chi}_j^0 P_L q + \text{h.c.}$. Contributing diagrams include W exchange and also \tilde{d}_L and \tilde{u}_L squark exchange. The X_i^j and Y_i^j couplings are new, and again convention-dependent: the cross section formulae works if the interaction Lagrangian is written in the above form, so that the couplings can be suitably extracted. The term $\theta_j = 0$ (1) if $m_{\tilde{\chi}_j^0} > 0$ (< 0); it comes about because the neutralino field must be re-defined by a $-i\gamma_5$ transformation if its mass eigenvalue is negative [15]. The subprocess cross section is given in terms of dot products of four momenta, where particle labels are used to denote their four-momenta; note that all mass terms in the cross section formulae are positive definite, so that the signs of mass eigenstates have been absorbed into the Lagrangian couplings, as for instance in Ref. [15]. We then have

$$\frac{d\sigma}{dt}(d\bar{u} \rightarrow \tilde{\chi}_i^- \tilde{\chi}_j^0) = \frac{1}{192\pi s^2} \left[T_W + T_{\tilde{d}_L} + T_{\tilde{u}_L} + T_{W\tilde{d}_L} + T_{W\tilde{u}_L} + T_{\tilde{d}_L \tilde{u}_L} \right] \quad (44.70)$$

where

$$T_W = 8g^4 |D_W(s)|^2 \left\{ [X_i^{j2} + Y_i^{j2}] (\tilde{\chi}_j^0 \cdot d\tilde{\chi}_i^- \cdot \bar{u} + \tilde{\chi}_j^0 \cdot \bar{u}\tilde{\chi}_i^- \cdot d) + 2(X_i^j Y_i^j) (\tilde{\chi}_j^0 \cdot d\tilde{\chi}_i^- \cdot \bar{u} - \tilde{\chi}_j^0 \cdot \bar{u}\tilde{\chi}_i^- \cdot d) + [X_i^{j2} - Y_i^{j2}] m_{\tilde{\chi}_i^-} m_{\tilde{\chi}_j^0} d \cdot \bar{u} \right\}, \quad (44.71)$$

$$T_{\tilde{d}_L} = \frac{4|A_{\tilde{\chi}_i^-}^u|^2 |A_{\tilde{\chi}_j^0}^d|^2}{[(\tilde{\chi}_i^- - \bar{u})^2 - m_{\tilde{d}_L}^2]^2} d \cdot \tilde{\chi}_j^0 \tilde{\chi}_i^- \cdot \bar{u}, \quad (44.72)$$

$$T_{\tilde{u}_L} = \frac{4|A_{\tilde{\chi}_i^-}^d|^2 |A_{\tilde{\chi}_j^0}^u|^2}{[(\tilde{\chi}_j^0 - \bar{u})^2 - m_{\tilde{u}_L}^2]^2} \bar{u} \cdot \tilde{\chi}_j^0 \tilde{\chi}_i^- \cdot d \quad (44.73)$$

$$T_{W\tilde{d}_L} = \frac{-\sqrt{2}g^2 \text{Re}[A_{\tilde{\chi}_j^0}^{d*} A_{\tilde{\chi}_i^-}^u (-i)^{\theta_j}] (s - M_W^2) |D_W(s)|^2}{(\tilde{\chi}_i^- - \bar{u})^2 - m_{\tilde{d}_L}^2} \times \left\{ 8(X_i^j + Y_i^j) \tilde{\chi}_j^0 \cdot d\bar{u} \cdot \tilde{\chi}_i^- + 4(X_i^j - Y_i^j) m_{\tilde{\chi}_i^-} m_{\tilde{\chi}_j^0} d \cdot \bar{u} \right\} \quad (44.74)$$

$$T_{W\tilde{u}_L} = \frac{\sqrt{2}g^2 \text{Re}[A_{\tilde{\chi}_i^-}^{d*} A_{\tilde{\chi}_j^0}^u (-i)^{\theta_j}] (s - M_W^2) |D_W(s)|^2}{(\tilde{\chi}_j^0 - \bar{u})^2 - m_{\tilde{u}_L}^2} \times \left\{ 8(X_i^j - Y_i^j) \tilde{\chi}_j^0 \cdot \bar{u}d \cdot \tilde{\chi}_i^- + 4(X_i^j + Y_i^j) m_{\tilde{\chi}_i^-} m_{\tilde{\chi}_j^0} d \cdot \bar{u} \right\} \quad (44.75)$$

and

$$T_{\tilde{d}_L \tilde{u}_L} = -\frac{4\text{Re}[A_{\tilde{\chi}_j^0}^d A_{\tilde{\chi}_i^-}^{u*} A_{\tilde{\chi}_i^-}^{d*} A_{\tilde{\chi}_j^0}^u] m_{\tilde{\chi}_i^-} m_{\tilde{\chi}_j^0} d \cdot \bar{u}}{[(\tilde{\chi}_i^- - \bar{u})^2 - m_{\tilde{d}_L}^2][(\tilde{\chi}_j^0 - \bar{u})^2 - m_{\tilde{u}_L}^2]}. \quad (44.76)$$

44.8.4.2. Chargino pair production:

The subprocess cross section for $d\bar{d} \rightarrow \tilde{\chi}_i^- \tilde{\chi}_i^+$ ($i = 1, 2$) depends on Lagrangian couplings $\mathcal{L} = e\tilde{\chi}_i^- \gamma_\mu \tilde{\chi}_i^+ A^\mu - e \cot \theta_W \tilde{\chi}_i^- \gamma_\mu (x_i - y_i \gamma_5) \tilde{\chi}_i^+ Z^\mu$ and also $\mathcal{L} \ni iA_{\tilde{\chi}_i^-}^d \bar{u} \tilde{\chi}_i^- P_L d + iA_{\tilde{\chi}_i^-}^u \bar{d} \tilde{\chi}_i^- P_L u + \text{h.c.}$. Contributing diagrams include s -channel γ , Z^0 exchange and t -channel \tilde{u}_L exchange [16,17]. The couplings x_i and y_i are again new and as usual convention-dependent.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(d\bar{d} \rightarrow \tilde{\chi}_i^- \tilde{\chi}_i^+) = \frac{1}{192\pi s^2} [T_\gamma + T_Z + T_{\tilde{u}_L} + T_{\gamma Z} + T_{\gamma \tilde{u}_L} + T_{Z\tilde{u}_L}] \quad (44.77)$$

where

$$T_\gamma = \frac{32e^4 q_d^2}{s^2} \left[d \cdot \tilde{\chi}_i^+ \bar{d} \cdot \tilde{\chi}_i^- + d \cdot \tilde{\chi}_i^- \bar{d} \cdot \tilde{\chi}_i^+ + m_{\tilde{\chi}_i^-}^2 d \cdot \bar{d} \right] \quad (44.78)$$

$$T_Z = 32e^4 \cot^2 \theta_W |D_Z(s)|^2$$

$$\left\{ (\alpha_d^2 + \beta_d^2) (x_i^2 + y_i^2) \left[d \cdot \tilde{\chi}_i^+ \bar{d} \cdot \tilde{\chi}_i^- + d \cdot \tilde{\chi}_i^- \bar{d} \cdot \tilde{\chi}_i^+ + m_{\tilde{\chi}_i^-}^2 d \cdot \bar{d} \right] \mp 4\alpha_d \beta_d x_i y_i \left[d \cdot \tilde{\chi}_i^+ \bar{d} \cdot \tilde{\chi}_i^- - d \cdot \tilde{\chi}_i^- \bar{d} \cdot \tilde{\chi}_i^+ \right] - 2y_i^2 (\alpha_d^2 + \beta_d^2) m_{\tilde{\chi}_i^-}^2 d \cdot \bar{d} \right\}, \quad (44.79)$$

$$T_{\tilde{u}_L} = \frac{4|A_{\tilde{\chi}_i^-}^d|^4}{[(d - \tilde{\chi}_i^-)^2 - m_{\tilde{u}_L}^2]^2} d \cdot \tilde{\chi}_i^- \bar{d} \cdot \tilde{\chi}_i^+ \quad (44.80)$$

$$T_{\gamma Z} = \frac{64e^4 \cot \theta_W q_d (s - M_Z^2) |D_Z(s)|^2}{s} \times \left\{ \alpha_d x_i \left(d \cdot \tilde{\chi}_i^+ \bar{d} \cdot \tilde{\chi}_i^- + d \cdot \tilde{\chi}_i^- \bar{d} \cdot \tilde{\chi}_i^+ + m_{\tilde{\chi}_i^-}^2 d \cdot \bar{d} \right) \pm \beta_d y_i \left(d \cdot \tilde{\chi}_i^- \bar{d} \cdot \tilde{\chi}_i^+ - d \cdot \tilde{\chi}_i^+ \bar{d} \cdot \tilde{\chi}_i^- \right) \right\} \quad (44.81)$$

$$T_{\gamma \tilde{u}_L} = \mp \frac{8e^2 q_d}{s} \frac{|A_{\tilde{\chi}_i^-}^d|^2}{[(d - \tilde{\chi}_i^-)^2 - m_{\tilde{u}_L}^2]} \left\{ 2\bar{d} \cdot \tilde{\chi}_i^+ d \cdot \tilde{\chi}_i^- + m_{\tilde{\chi}_i^-}^2 d \cdot \bar{d} \right\} \quad (44.82)$$

and

$$T_{Z\tilde{u}_L} = \mp 8e^2 \cot \theta_W |D_Z(s)|^2 \frac{|A_{\tilde{\chi}_i^-}^d|^2 (s - M_Z^2)}{[(d - \tilde{\chi}_i^-)^2 - m_{\tilde{u}_L}^2]} (\alpha_d - \beta_d) \\ \times \left\{ 2(x_i \mp y_i) d \cdot \tilde{\chi}_i^- \bar{d} \cdot \tilde{\chi}_i^+ + m_{\tilde{\chi}_i^-}^2 (x_i \pm y_i) d \cdot \bar{d} \right\} \quad (44.83)$$

using the upper of the sign choices.

The cross section for $u\bar{u} \rightarrow \tilde{\chi}_i^+ \tilde{\chi}_i^-$ can be obtained from the above by replacing $\alpha_d \rightarrow \alpha_u$, $\beta_d \rightarrow \beta_u$, $q_d \rightarrow q_u$, $\tilde{u}_L \rightarrow \tilde{d}_L$, $A_{\tilde{\chi}_i^-}^d \rightarrow A_{\tilde{\chi}_i^-}^u$, $d \rightarrow \bar{u}$, $\bar{d} \rightarrow u$ and adopting the lower of the sign choices everywhere.

The cross section for $q\bar{q} \rightarrow \tilde{\chi}_1^- \tilde{\chi}_2^+$, $\tilde{\chi}_1^+ \tilde{\chi}_2^-$ can occur via Z and \tilde{q}_L exchange. It is usually much smaller than $\tilde{\chi}_{1,2}^- \tilde{\chi}_{1,2}^+$ production, so the cross section will not be presented here. It can be found in Appendix A of Ref. 15.

44.8.4.3. Neutralino pair production:

Neutralino pair production via $q\bar{q}$ fusion takes place via s -channel Z exchange plus t - and u -channel left- and right- squark exchange (5 diagrams) [17,18]. The Lagrangian couplings (see previous footnote*) needed include terms given above plus terms of the form $\mathcal{L} = W_{ij} \tilde{\chi}_i^0 \gamma^\mu (\gamma_5)^{\theta_i + \theta_j + 1} \tilde{\chi}_j^0 Z^\mu$. The couplings W_{ij} depend only on the *higgsino* components of the neutralinos i and j . The subprocess cross section is given by:

$$\frac{d\sigma}{dt}(q\bar{q} \rightarrow \tilde{\chi}_i^0 \tilde{\chi}_j^0) = \frac{1}{192\pi s^2} [T_Z + T_{\tilde{q}_L} + T_{\tilde{q}_R} + T_{Z\tilde{q}_L} + T_{Z\tilde{q}_R}] \quad (44.84)$$

where

$$T_Z = 128e^2 |W_{ij}|^2 (\alpha_q^2 + \beta_q^2) |D_Z(s)|^2 \\ \left[q \cdot \tilde{\chi}_i^0 \bar{q} \cdot \tilde{\chi}_j^0 + q \cdot \tilde{\chi}_j^0 \bar{q} \cdot \tilde{\chi}_i^0 - \eta_i \eta_j m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q} \right], \quad (44.85)$$

$$T_{\tilde{q}_L} = 4 |A_{\tilde{\chi}_i^0}^q|^2 |A_{\tilde{\chi}_j^0}^q|^2 \left\{ \frac{q \cdot \tilde{\chi}_i^0 \bar{q} \cdot \tilde{\chi}_j^0}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_L}^2]^2} + \frac{q \cdot \tilde{\chi}_j^0 \bar{q} \cdot \tilde{\chi}_i^0}{[(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_L}^2]^2} \right. \\ \left. - \eta_i \eta_j \frac{m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q}}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_L}^2][(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_L}^2]} \right\} \quad (44.86)$$

$$T_{\tilde{q}_R} = 4 |B_{\tilde{\chi}_i^0}^q|^2 |B_{\tilde{\chi}_j^0}^q|^2 \left\{ \frac{q \cdot \tilde{\chi}_i^0 \bar{q} \cdot \tilde{\chi}_j^0}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_R}^2]^2} + \frac{q \cdot \tilde{\chi}_j^0 \bar{q} \cdot \tilde{\chi}_i^0}{[(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_R}^2]^2} \right. \\ \left. - \eta_i \eta_j \frac{m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q}}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_R}^2][(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_R}^2]} \right\} \quad (44.87)$$

$$T_{Z\tilde{q}_L} = 16e(\alpha_q - \beta_q)(s - M_Z^2) |D_Z(s)|^2 \\ \left\{ \frac{\text{Re}(W_{ij} A_{\tilde{\chi}_i^0}^{q*} A_{\tilde{\chi}_j^0}^q)}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_L}^2]} \left[2q \cdot \tilde{\chi}_i^0 \bar{q} \cdot \tilde{\chi}_j^0 - \eta_i \eta_j m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q} \right] \right. \\ \left. + \eta_i \eta_j \frac{\text{Re}(W_{ij} A_{\tilde{\chi}_i^0}^q A_{\tilde{\chi}_j^0}^{q*})}{[(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_L}^2]} \left[2q \cdot \tilde{\chi}_j^0 \bar{q} \cdot \tilde{\chi}_i^0 - \eta_i \eta_j m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q} \right] \right\} \quad (44.88)$$

$$T_{Z\tilde{q}_R} = 16e(\alpha_q + \beta_q)(s - M_Z^2) |D_Z(s)|^2 \\ \left\{ \frac{\text{Re}(W_{ij} B_{\tilde{\chi}_i^0}^{q*} B_{\tilde{\chi}_j^0}^q)}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_R}^2]} \left[2q \cdot \tilde{\chi}_i^0 \bar{q} \cdot \tilde{\chi}_j^0 - \eta_i \eta_j m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q} \right] \right. \\ \left. - \frac{\text{Re}(W_{ij} B_{\tilde{\chi}_i^0}^q B_{\tilde{\chi}_j^0}^{q*})}{[(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_R}^2]} \left[2q \cdot \tilde{\chi}_j^0 \bar{q} \cdot \tilde{\chi}_i^0 - \eta_i \eta_j m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q} \right] \right\}. \quad (44.89)$$

As before, $\eta_i = \pm 1$ corresponding to whether the neutralino mass eigenvalue is positive or negative. When $i = j$ in the above formula, one must remember to integrate over just 2π steradians of solid angle to avoid double counting in the total cross section.

44.9. Universal extra dimensions

In the Universal Extra Dimension (UED) model of Ref. [19] (see Ref. [20] for a review of models with extra spacetime dimensions), the Standard Model is embedded in a five dimensional theory, where the fifth dimension is compactified on an S_1/Z_2 orbifold. Each SM chirality state is then the zero mode of an infinite tower of Kaluza-Klein excitations labelled by $n = 0 - \infty$. A KK parity is usually assumed to hold, where each state is assigned KK-parity $P = (-1)^n$. If the compactification scale is around a TeV, then the $n = 1$ (or even higher) KK modes may be accessible to collider searches.

Of interest for hadron colliders are the production of massive $n \geq 1$ quark or gluon pairs. These production cross sections have been calculated in Ref. [21,22]. We list here results for the $n = 1$ case only with $M_1 = 1/R$ (R is the compactification radius) and s , t and u are the usual Mandelstam variables; more general formulae can be found in Ref. [22]. The superscript $*$ stands for any KK excited state, while \bullet stands for left chirality states and \circ stands for right chirality states.

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2} T \quad (44.90)$$

where

$$T(q\bar{q} \rightarrow g^* g^*) = \frac{2g_s^4}{27} \left[M_1^2 \left(-\frac{4s^3}{t'^2 u'^2} + \frac{57s}{t' u'} - \frac{108}{s} \right) \right. \\ \left. + \frac{20s^2}{t' u'} - 93 + \frac{108t' u'}{s^2} \right] \quad (44.91)$$

and

$$T(gg \rightarrow g^* g^*) = \\ \frac{9g_s^4}{27} \left[3M_1^4 \frac{s^2 + t'^2 + u'^2}{t'^2 u'^2} - 3M_1^2 \frac{s^2 + t'^2 + u'^2}{s t' u'} + 1 \right. \\ \left. + \frac{(s^2 + t'^2 + u'^2)^3}{4s^2 t'^2 u'^2} - \frac{t' u'}{s^2} \right] \quad (44.92)$$

where $t' = t - M_1^2$ and $u' = u - M_1^2$.

Also,

$$T(q\bar{q} \rightarrow q_1^* \bar{q}_1^*) = \frac{4g_s^4}{9} \left[\frac{2M_1^2}{s} + \frac{t'^2 + u'^2}{s^2} \right],$$

$$T(q\bar{q} \rightarrow q_1^* \bar{q}_1^*) = \frac{g_s^4}{9} \left[2M_1^2 \left(\frac{4}{s} + \frac{s}{t'^2} - \frac{1}{t'} \right) \right. \\ \left. + \frac{23}{6} + \frac{2s^2}{t'^2} + \frac{8s}{3t'} + \frac{6t'}{s} + \frac{8t'^2}{s^2} \right],$$

$$T(qq \rightarrow q_1^* \bar{q}_1^*) = \frac{g_s^4}{27} \left[M_1^2 \left(6 \frac{t'}{u'^2} + 6 \frac{u'}{t'^2} - \frac{s}{t' u'} \right) \right. \\ \left. + 2 \left(3 \frac{t'^2}{u'^2} + 3 \frac{u'^2}{t'^2} + 4 \frac{s^2}{t' u'} - 5 \right) \right],$$

$$T(gg \rightarrow q_1^* \bar{q}_1^*) = g_s^4 \left[M_1^4 \frac{4}{t' u'} \left(\frac{s^2}{6t' u'} - \frac{3}{8} \right) \right. \\ \left. + M_1^2 \frac{4}{s} \left(\frac{s^2}{6t' u'} - \frac{3}{8} \right) + \frac{s^2}{6t' u'} - \frac{17}{24} + \frac{3t' u'}{4s^2} \right],$$

$$T(gg \rightarrow g^* q_1^*) = \frac{-g_s^4}{3} \left[\frac{5s^2}{12t'^2} + \frac{s^3}{t'^2 u'} + \frac{11s u'}{6t'^2} + \frac{5u'^2}{12t'^2} + \frac{u'^3}{s t'^2} \right],$$

$$T(qq' \rightarrow q_1^* \bar{q}_1^*) = \frac{g_s^4}{18} \left[4M_1^4 \frac{s}{t'^2} + 5 + 4 \frac{s^2}{t'^2} + 8 \frac{s}{t'} \right],$$

$$T(qq' \rightarrow q_1^* \bar{q}_1^*) = \frac{2g_s^4}{9} \left[-M_1^2 \frac{s}{t'^2} + \frac{1}{4} + \frac{s^2}{t'^2} \right],$$

$$T(qq \rightarrow q_1^{\bullet} q_1^{\circ}) = \frac{g_s^4}{9} \left[M_1^2 \left(\frac{2s^3}{t'^2 u'^2} - \frac{4s}{t' u'} \right) + 2 \frac{s^4}{t'^2 u'^2} - 8 \frac{s^2}{t' u'} + 5 \right],$$

$$T(q\bar{q}' \rightarrow q_1^{\bullet} \bar{q}_1^{\circ}) = \frac{g_s^4}{9} \left[2M_1^2 \left(\frac{1}{t'} + \frac{u'}{t'^2} \right) + \frac{5}{2} + \frac{4u'}{t'} + \frac{2u'^2}{t'^2} \right],$$

and

$$T(qq' \rightarrow q_1^{\bullet} q_1^{\circ}) = \frac{g_s^4}{9} \left[-2M_1^2 \left(\frac{1}{t'} + \frac{u'}{t'^2} \right) + \frac{1}{2} + \frac{2u'^2}{t'^2} \right].$$

44.10. Large extra dimensions

In the ADD theory [23] with large extra dimensions (LED), the SM particles are confined to a 3-brane, while gravity propagates in the bulk. It is assumed that the n extra dimensions are compactified on an n -dimensional torus of volume $(2\pi r)^n$, so that the fundamental $4+n$ dimensional Planck scale M_* is related to the usual 4-dimensional Planck scale M_{Pl} by $M_{Pl}^2 = M_*^{n+2} (2\pi r)^n$. If $M_* \sim 1$ TeV, then the $M_W - M_{Pl}$ hierarchy problem is just due to gravity propagating in the large extra dimensions.

In these theories, the KK-excited graviton states $G_{\mu\nu}^n$ for $n = 1 - \infty$ can be produced at collider experiments. The graviton couplings to matter are suppressed by $1/M_{Pl}$, so that graviton emission cross sections $d\sigma/dt \sim 1/M_{Pl}^2$. However, the mass splittings between the excited graviton states can be tiny, so the graviton eigenstates are usually approximated by a continuum distribution. A summation (integration) over all allowed graviton emissions ends up cancelling the $1/M_{Pl}^2$ factor, so that observable cross section rates can be attained. Some of the fundamental production formulae for a KK graviton (denoted G) of mass m at hadron colliders include the subprocesses

$$\frac{d\sigma_m}{dt}(f\bar{f} \rightarrow \gamma G) = \frac{\alpha Q_f^2}{16N_f s M_{Pl}^2} F_1\left(\frac{t}{s}, \frac{m^2}{s}\right), \quad (44.93)$$

where Q_f is the charge of fermion f and N_f is the number of QCD colors of f . Also,

$$\frac{d\sigma_m}{dt}(q\bar{q} \rightarrow gG) = \frac{\alpha_s}{36 s M_{Pl}^2} F_1\left(\frac{t}{s}, \frac{m^2}{s}\right), \quad (44.94)$$

$$\frac{d\sigma_m}{dt}(qq \rightarrow qG) = \frac{\alpha_s}{96 s M_{Pl}^2} F_2\left(\frac{t}{s}, \frac{m^2}{s}\right), \quad (44.95)$$

$$\frac{d\sigma_m}{dt}(gg \rightarrow gG) = \frac{3\alpha_s}{16 s M_{Pl}^2} F_3\left(\frac{t}{s}, \frac{m^2}{s}\right), \quad (44.96)$$

where

$$F_1(x, y) = \frac{1}{x(y-1-x)} \left[-4x(1+x)(1+2x+2x^2) + y(1+6x+18x^2+16x^3) - 6y^2x(1+2x) + y^3(1+4x) \right] \quad (44.97)$$

$$F_2(x, y) = -(y-1-x) F_1\left(\frac{x}{y-1-x}, \frac{y}{y-1-x}\right) \quad (44.98)$$

and

$$F_3(x, y) = \frac{1}{x(y-1-x)} \left[1 + 2x + 3x^2 + 2x^3 + x^4 - 2y(1+x^3) + 3y^2(1+x^2) - 2y^3(1+x) + y^4 \right]. \quad (44.99)$$

These formulae must then be multiplied by the graviton density of states formula $dN = S_{n-1} \frac{M_{Pl}^2}{M_*^{n+2}} m^{n-1} dm$ to gain the cross section

$$\frac{d^2\sigma}{dt dm} = S_{n-1} \frac{M_{Pl}^2}{M_*^{n+2}} m^{n-1} \frac{d\sigma_m}{dt} \quad (44.100)$$

where $S_n = \frac{(2\pi)^{n/2}}{\Gamma(n/2)}$ is the surface area of an n -dimensional sphere of unit radius.

Virtual graviton processes can also be searched for at colliders. For instance, in Ref. [24] the cross section for Drell-Yan production of lepton pairs via gluon fusion was calculated, where it is found that, in the center-of-mass system

$$\frac{d\sigma}{dz}(gg \rightarrow \ell^+ \ell^-) = \frac{\lambda^2 s^3}{64\pi M_*^8} (1-z^2)(1+z^2) \quad (44.101)$$

where $z = \cos\theta$ and λ is a model-dependent coupling constant ~ 1 . Formulae for Drell-Yan production via $q\bar{q}$ fusion can also be found in Ref. [24,25].

44.11. Warped extra dimensions

In the Randall-Sundrum model [26] of warped extra dimensions, the arena for physics is a 5-d anti-deSitter (AdS_5) spacetime, for which a non-factorizable metric exists with a metric warp factor $e^{-2\sigma(\phi)}$. It is assumed that two opposite tension 3-branes exist within AdS_5 at the two ends of an S_1/Z_2 orbifold parametrized by co-ordinate ϕ which runs from $0 - \pi$. The 4-D solution of the Einstein equations yields $\sigma(\phi) = kr_c|\phi|$, where r_c is the compactification radius of the extra dimension and $k \sim M_{Pl}$. The 4-D effective action allows one to identify $\overline{M}_{Pl}^2 = \frac{M^3}{k}(1 - e^{-2kr_c\pi})$, where M is the 5-D Planck scale. Physical particles on the TeV scale (SM) brane have mass $m = e^{-kr_c\pi} m_0$, where m_0 is a fundamental mass of order the Planck scale. Thus, the weak scale-Planck scale hierarchy occurs due to the existence of the exponential warp factor if $kr_c \sim 12$.

In the simplest versions of the RS model, the TeV-scale brane contains only SM particles plus a tower of KK gravitons. The RS gravitons have mass $m_n = kx_n e^{-kr_c\pi}$, where the x_i are roots of Bessel functions $J_1(x_n) = 0$, with $x_1 \simeq 3.83$, $x_2 \simeq 7.02$ etc. While the RS zero-mode graviton couplings suppressed by $1/\overline{M}_{Pl}$ and are thus inconsequential for collider searches, the $n=1$ and higher modes have couplings suppressed instead by $\Lambda_\pi = e^{-kr_c\pi} \overline{M}_{Pl} \sim TeV$. The $n=1$ RS graviton should have width $\Gamma_1 = \rho m_1 x_1^2 (k/\overline{M}_{Pl})^2$, where ρ is a constant depending on how many decay modes are open. The formulae for dilepton production via virtual RS graviton exchange can be gained from the above formulae for the ADD scenario via the replacement [27]

$$\frac{\lambda}{M_*^4} \rightarrow \frac{i^2}{8\Lambda_\pi^2} \sum_{n=1}^{\infty} \frac{1}{s - m_n^2 + im_n\Gamma_n}. \quad (44.102)$$

45. NEUTRINO CROSS SECTION MEASUREMENTS

Written in April 2012 by G.P. Zeller (Fermilab).

Neutrino interaction cross sections are an essential ingredient in most neutrino experiments. Interest in neutrino scattering has recently increased due to the need for such information in the interpretation of neutrino oscillation data. Scattering results on both charged current (CC) and neutral current (NC) neutrino channels have been collected over many decades using a variety of targets, analysis techniques, and detector technologies. With the advent of intense neutrino sources for oscillation measurements, experiments are remeasuring these cross sections with a renewed appreciation for nuclear effects† and precise knowledge of their incoming neutrino fluxes. This review summarizes accelerator-based neutrino cross section measurements made in the $\sim 0.1 - 300$ GeV range with an emphasis on inclusive, quasi-elastic, and single pion production processes (areas where we have the most experimental input at present). For a more comprehensive discussion of neutrino interaction cross sections, including neutrino-electron scattering and lower energy measurements, the reader is directed to a recent review of this subject [1].

by NuTeV [2] and at lower energies on argon by ArgoNeuT [3]. At high energy, the inclusive cross section is dominated by deep inelastic scattering (DIS). Several high energy neutrino experiments have measured the DIS cross sections for specific final states, for example opposite-sign dimuon production. The most recent dimuon cross section measurements include those from CHORUS [4], NOMAD [5], and NuTeV [6]. At lower neutrino energies, the inclusive cross section is largely a combination of quasi-elastic scattering and resonance production processes, two areas we will turn to next.

45.2. Quasi-elastic scattering

Historically, neutrino (or antineutrino) quasi-elastic scattering refers to the processes, $\nu_\mu n \rightarrow \mu^- p$ and $\bar{\nu}_\mu p \rightarrow \mu^+ n$, where a charged lepton and single nucleon are ejected in the elastic interaction of a neutrino (or antineutrino) with a nucleon in the target material. This is the final state one would strictly observe, for example, in scattering off of a free nucleon target. QE scattering is important as it is the dominant neutrino interaction at energies less than about 1 GeV and is a large signal sample in many neutrino oscillation experiments.

Fig. 45.1: Measurements of ν_μ and $\bar{\nu}_\mu$ CC inclusive scattering cross sections divided by neutrino energy as a function of neutrino energy. Note the transition between logarithmic and linear scales occurring at 100 GeV. Neutrino-nucleon cross sections are typically twice as large as the corresponding antineutrino cross sections, though this difference can be larger at lower energies. NC cross sections (not shown) are generally smaller (but non-negligible) compared to their CC counterparts.

45.1. Inclusive Scattering

Over the years, many experiments have measured the total cross section for neutrino ($\nu_\mu N \rightarrow \mu^- X$) and antineutrino ($\bar{\nu}_\mu N \rightarrow \mu^+ X$) scattering off nucleons covering a broad range of energies (Fig. 45.1). As can be seen, the inclusive cross section approaches a linear dependence on neutrino energy. Such behavior is expected for point-like scattering of neutrinos from quarks, an assumption which breaks down at lower energies.

To provide a more complete picture, differential cross sections for such inclusive scattering processes have also been reported on iron

† Kinematic and final state effects which impact neutrino scattering off nuclei. Note that most modern neutrino experiments use nuclear targets to increase their event yields.

Fig. 45.2 displays the current status of existing measurements of ν_μ and $\bar{\nu}_\mu$ QE scattering cross sections as a function of neutrino energy. In this plot, and all others in this review, the prediction from a representative neutrino event generator (NUANCE) [7] provides a theoretical comparator. Other generators and more sophisticated calculations exist which can give different predictions [8].

In many of these initial measurements of the neutrino QE cross section, bubble chamber experiments typically employed light targets (H_2 or D_2) and required both the detection of the final state muon and single nucleon‡; thus the final state was clear and elastic kinematic conditions could be verified. The situation is more complicated of course for heavier nuclear targets. In this case, nuclear effects can

‡ In the case of D_2 , many experiments additionally observed the spectator proton.

impact the size and shape of the cross section as well as the final state kinematics and topology. Due to intranuclear rescattering and the possible effects of correlations between target nucleons, additional nucleons may be ejected in the final state; hence, a QE interaction on a nuclear target does not always imply the ejection of a *single* nucleon. Thus, one needs to take some care in defining what one means by neutrino QE scattering when scattering off targets heavier than H_2 or D_2 . Adding to the complexity, recent measurements [9] of the ν_μ QE scattering cross section on carbon at low energy have observed a significantly larger than expected cross section, an enhancement believed to be signaling the presence of sizable nuclear effects. Such cross sections have also been reported for the first time in the form of double-differential distributions [9], thus reducing the model-dependence of the data and allowing a much more stringent test of the underlying nuclear theory. The impact of nuclear effects on neutrino QE scattering has been the subject of intense theoretical scrutiny over the past year [19] with potential implications on nucleon ejection [20], neutrino energy reconstruction [21], and the neutrino/antineutrino cross section ratio [22]. The reader is referred to a recent review of the situation in [23]. Additional measurements are clearly needed before a complete understanding is achieved. In addition to such CC investigations, measurements of the NC counterpart of this channel have also been performed. The most recent NC elastic scattering cross section measurements include those from BNL E734 [24] and MiniBooNE [25]. A number of measurements of the Cabibbo-suppressed antineutrino QE hyperon production cross section have additionally been reported [18,26], although none in recent years.

Figure 45.2: Measurements of ν_μ (black) and $\bar{\nu}_\mu$ (red) quasi-elastic scattering cross sections (per nucleon) as a function of neutrino energy. Data on a variety of nuclear targets are shown, including measurements from ANL [10], BEBC [11], BNL [12], FNAL [13], Gargamelle [14], LSND [15], MiniBooNE [9], NOMAD [16], Serpukhov [17], and SKAT [18]. Also shown is the QE free nucleon scattering prediction [7] assuming $M_A = 1.0$ GeV. This prediction is significantly altered by nuclear corrections in the case of neutrino-nucleus scattering. Care should be taken in interpreting measurements on targets heavier than deuterium.

45.3. Pion Production

In addition to such elastic processes, neutrinos can also inelastically scatter producing a nucleon excited state (Δ , N^*). Such baryonic resonances quickly decay, most often to a nucleon and single pion final state. Fig. 45.3 and Fig. 45.4 show a collection of resonance single pion production cross section data for both CC and NC neutrino scattering. Decades ago, BEBC, FNAL, Gargamelle, and SKAT also performed similar measurements for antineutrinos [27]. Most often these experiments reported measurements of NC/CC single pion cross section ratios [28].

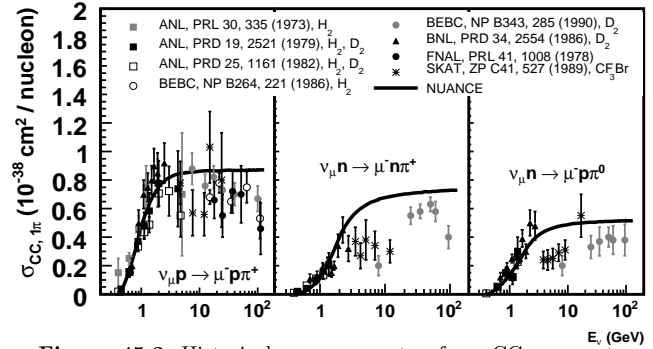

Figure 45.3: Historical measurements of ν_μ CC resonant single pion production. The data appear as reported by the experiments; no additional corrections have been applied to account for differing nuclear targets or invariant mass ranges. The free scattering prediction is from [7] with $M_A = 1.1$ GeV. Note that other absolute measurements have been made by MiniBooNE [30] but cannot be directly compared with this historical data - the modern measurements are more inclusive and have quantified the production of pions leaving the target nucleus rather than specific $\pi + N$ final states as identified at the neutrino interaction vertex.

It should be noted that baryonic resonances can also decay to multi-pion, other mesonic (K , η , ρ , etc.), and even photon final states. Experimental results for these channels are typically sparse or non-existent [1]; however, photon production processes can be an important background for $\nu_\mu \rightarrow \nu_e$ appearance searches and thus have become the focus of some recent experimental investigations [29].

Figure 45.4: Same as Fig. 45.3 but for NC neutrino (black) and antineutrino (red) scattering. The Gargamelle measurements come from a re-analysis of this data [31]. Note that more recent absolute measurements exist [32] but cannot be directly compared with this data for the same reasons as in Fig. 45.3.

In addition to resonance production processes, neutrinos can also coherently scatter off of the entire nucleus and produce a distinctly forward-scattered single pion final state. Both CC ($\nu_\mu A \rightarrow \mu^- A \pi^+$, $\bar{\nu}_\mu A \rightarrow \mu^+ A \pi^-$) and NC ($\nu_\mu A \rightarrow \nu_\mu A \pi^0$, $\bar{\nu}_\mu A \rightarrow \bar{\nu}_\mu A \pi^0$) processes are possible in this case. The level of coherent pion production is predicted to be small compared to incoherent processes [33], but observations exist across a broad energy range and on multiple nuclear targets [34–36]. Most of these measurements have been performed at energies above 2 GeV, but several modern experiments have started to search for coherent pion production at lower neutrino energies, including K2K [37], MiniBooNE [38], and SciBooNE [39].

As with QE scattering, a new appreciation for the significance of nuclear effects has surfaced in pion production channels, again due to the use of heavy targets in modern neutrino experiments. Many experiments have been careful to report cross sections for various detected final states, thereby not correcting for large and uncertain nuclear effects (e.g., pion rescattering, charge exchange, and absorption) which can introduce unwanted sources of uncertainty and

model dependence. Recent measurements of single pion cross sections, as published by K2K [40], MiniBooNE [41], and SciBooNE [42], take the form of ratios with respect to QE or CC inclusive scattering samples. Providing the most comprehensive survey of neutrino single pion production to date, MiniBooNE has recently published a total of 16 single- and double-differential cross sections for both the final state muon (in the case of CC scattering) and pion in these interactions; thus, providing the first measurements of these distributions [30,32]. Regardless of the interaction channel, such differential cross section measurements (in terms of observed final state particle kinematics) are now preferred for their reduced model dependence and for the additional kinematic information they provide. Such a new direction has been the focus of modern measurements as opposed to the reporting of (model-dependent) cross sections as a function of neutrino energy. Together with similar results for other interaction channels, a better understanding and modeling of nuclear effects will be possible moving forward.

45.4. Outlook

Coming soon, additional neutrino and antineutrino cross section measurements in the few-GeV energy range are anticipated from ArgoNeuT, MiniBooNE, MINOS, NOMAD, and SciBooNE. In addition, a few new experiments are now collecting data or will soon be commissioning their detectors. Analysis of a broad energy range of data on a variety of targets in the MINER ν A experiment will provide the most detailed analysis yet of nuclear effects in neutrino interactions. Data from ICARUS and MicroBooNE will probe deeper into complex neutrino final states using the superior capabilities of liquid argon time projection chambers, while the T2K and NO ν A near detectors will collect high statistics samples in intense neutrino beams. Together, these investigations should significantly advance our understanding of neutrino-nucleus scattering in the years to come.

46. PLOTS OF CROSS SECTIONS AND RELATED QUANTITIES

(For neutrino plots, see review article "Neutrino Cross Section Measurements" by G.P. Zeller in this edition of RPP)

Jet Production in pp and $\bar{p}p$ Interactions

Figure 46.1: Inclusive differential jet cross sections plotted as a function of the jet transverse energy. The CDF and D0 measurements use a cone algorithm of radius 0.7 for all results shown except for the CDF measurements at 1.96 TeV which also use k_T with a D parameter of 0.7 and midpoint algorithms. The cone/ k_T results should be similar if $R_{cone} = D$. UA1 (UA2) uses a non-iterative cone algorithm with a radius of 1.0 (1.3). Recent NLO QCD predictions (such as CTEQ6M) provide a good description of the CDF and D0 jet cross sections, Rept. on Prog. in Phys. **70**, 89 (2007). Comparisons with the older cross sections are more difficult due to the nature of the jet algorithms used. CDF: Phys. Rev. **D75**, 092006 (2007), Phys. Rev. **D64**, 032001 (2001), Phys. Rev. Lett. **70**, 1376 (1993); D0: Phys. Rev. **D64**, 032003 (2001); UA2: Phys. Lett. **B257**, 232 (1991); UA1: Phys. Lett. **B172**, 461 (1986); R807: Phys. Lett. **B123**, 133 (1983). (Courtesy of J. Huston, Michigan State University, 2010.)

Direct γ Production in $\bar{p}p$ Interactions

Figure 46.2: Isolated photon cross sections plotted as a function of the photon transverse momentum. The errors are either statistical only (CDF, D0 (1.96 TeV), UA1, UA2, UA6) or uncorrelated (D0 1.8 TeV, 630 GeV). The data are generally in good agreement with NLO QCD predictions, albeit with a tendency for the data to be above (below) the theory for lower (large) transverse momenta, Phys. Rev. **D59**, 074007 (1999). D0: Phys. Lett. **B639**, 151 (2006), Phys. Rev. Lett. **87**, 251805 (2001); CDF: Phys. Rev. **D65**, 112003 (2002); UA6: Phys. Lett. **B206**, 163 (1988); UA1: Phys. Lett. **B209**, 385 (1988); UA2: Phys. Lett. **B288**, 386 (1992). (Courtesy of J. Huston, Michigan State University, 2007.)

Differential Cross Section for W and Z Boson Production

Figure 46.3: Differential cross sections for W and Z production shown as a function of the boson transverse momentum. The D0 results include only the statistical error while the CDF results include all errors except for the 3.9% integrated luminosity error. The results are in good agreement with theoretical predictions that include both the effects of NLO corrections and of q_T resummation, such as the ResBos (Phys. Rev. **D67**, 073016 (2003)) predictions indicated on the plot. **D0:** Phys. Lett. **B513**, 292 (2001), Phys. Rev. Lett. **84**, 2792 (2000). **CDF:** Phys. Rev. Lett. **84**, 845 (2000). (Courtesy of J. Huston, Michigan State University, 2007)

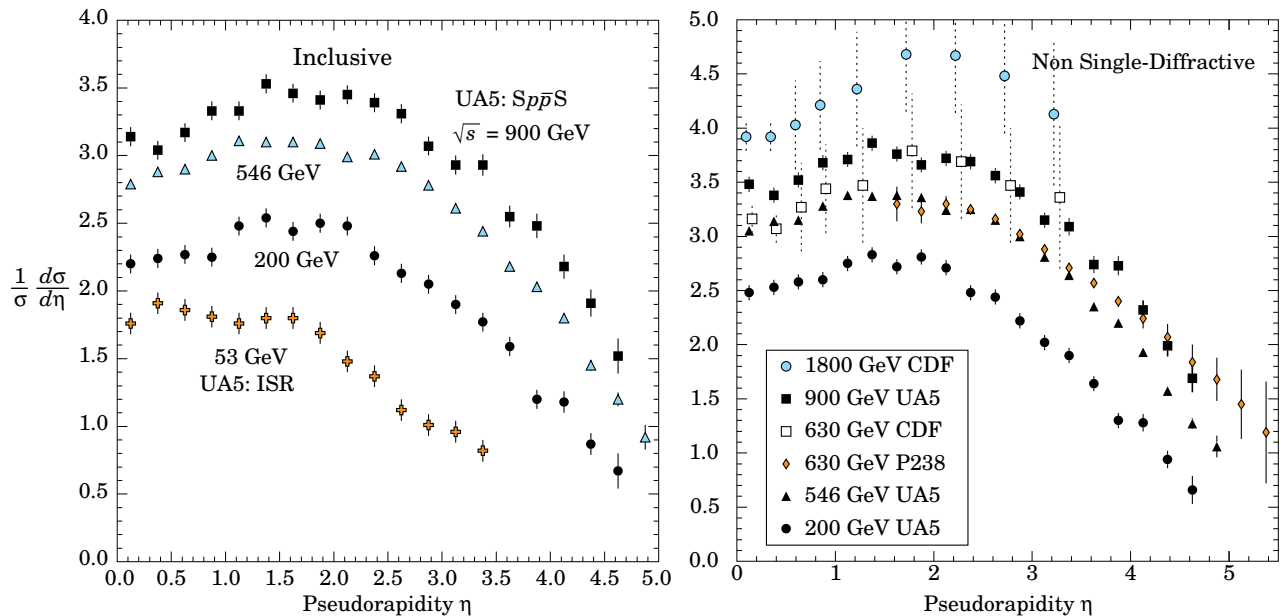

Pseudorapidity Distributions in $p\bar{p}$ Interactions

Figure 46.4: Charged particle pseudorapidity distributions in $p\bar{p}$ collisions for $53 \text{ GeV} \leq \sqrt{s} \leq 1800 \text{ GeV}$. UA5 data from the $S\bar{p}\bar{p}S$ are taken from G.J. Alner *et al.*, Z. Phys. **C33**, 1 (1986), and from the ISR from K. Alpgöard *et al.*, Phys. Lett. **112B**, 193 (1982). The UA5 data are shown for both the full inelastic cross section and with singly diffractive events excluded. Additional non single-diffractive measurements are available from CDF at the Tevatron, F. Abe *et al.*, Phys. Rev. **D41**, 2330 (1990) and Experiment P238 at the $S\bar{p}\bar{p}S$, R. Harr *et al.*, Phys. Lett. **B401**, 176 (1997). (Courtesy of D.R. Ward, Cambridge Univ., 1999)

Average Hadron Multiplicities in Hadronic e^+e^- Annihilation Events

Table 46.1: Average hadron multiplicities per hadronic e^+e^- annihilation event at $\sqrt{s} \approx 10, 29\text{--}35, 91,$ and $130\text{--}200$ GeV. The rates given include decay products from resonances with $c\tau < 10$ cm, and include the corresponding anti-particle state. Correlations of the systematic uncertainties were considered for the calculation of the averages. (Updated May 2010 by O. Biebel, LMU, Munich)

Particle	$\sqrt{s} \approx 10$ GeV	$\sqrt{s} = 29\text{--}35$ GeV	$\sqrt{s} = 91$ GeV	$\sqrt{s} = 130\text{--}200$ GeV

Notes for Table 46.1:

- (a) $\sigma_{\text{had}} = 3.33 \pm 0.05 \pm 0.21$ nb (CLEO: Phys. Rev. **D29**, 1254 (1984)) has been used in converting the measured cross sections to average hadron multiplicities.
- (b) $B(D_s \rightarrow \eta\pi, \eta'\pi)$ was used (RPP 1994).
- (c) Comprises both charged and neutral B meson states.
- (d) The Standard Model $B(Z \rightarrow b\bar{b}) = 0.217$ was used.
- (e) $x_p = p/p_{\text{beam}} > 0.1$ only.
- (f) Both charge states.
- (g) $B(D^*(2010)^+ \rightarrow D^0\pi^+) \times B(D^0 \rightarrow K^-\pi^+)$ has been used (RPP 2000).
- (h) $B(D_s^* \rightarrow D_s^+\gamma)$, $B(D_s^+ \rightarrow \phi\pi^+)$, $B(\phi \rightarrow K^+K^-)$ have been used (RPP 1998).
- (i) Any charge state (i.e., B_d^* , B_u^* , or B_s^*).
- (j) $B(Z \rightarrow \text{hadrons}) = 0.699$ was used (RPP 1994).
- (k) Any charge state (i.e., B_d^{**} , B_u^{**} , or B_s^{**}).
- (l) Assumes $B(D_{s1}^+ \rightarrow D^{*+}K^0 + D^{*0}K^+) = 100\%$ and $B(D_{s2}^+ \rightarrow D^0K^+) = 45\%$.
- (m) The value was derived from the cross section of $\Lambda_c^+ \rightarrow p\pi K$ using (a) and assuming the branching fraction to be $(5.0 \pm 1.3)\%$ (RPP 2004).

Average e^+e^- , pp , and $p\bar{p}$ Multiplicity

Figure 46.5: Average multiplicity as a function of \sqrt{s} for e^+e^- and $p\bar{p}$ annihilations, and pp and ep collisions. The indicated errors are statistical and systematic errors added in quadrature, except when no systematic errors are given. Files of the data shown in this figure are given in <http://pdg.lbl.gov/current/avg-multiplicity/>.

e^+e^- : Most e^+e^- measurements include contributions from K_S^0 and Λ decays. The $\gamma\gamma 2$ and MARK I measurements contain a systematic 5% error. Points at identical energies have been spread horizontally for clarity:

ALEPH: D. Buskulic *et al.*, Z. Phys. **C69**, 15 (1995); and Z. Phys. **C73**, 409 (1997);
A. Heister *et al.*, Eur. Phys. J. **C35**, 457 (2004).

ARGUS: H. Albrecht *et al.*, Z. Phys. **C54**, 13 (1992).

σ and R in e^+e^- Collisions

Figure 46.6: World data on the total cross section of $e^+e^- \rightarrow \text{hadrons}$ and the ratio $R(s) = \sigma(e^+e^- \rightarrow \text{hadrons}, s) / \sigma(e^+e^- \rightarrow \mu^+\mu^-, s)$. $\sigma(e^+e^- \rightarrow \text{hadrons}, s)$ is the experimental cross section corrected for initial state radiation and electron-positron vertex loops, $\sigma(e^+e^- \rightarrow \mu^+\mu^-, s) = 4\pi\alpha^2(s)/3s$. Data errors are total below 2 GeV and statistical above 2 GeV. The curves are an educative guide: the broken one (green) is a naive quark-parton model prediction, and the solid one (red) is 3-loop pQCD prediction (see “Quantum Chromodynamics” section of this Review, Eq. (9.7) or, for more details, K. G. Chetyrkin *et al.*, Nucl. Phys. **B586**, 56 (2000) (Erratum *ibid.* **B634**, 413 (2002))). Breit-Wigner parameterizations of J/ψ , $\psi(2S)$, and $\Upsilon(nS)$, $n = 1, 2, 3, 4$ are also shown. The full list of references to the original data and the details of the R ratio extraction from them can be found in [arXiv:hep-ph/0312114]. Corresponding computer-readable data files are available at <http://pdg.lbl.gov/current/xsect/>. (Courtesy of the COMPAS (Protvino) and HEPDATA (Durham) Groups, May 2010.)

R in Light-Flavor, Charm, and Beauty Threshold Regions

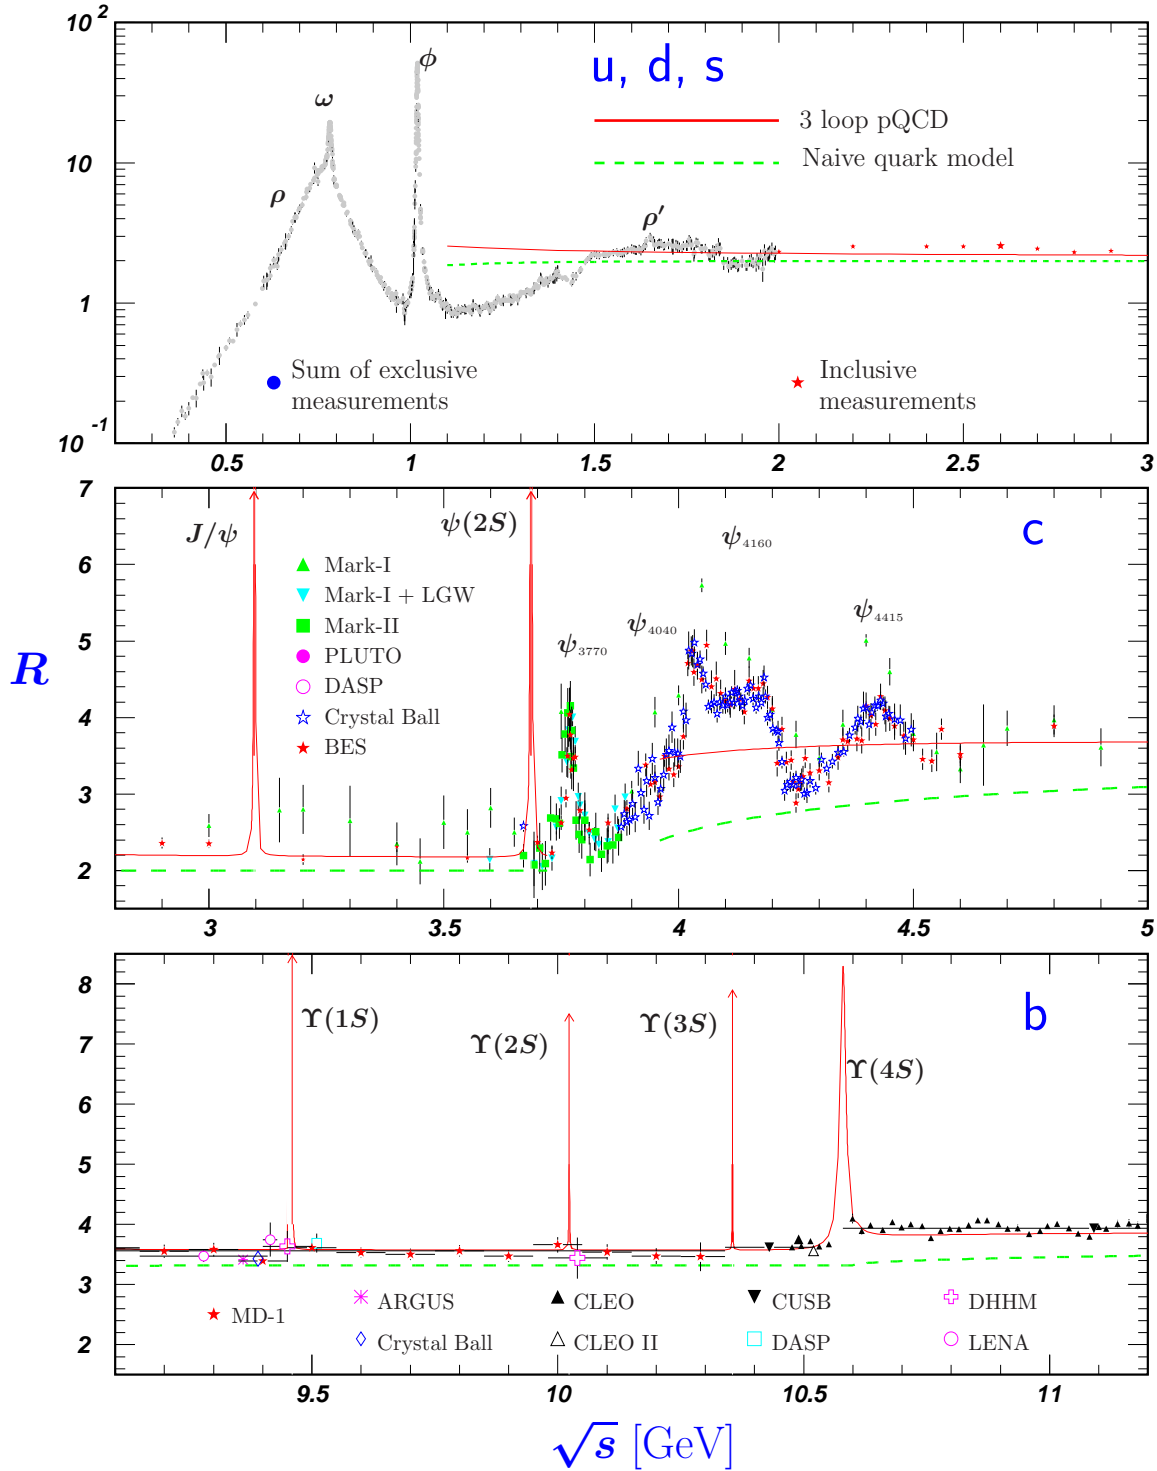

Figure 46.7: R in the light-flavor, charm, and beauty threshold regions. Data errors are total below 2 GeV and statistical above 2 GeV. The curves are the same as in Fig. 46.6. **Note:** CLEO data above $\Upsilon(4S)$ were not fully corrected for radiative effects, and we retain them on the plot only for illustrative purposes with a normalization factor of 0.8. The full list of references to the original data and the details of the R ratio extraction from them can be found in [arXiv:hep-ph/0312114]. The computer-readable data are available at <http://pdg.lbl.gov/current/xsect/>. (Courtesy of the COMPAS (Protvino) and HEPDATA (Durham) Groups, May 2010.)

Annihilation Cross Section Near M_Z 

Figure 46.8: Combined data from the ALEPH, DELPHI, L3, and OPAL Collaborations for the cross section in e^+e^- annihilation into hadronic final states as a function of the center-of-mass energy near the Z pole. The curves show the predictions of the Standard Model with two, three, and four species of light neutrinos. The asymmetry of the curve is produced by initial-state radiation. Note that the error bars have been increased by a factor ten for display purposes. References:

Table 46.2: Total hadronic cross section. Analytic S -matrix and Regge theory suggest a variety of parameterizations of total cross sections at high energies with different areas of applicability and fits quality.

A ranking procedure, based on measures of different aspects of the quality of the fits to the current evaluated experimental database, allows one to single out the following parameterization of highest rank [1]

$$\sigma^{ab} = Z^{ab} + B^{ab} \log^2(s/s_M) + Y_1^{ab}(s_M/s)^{\eta_1} - Y_2^{ab}(s_M/s)^{\eta_2} \quad \sigma^{\bar{a}b} = Z^{ab} + B^{ab} \log^2(s/s_M) + Y_1^{ab}(s_M/s)^{\eta_1} + Y_2^{ab}(s_M/s)^{\eta_2} ,$$

where Z^{ab} , $B^{a(p,n,\gamma^*)} = \pi \frac{(hc)^2}{M^2}$, $B^{ad} = \lambda \pi \frac{(hc)^2}{M^2}$ (dimensionless factor λ introduced to test the universality for nuclei targets), Y_i^{ab} are in mb; s , $s_M = (m_a + m_b + M)^2$ are in GeV^2 ; m_a , m_b , [$m_{\gamma^*} = m_{\rho(770)}$] are the masses of initial state particles, and M – the mass parameter defining the rate of universal rise of the cross sections are all in GeV . Parameters M , η_1 and η_2 are universal for all collisions considered. Terms $Z^{ab} + B^{ab} \log^2(s/s_M)$ represent the pomerons. The exponents η_1 and η_2 represent lower-lying C-even and C-odd exchanges, respectively. In addition to total cross sections σ , the measured ratios of the real-to-imaginary parts of the forward scattering amplitudes $\rho = \text{Re}(T)/\text{Im}(T)$ are included in the fits by using s to u crossing symmetry and differential dispersion relations.

Exact factorization hypothesis was used for both Z^{ab} and $B^{ab} \log^2(s/s_M)$ to extend the universal rise of the total hadronic cross sections to the $\gamma p \rightarrow \text{hadrons}$ and $\gamma \gamma \rightarrow \text{hadrons}$ collisions. This results in substitutions: $Z^{\gamma p} + \pi \frac{(hc)^2}{M^2} \log^2(s/s_M) \Rightarrow \delta [Z^{pp} + \pi \frac{(hc)^2}{M^2} \log^2(s/s_M)]$, and $Z^{\gamma \gamma} + \pi \frac{(hc)^2}{M^2} \log^2(s/s_M) \Rightarrow \delta^2 [Z^{pp} + \pi \frac{(hc)^2}{M^2} \log^2(s/s_M)]$, with the additional parameter δ . Simultaneous fit was made to the 2011-updated data for all collisions listed in the central column of the table. The total number of adjusted parameters is **34**. Asymptotic parameters (Z , M , λ , δ , η_1 , η_2) thus obtained were then fixed and used as inputs to fits by groups to check a stability of the whole situation with description of the high energy data. Results are shown in the right hand part of the table. All fits included data above $\sqrt{s_{\min}} = 5 \text{ GeV}$ with overall $\chi^2/\text{dof} = 0.96$.

	0.0128(12)		γ/p		0.00128(4)		
	$-0.034(0.183) \cdot 10^{-4}$		γ/γ		$-0.034(166) \cdot 10^{-4}$		0.722
65.02(38)	29.04(44)	14.9(2)	$\bar{p}(p)/d$	65.02(16)	29.04(39)	14.9(2)	1.524
37.06(30)	18.28(41)	0.34(9)	π^\pm/d	37.06(7)	18.28(19)	0.34(9)	0.747
32.34(22)	7.33(34)	5.59(9)	K^\pm/d	32.34(6)	7.33(16)	5.59(7)	0.819

The fitted functions are shown in the following figures, along with one-standard-deviation error bands. Whenever the reduced χ^2 is greater than one, a scale factor has been included to evaluate the parameter values and to draw the error bands. Where appropriate, statistical and systematic errors were combined quadratically in constructing weights for all fits. Only statistical error bars are shown on the plots. Vertical arrows indicate lower limits on the p_{lab} or \sqrt{s} range used in the fits. Database used in the fits now includes pp data from TOTEM experiment [2] and new data in the RHIC energy range from ARGO-YBJ cosmic ray experiment [3]. The modifications of the universal asymptotic term are motivated by ideas, suggestions and results from the old and recent papers [4-13]. Computer-readable data files are available at <http://pdg.lbl.gov/current/xsect/>. (Courtesy of the COMPAS group, IHEP, Protvino, April 2012)

INTRODUCTION TO THE PARTICLE LISTINGS

Illustrative key	457
Abbreviations	458

Illustrative Key to the Particle Listings

Name of particle. "Old" name used before 1986 renaming scheme also given if different. See the section "Naming Scheme for Hadrons" for details.

$a_0(1200)$

$$I^G(J^{PC}) = 1^-(0^+)$$

Particle quantum numbers (where known).

OMITTED FROM SUMMARY TABLE
Evidence not compelling, may be a kinematic effect.

Indicates particle omitted from Particle Physics Summary Table, implying particle's existence is not confirmed.

Quantity tabulated below.

$a_0(1200)$ MASS

Top line gives our best value (and error) of quantity tabulated here, based on weighted average of measurements used. Could also be from fit, best limit, estimate, or other evaluation. See next page for details.

VALUE (MeV)	EVTS	DOCUMENT ID	TECN	CHG	COMMENT
1206 ± 7 OUR AVERAGE					
1210 ± 8 ± 9	3000	FENNER 87	MMS	-	3.5 $\pi^- p$
1198 ± 10		PIERCE 83	ASPK	+	2.1 $K^- p$
1216 ± 11 ± 9	1500	MERRILL 81	HBC	0	3.2 $K^- p$
1192 ± 16		LYNCH 81	HBC	±	2.7 $\pi^- p$

General comments on particle.

Footnote number linking measurement to text of footnote.

¹Systematic error was added quadratically by us in our 1986 edition.

"Document id" for this result; full reference given below.

Measurement technique. (See abbreviations on next page.)

$a_0(1200)$ WIDTH

Number of events above background.

Measured value used in averages, fits, limits, etc.

Error in measured value (often statistical only; followed by systematic if separately known; the two are combined in quadrature for averaging and fitting.)

Measured value *not* used in averages, fits, limits, etc. See the Introductory Text for explanations.

Arrow points to weighted average.

Shaded pattern extends $\pm 1\sigma$ (scaled by "scale factor" S) from weighted average.

Value and error for each experiment.

Scale factor > 1 indicates possibly inconsistent data.

Reaction producing particle, or general comments.

"Change bar" indicates result added or changed since previous edition.

Charge(s) of particle(s) detected.

Ideogram to display possibly inconsistent data. Curve is sum of Gaussians, one for each experiment (area of Gaussian = 1/error; width of Gaussian = ±error). See Introductory Text for discussion.

Contribution of experiment to χ^2 (if no entry present, experiment not used in calculating χ^2 or scale factor because of very large error).

$a_0(1200)$ DECAY MODES

Partial decay mode (labeled by Γ_i).

Mode	Fraction (Γ_i/Γ)	Scale factor/ Confidence level
Γ_1 3π	(65.2 ± 1.3) %	S=1.7
Γ_2 $K\bar{K}$	(34.8 ± 1.3) %	S=1.7
Γ_3 $\eta\pi^\pm$	< 4.9 × 10 ⁻⁴	CL=95%

Our best value for branching fraction as determined from data averaging, fitting, evaluating, limit selection, etc. This list is basically a compact summary of results in the Branching Ratio section below.

$a_0(1200)$ BRANCHING RATIOS

Branching ratio.

Our best value (and error) of quantity tabulated, as determined from constrained fit (using *all significant* measured branching ratios for this particle).

Weighted average of measurements of this ratio only.

Footnote (referring to LYNCH 81).

Confidence level for measured upper limit.

References, ordered inversely by year, then author.

"Document id" used on data entries above.

Journal, report, preprint, etc. (See abbreviations on next page.)

Abbreviations Used in the Particle Listings

Indicator of Procedure Used to Obtain Our Result

OUR AVERAGE	From a weighted average of selected data.
OUR FIT	From a constrained or overdetermined multiparameter fit of selected data.
OUR EVALUATION	Not from a direct measurement, but evaluated from measurements of other quantities.
OUR ESTIMATE	Based on the observed range of the data. Not from a formal statistical procedure.
OUR LIMIT	For special cases where the limit is evaluated by us from measured ratios or other data. Not from a direct measurement.

Measurement Techniques

(i.e., Detectors and Methods of Analysis)

ACCM	ACCMOR Collaboration	CLE3	CLEO III detector at CESR
ADMX	Axion Dark Matter Experiment	CLEO	Cornell magnetic detector at CESR
AEMS	Argonne effective mass spectrometer	CMB	Cosmic Microwave Background
ALEP	ALEPH – CERN LEP detector	CMD	Cryogenic magnetic detector at VEPP-2M, Novosibirsk
ALPS	Photon regeneration experiment	CMD2	Cryogenic magnetic detector 2 at VEPP-2M, Novosibirsk
AMND	AMANDA South Pole neutrino detector	CMS	CMS detector at CERN LHC
AMY	AMY detector at KEK-TRISTAN	CNTR	Counters
ANIT	Antarctic Impulsive Transient Antenna balloon mission	COMP	COMPASS experiment at the CERN SPS
APEX	FNAL APEX Collab.	COSM	Cosmology and astrophysics
ARG	ARGUS detector at DORIS	COSY	COSY-TOF Collaboration
ARGD	Fit to semicircular amplitude path on Argand diagram	COUP	COUPP (the Chicagoland Observatory for Underground Particle Physics) Collab.
ASP	Anomalous single-photon detector	CPLR	CLEAR Collaboration
ASPK	Automatic spark chambers	CRES	CRESST cryogenic detector
ASTE	ASTERIX detector at LEAR	CRYB	Crystal Ball at BNL
ASTR	Astronomy	CRYM	Crystal Ball detector at Mainz Microtron MAMI
ATLS	ATLAS detector at CERN LHC	CSB2	Columbia U. - Stony Brook BGO calorimeter inserted in NaI array
B787	BNL experiment 787 detector	CSME	COSME Collaboration
B791	BNL experiment 791 detector	CUOR	CUORICINO experiment at Gran Sasso Laboratory.
B845	BNL experiment 845 detector	CUSB	Columbia U. - Stony Brook segmented NaI detector at CESR
B852	BNL E-852	D0	D0 detector at Fermilab Tevatron Collider
B865	BNL E865 detector	DAMA	DAMA, dark matter detector at Gran Sasso National Lab.
B871	BNL experiment 871 detector	DASP	DESY double-arm spectrometer
B949	BNL E949 detector at AGS	DAYA	Daya Bay Collaboration
BABR	BaBar Collab.	DBC	Deuterium bubble chamber
BAKS	Baksan underground scintillation telescope	DCHZ	Double Chooz Collaboration
BC	Bubble chamber	DLCO	DELCO detector at SLAC-SPEAR or SLAC-PEP
BDMP	Beam dump	DLPH	DELPHI detector at LEP
BEAT	CERN BEATRICE Collab.	DM1	Magnetic detector no. 1 at Orsay DCI collider
BEBC	Big European bubble chamber at CERN	DM2	Magnetic detector no. 2 at Orsay DCI collider
BELL	Belle Collab.	DMTP	Dark Matter Time Projection Chamber (DMTPC) directional detection experiment
BES	BES Beijing Spectrometer at Beijing Electron-Positron Collider	DONU	DONUT Collab.
BES2	BES Beijing Spectrometer at Beijing Electron-Positron Collider	DPWA	Energy-dependent partial-wave analysis
BES3	BES Beijing Spectrometer at Beijing Electron-Positron Collider	E621	Fermilab E621 detector
BIS2	BIS-2 spectrometer at Serpukhov	E653	Fermilab E653 detector
BKEI	BENKEI spectrometer system at KEK Proton Synchrotron	E665	Fermilab E665 detector
BOLO	Bolometer, a cryogenic thermal detector	E687	Fermilab E687 detector
BONA	Bonanza nonmagnetic detector at DORIS	E691	Fermilab E691 detector
BORX	BOREXINO	E705	Fermilab E705 Spectrometer-Calorimeter
BPWA	Barrelet-zero partial-wave analysis	E731	Fermilab E731 Spectrometer-Calorimeter
CALO	Calorimeter	E756	Fermilab E756 detector
CAST	CAST experiment at CERN	E760	Fermilab E760 detector
CBAL	Crystal Ball detector at SLAC-SPEAR or DORIS	E761	Fermilab E761 detector
CBAR	Crystal Barrel detector at CERN-LEAR	E771	Fermilab E771 detector
CBOX	Crystal Box at LAMPF	E773	Fermilab E773 Spectrometer-Calorimeter
CBTP	CBELSA/TAPS Collaboration	E789	Fermilab E789 detector
CC	Cloud chamber	E791	Fermilab E791 detector
CCFR	Columbia-Chicago-Fermilab-Rochester detector	E799	Fermilab E799 Spectrometer-Calorimeter
CDF	Collider detector at Fermilab	E835	Fermilab E835 detector
CDF2	CDF-II Collab.	EDE2	EDELWEISS II dark matter search Collaboration
CDHS	CDHS neutrino detector at CERN	EDEL	EDELWEISS dark matter search Collaboration
CDM2	CDMS II, Cryogenic Dark Matter Search at Soudan Underground Lab.	EHS	Four-pi detector at CERN
CDMS	CDMS Collab.	ELEC	Electronic combination
CELL	CELLO detector at DESY	EMC	European muon collaboration detector at CERN
CGNT	CoGeNT dark matter search experiment	EMUL	Emulsions
CHER	Cherenkov detector	FAST	Fiber Active Scintillator Target detector at PSI
CHM2	CHARM-II neutrino detector (glass) at CERN	FBC	Freon bubble chamber
CHOZ	Nuclear Power Station near Chooz, France	FENI	FENICE (at the ADONE collider of Frascati)
CHRM	CHARM neutrino detector (marble) at CERN	FIT	Fit to previously existing data
CHRS	CHORUS Collaboration – CERNS SPS	FLAT	Large Area Telescope onboard the Fermi Gamma-Ray Space Telescope
CIB	Cosmic Infrared Background	FMPS	Fermilab Multiparticle Spectrometer
CIBS	CERN-IHEP boson spectrometer	FOCS	FNAL E831 FOCUS Collab.
CLAS	Jefferson CLAS Collab.	FRAB	ADONE $B\bar{B}$ group detector
CLE2	CLEO II detector at CESR	FRAG	ADONE $\gamma\gamma$ group detector
		FRAM	ADONE MEA group detector
		FREJ	FREJUS Collaboration – modular flash chamber detector (calorimeter)
		FRMI	Fermi large area telescope (Fermi-LAT)
		GA24	Hodoscope Cherenkov γ calorimeter (IHEP GAMS-2000) (CERN GAMS-4000)
		GALX	GALLEX solar neutrino detector in the Gran Sasso Underground Lab.
		GAM2	IHEP hodoscope Cherenkov γ calorimeter GAMS-2000
		GAM4	CERN hodoscope Cherenkov γ calorimeter GAMS-4000
		GAMS	IHEP hodoscope Cherenkov γ calorimeter GAMS-4 π
		GNO	Gallium Neutrino Observatory in the Gran Sasso Underground Lab.

Abbreviations Used in the Particle Listings

GOLI	CERN Goliath spectrometer	MRKJ	Mark-J detector at DESY
GRAL	GRAAL Collaboration	MRS	Magnetic resonance spectrometer
H1	H1 detector at DESY/HERA	MUG2	MUON(g-2)
HBC	Hydrogen bubble chamber	MWPC	Multi-Wire Proportional Chamber
HDBC	Hydrogen and deuterium bubble chambers	NA14	CERN NA14
HDMO	Heidelberg-Moscow Experiment	NA31	CERN NA31 Spectrometer-Calorimeter
HDMS	Heidelberg Dark Matter Search Experiment	NA32	CERN NA32 Spectrometer
HEBC	Helium bubble chamber	NA48	CERN NA48 Collaboration
HEPT	Helium proportional tubes	NA49	CERN NA49 Collaboration
HERB	HERA-B detector at DESY/HERA	NA60	CERN NA60 Collaboration
HERM	HERMES detector at DESY/HERA	NA62	CERN NA62 Experiment
HESS	High Energy Stereoscopic System gamma-ray instrument	NAGE	NEWAGE, New generation WIMP-search experiment with advanced gaseous tracking
HFS	Hyperfine structure	NAIA	NAIAD (NaI Advanced Detector) dark matter search experiment
HLBC	Heavy-liquid bubble chamber	ND	NaI detector at VEPP-2M, Novosibirsk
HOME	Homestake underground scintillation detector	NICE	Serpukhov nonmagnetic precision spectrometer
HPGE	High-purity Germanium detector	NMR	Nuclear magnetic resonance
HPW	Harvard-Pennsylvania-Wisconsin detector	NOMD	NOMAD Collaboration, CERN SPS
HRS	SLAC high-resolution spectrometer	NTEV	NuTeV Collab. at Fermilab
HYBR	Hybrid: bubble chamber + electronics	NUSX	Mont Blanc NUSEX underground detector
HYCP	HyperCP Collab. (FNAL E-871)	OBLX	OBELIX detector at LEAR
ICAR	ICARUS experiment at Gran Sasso Laboratory.	OLYA	Detector at VEPP-2M and VEPP-4, Novosibirsk
ICCB	IceCube neutrino detector at South Pole	OMEG	CERN OMEGA spectrometer
IGEX	IGEX Collab.	OPAL	OPAL detector at LEP
IMB	Irvine-Michigan-Brookhaven underground Cherenkov detector	OSPK	Optical spark chamber
IMB3	Irvine-Michigan-Brookhaven underground Cherenkov detector	PIBE	The PIBETA detector at the Paul Scherrer Institute (PSI), Switzerland.
INDU	Magnetic induction	PICA	PICASSO dark matter search experiment
IPWA	Energy-independent partial-wave analysis	PLAS	Plastic detector
ISTR	IHEP ISTRA+ spectrometer-calorimeter	PLUT	DESY PLUTO detector
JADE	JADE detector at DESY	PRMX	The PRIMEX detector in Hall B at TJNAF
K246	KEK E246 detector with polarimeter	PWA	Partial-wave analysis
K2K	KEK to Super-Kamiokande	REDE	Resonance depolarization
K391	KEK E391a detector	RENO	RENO Collaboration
K470	KEK-E470 Stopping K detector	RICE	Radio Ice Cherenkov Experiment
KAM2	KAMIOKANDE-II underground Cherenkov detector	RVUE	Review of previous data
KAMI	KAMIOKANDE underground Cherenkov detector	SAGE	US - Russian Gallium Experiment
KAR2	KARMEN2 calorimeter at the ISIS neutron spallation source at Rutherford	SELX	FNAL SELEX Collab.
KARM	KARMEN calorimeter at the ISIS neutron spallation source at Rutherford	SFM	CERN split-field magnet
KEDR	detector operating at VEPP-4M collider (Novosibirsk)	SHF	SLAC Hybrid Facility Photon Collaboration
KIMS	Korea Invisible Mass Search experiment at YangYang, Korea	SIGM	Serpukhov CERN-IHEP magnetic spectrometer (SIGMA)
KLND	KamLand Collab. (Japan)	SILI	Silicon detector
KLOE	KLOE detector at DAFNE (the Frascati e+e- collider Italy)	SIMP	SIMPLE, dark matter detector at Laboratori Nazionali del Sud
KOLR	Kolar Gold Field underground detector	SKAM	Super-Kamiokande Collab.
KTEV	KTeV Collaboration	SLAX	Solar Axion Experiment in Canfranc Underground Laboratory
L3	L3 detector at LEP	SLD	SLC Large Detector for e+e- colliding beams at SLAC
LASS	Large-angle superconducting solenoid spectrometer at SLAC	SMPL	SIMPLE, Superheated Instrument for Massive Particle Experiments
LATT	Lattice calculations	SND	Novosibirsk Spherical neutral detector at VEPP-2M
LEBC	Little European bubble chamber at CERN	SNDR	SINDRUM spectrometer at PSI
LEGS	BNL LEGS Collab.	SNO	SNO Collaboration (Sudbury Neutrino Observatory)
LENA	Nonmagnetic lead-glass NaI detector at DORIS	SOU2	Soudan 2 underground detector
LEP	From combination of all 4 LEP experiments: ALEPH, DELPHI, L3, OPAL	SODU	Soudan underground detector
LEPS	Low-Energy Pion Spectrometer at the Paul Scherrer Institute	SPEC	Spectrometer
LGW	Lead Glass Wall collaboration at SPEAR/SLAC	SPED	From maximum of speed plot or resonant amplitude
LHCb	LHCb detector at CERN LHC	SPHR	Bonn SAPHIR Collab.
LSD	Mont Blanc liquid scintillator detector	SPNX	SPHINX spectrometer at IHEP accelerator
LSND	Liquid Scintillator Neutrino Detector	SPRK	Spark chamber
MAC	MAC detector at PEP/SLAC	SQID	SQUID device
MBOO	Fermilab MiniBooNE neutrino experiment	STRC	Streamer chamber
MBR	Molecular beam resonance technique	SVD2	SVD-2 experiment at IHEP, Protvino
MCRO	MACRO detector in Gran Sasso	T2K	T2K Collaboration
MD1	Magnetic detector at VEPP-4, Novosibirsk	TASS	DESY TASSO detector
MDRP	Millikan drop measurement	TEVA	Combined analysis of CDF and DØ experiments
MEG	Muon to electron conversion detector at PSI	TEXO	TEXONO Collab., ultra low energy Ge detector at Kuo-Sheng Laboratory
MICA	Underground mica deposits	THEO	Theoretical or heavily model-dependent result
MINS	Fermilab MINOS experiment	TNF	TNF-IHEP facility at 70 GeV IHEP accelerator
MIRA	MIRABELLE Liquid-hydrogen bubble chamber	TOF	Time-of-flight
MLEV	Magnetic levitation	TOPZ	TOPAZ detector at KEK-TRISTAN
MMS	Missing mass spectrometer	TPC	TPC detector at PEP/SLAC
MPS	Multiparticle spectrometer at BNL	TPS	Tagged photon spectrometer at Fermilab
MPS2	Multiparticle spectrometer upgrade at BNL	TRAP	Penning trap
MPSF	Multiparticle spectrometer at Fermilab	TWST	TWIST spectrometer at TRIUMF
MPWA	Model-dependent partial-wave analysis	UA1	UA1 detector at CERN
MRK1	SLAC Mark-I detector	UA2	UA2 detector at CERN
MRK2	SLAC Mark-II detector	UA5	UA5 detector at CERN
MRK3	SLAC Mark-III detector		

Abbreviations Used in the Particle Listings

UCNA	UCNA collaboration using polarized ultracold neutrons at LANSCE
UKDM	UK Dark Matter Collab.
VES	Vertex Spectrometer Facility at 70 GeV IHEP accelerator
VLBI	Very Long Baseline Interferometer
VNS	VENUS detector at KEK-TRISTAN
WA75	CERN WA75 experiment
WA82	CERN WA82 experiment
WA89	CERN WA89 experiment
WARP	Liquid argon detector for CDM searches at Gran Sasso
WASA	WASA detector at CELSIUS, Uppsala and at COSY, Juelich
WIRE	Wire chamber
X100	XENON100 dark matter search experiment at Gran Sasso National Laboratory
XE10	XENON10 experiment at Gran Sasso National Laboratory
XEBC	Xenon bubble chamber
ZEP2	ZEPLIN-II dark matter detector
ZEP3	ZEPLIN-III dark matter detector at Palmer Underground Lab.
ZEPL	ZEPLIN-I galactic dark matter detector
ZEUS	ZEUS detector at DESY/HERA

Conferences

Conferences are generally referred to by the location at which they were held (e.g., HAMBURG, TORONTO, CORNELL, BRIGHTON, etc.).

- RYUTOV 07 extends the method of RYUTOV 97 to the radius of Pluto's orbit.
- ACCIOLY 10 limits come from possible alterations of anomalous magnetic moment of electron and gravitational deflection of electromagnetic radiation. Reported limits are not "claimed" by the authors and in any case are not competitive.
- When trying to measure m one must distinguish between measurements performed on large and small scales. If the photon acquires mass by the Higgs mechanism, the large-scale behavior of the photon might be effectively Maxwellian. If, on the other hand, one postulates the Proca regime for all scales, the very existence of the galactic field implies $m < 10^{-26} \text{ eV}$, as correctly calculated by YAMAGUCHI 59 and CHIBISOV 76.
- LUO 03 determine a limit on $\mu^2 A < 1.1 \times 10^{-11} \text{ T m/m}^2$ (with μ^{-1} =characteristic length for photon mass; A =ambient vector potential) — similar to the LAKES 98 technique. Unlike LAKES 98 who used static, the authors used dynamic torsion balance. Assuming A to be 10^{12} T m , they obtain $\mu < 1.2 \times 10^{-51} \text{ g}$, equivalent to $6.7 \times 10^{-19} \text{ eV}$. The rotating modified Cavendish balance removes dependence on the direction of A . GOLDHABER 03 argue that because plasma current effects are neglected, the LUO 03 limit does not provide the best available limit on $\mu^2 A$ nor a reliable limit at all on μ . The reason is that the A associated with cluster magnetic fields could become arbitrarily small in plasma voids, whose existence would be compatible with present knowledge. LUO 03B reply that fields of distant clusters are not accurately mapped, but assert that a zero A is unlikely given what we know about the magnetic field in our galaxy.
- LAKES 98 reports limits on torque on a toroid Cavendish balance, obtaining a limit on $\mu^2 A < 2 \times 10^{-9} \text{ Tm/m}^2$ via the Maxwell-Proca equations, where μ^{-1} is the characteristic length associated with the photon mass and A is the ambient vector potential in the Lorentz gauge. Assuming $A \approx 1 \times 10^{12} \text{ Tm}$ due to cluster fields he obtains $\mu^{-1} > 2 \times 10^{10} \text{ m}$, corresponding to $\mu < 1 \times 10^{-17} \text{ eV}$. A more conservative limit, using $A \approx (1 \mu\text{G}) \times (600 \text{ pc})$ based on the galactic field, is $\mu^{-1} > 1 \times 10^9 \text{ m}$ or $\mu < 2 \times 10^{-16} \text{ eV}$.
- RYUTOV 97 uses a magnetohydrodynamics argument concerning survival of the Sun's field to the radius of the Earth's orbit. "To reconcile observations to theory, one has to reduce [the photon mass] by approximately an order of magnitude compared with" DAVIS 75.
- FISCHBACH 94 report $< 8 \times 10^{-16}$ with unknown CL. We report Bayesian CL used elsewhere in these Listings and described in the Statistics section.
- CHERNIKOV 92 measures the photon mass at 1.24 K, following a theoretical suggestion that electromagnetic gauge invariance might break down at some low critical temperature. See the erratum for a correction, included here, to the published result.
- RYAN 85 measures the photon mass at 1.36 K (see the footnote to CHERNIKOV 92).
- CHIBISOV 76 depends in critical way on assumptions such as applicability of virial theorem. Some of the arguments given only in unpublished references.
- See criticism questioning the validity of these results in GOLDHABER 71, PARK 71 and KROLL 71. See also review GOLDHABER 71B.

γ CHARGE

OKUN 06 has argued that schemes in which all photons are charged are inconsistent. He says that if a neutral photon is also admitted to avoid this problem, then other problems emerge, such as those connected with the emission and absorption of charged photons by charged particles. He concludes that in the absence of a self-consistent phenomenological basis, interpretation of experimental data is at best difficult.

VALUE (e)	CHARGE	DOCUMENT ID	TECN	COMMENT
< 1	$\times 10^{-46}$	12 ALTSCHUL 07b	VLBI	Aharonov-Bohm effect
< 1	$\times 10^{-35}$	13 CAPRINI 05	CMB	Isotropy constraint

• • • We do not use the following data for averages, fits, limits, etc. • • •

- ALTSCHUL 07b looks for Aharonov-Bohm phase shift in addition to geometric phase shift in radio interference fringes (VSOP mission).
- CAPRINI 05 uses isotropy of the cosmic microwave background to place stringent limits on possible charge asymmetry of the Universe. Charge limits are set on the photon, neutrino, and dark matter particles. Valid if charge asymmetries produced by different particles are not anticorrelated.
- KOBYCHEV 05 considers a variety of observable effects of photon charge for extragalactic compact radio sources. Best limits if source observed through a foreground cluster of galaxies.
- SEMERTZIDIS 03 reports the first laboratory limit on the photon charge in the last 30 years. Straightforward improvements in the apparatus could attain a sensitivity of 10⁻²⁰ e.
- SIVARAM 95 requires that CMB photon charge density not overwhelm gravity. Result scales as Ω_M h².
- RAFFELT 94 notes that COCCONI 88 neglects the fact that the time delay due to dispersion by free electrons in the interstellar medium has the same photon energy dependence as that due to bending of a charged photon in the magnetic field. His limit is based on the assumption that the entire observed dispersion is due to photon charge. It is a factor of 200 less stringent than the COCCONI 88 limit.
- See COCCONI 92 for less stringent limits in other frequency ranges. Also see RAFFELT 94 note.

¹ CHOUDHURY 04 sets limits based on nonobservation of a distortion in the measured values of the variance of the power spectrum.

² FINN 02 analyze the orbital decay rates of PSR B1913+16 and PSR B1534+12 with a possible graviton mass as a parameter. The combined frequentist mass limit is at 90%CL.

³ DAMOUR 91 is an analysis of the orbital period change in binary pulsar PSR 1913+16, and confirms the general relativity prediction to 0.8%. "The theoretical importance of the [rate of orbital period decay] measurement has long been recognized as a direct confirmation that the gravitational interaction propagates with velocity c (which is the immediate cause of the appearance of a damping force in the binary pulsar system) and thereby as a test of the existence of gravitational radiation and of its quadrupolar nature." TAYLOR 93 adds that orbital parameter studies now agree with general relativity to 0.5%, and set limits on the level of scalar contribution in the context of a family of tensor [spin 2]-biscalar theories.

 $J = 1$

THE MASS AND WIDTH OF THE W BOSON

Revised March 2012 by M.W. Gr unewald (U Ghent) and A. Gurtu (King Abdulaziz University).

Precision determination of the W-mass is of great importance in testing the internal consistency of the Standard Model and, together with other electroweak data, in constraining the mass of the undiscovered Higgs boson. From the time of its discovery in 1983, the W-boson has been studied and its mass determined in $p\bar{p}$ and e^+e^- interactions; it is currently studied in pp interactions at the LHC. The W mass and width definition used here corresponds to a Breit-Wigner with mass-dependent width.

Production of on-shell W bosons at hadron colliders is tagged by the high p_T charged lepton from its decay. Owing to the unknown parton-parton effective energy and missing energy in the longitudinal direction, the collider experiments reconstruct the transverse mass of the W, and derive the W mass from comparing the transverse mass distribution with Monte Carlo predictions as a function of M_W . These analyses use the electron and muon decay modes of the W boson.

In the e^+e^- collider (LEP) a precise knowledge of the beam energy enables one to determine the $e^+e^- \rightarrow W^+W^-$ cross section as a function of center of mass energy, as well as

to reconstruct the W mass precisely from its decay products, even if one of them decays leptonically. Close to the W^+W^- threshold (161 GeV), the dependence of the W-pair production cross section on M_W is large, and this was used to determine M_W . At higher energies (172 to 209 GeV) this dependence is much weaker and W-bosons were directly reconstructed and the mass determined as the invariant mass of its decay products, improving the resolution with a kinematic fit.

Figure 1: Measurements of the W-boson mass by the LEP and Tevatron experiments.

In order to compute the LEP average W mass, each experiment provided its measured W mass for the $q\bar{q}q\bar{q}$ and $q\bar{q}\ell\bar{\nu}_\ell$, $\ell = e, \mu, \tau$ channels at each center-of-mass energy, along with a detailed break-up of errors: statistical, uncorrelated, partially correlated and fully correlated systematics [1]. These have been combined to obtain a LEP W mass of $M_W = 80.376 \pm 0.033 \text{ GeV}$. Errors due to uncertainties in LEP energy (9 MeV), and possible effect of color reconnection (CR) and Bose-Einstein correlations (BEC) between quarks from different W's (8 MeV) are included. The mass difference between $q\bar{q}q\bar{q}$ and $q\bar{q}\ell\bar{\nu}_\ell$ final states (due to possible CR and BEC effects) is $-12 \pm 45 \text{ MeV}$. In a similar manner, the width results obtained at LEP have been combined, resulting in $\Gamma_W = 2.196 \pm 0.083 \text{ GeV}$ [1].

The two Tevatron experiments have also identified common systematic errors. Between the two experiments, uncertainties due to the parton distribution functions, radiative corrections, and choice of mass (width) in the width (mass) measurements are treated as correlated. An average W mass of $M_W = 80.420 \pm 0.031 \text{ GeV}$ [2] and a W width of $\Gamma_W = 2.046 \pm 0.049 \text{ GeV}$ [3] are obtained. Errors of 12 MeV (20 MeV) and 9 MeV (7 MeV) accounting for PDF and radiative correction

Figure 2: Measurements of the W-boson width by the LEP and Tevatron experiments.

uncertainties in the mass (width) combination dominate the correlated uncertainties.

At the 2012 winter conferences, the CDF and D0 experiments have presented new results for the mass of the W boson based on 2 – 4 fb⁻¹ of Run-II data, 80.387 ± 0.019 GeV [4] and 80.375 ± 0.023 GeV [5], respectively. The W-mass determination from the Tevatron experiments has thus become very precise. Combining all Tevatron results from Run-I and Run-II using an improved treatment of correlations, a new average of 80.387 ± 0.016 GeV is obtained [6], with common uncertainties of 10 MeV (PDF) and 4 MeV (radiative corrections).

The LEP and Tevatron results on mass and width, which are based on all results available, are compared in Fig. 1 and Fig. 2. Good agreement between the results is observed. Combining these results, assuming no common systematic uncertainties between the LEP and the Tevatron measurements, yields an average W mass of $M_W = 80.385 \pm 0.015$ GeV and a W width of $\Gamma_W = 2.085 \pm 0.042$ GeV.

The Standard Model prediction from the electroweak fit, using Z-pole data plus m_{top} measurement, gives a W-boson mass of $M_W = 80.365 \pm 0.020$ GeV and a W-boson width of $\Gamma_W = 2.091 \pm 0.002$ GeV [7].

W MASS

The W-mass listed here corresponds to the mass parameter in a Breit-Wigner distribution with mass-dependent width. To obtain the world average, common systematic uncertainties between experiments are properly taken into account. The LEP-2 average W mass based on published results is 80.376 ± 0.033 GeV [CERN-PH-EP/2006-042]. The combined Tevatron data yields an average W mass of 80.387 ± 0.016 GeV [FERMLAB-TM-2532-E].

OUR FIT uses these average LEP and Tevatron mass values and combines them assuming no correlations.

¹ AALTONEN 12E select 470k $W \rightarrow e\nu$ decays and 625k $W \rightarrow \mu\nu$ decays in 2.2 fb⁻¹ of Run-II data. The mass is determined using the transverse mass, transverse lepton momentum and transverse missing energy distributions, accounting for correlations. This result supersedes AALTONEN 07F.

² ABAZOV 12F select 1677k $W \rightarrow e\nu$ decays in 4.3 fb⁻¹ of Run-II data. The mass is determined using the transverse mass and transverse lepton momentum distributions, accounting for correlations.

³ ABAZOV 09AB study the transverse mass, transverse electron momentum, and transverse missing energy in a sample of 0.5 million $W \rightarrow e\nu$ decays selected in Run-II data. The quoted result combines all three methods, accounting for correlations.

⁴ ABDALLAH 08A use direct reconstruction of the kinematics of $W^+W^- \rightarrow q\bar{q}\ell\nu$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events for energies 172 GeV and above. The W mass was also extracted from the dependence of the WW cross section close to the production threshold and combined appropriately to obtain the final result. The systematic error includes ± 0.025 GeV due to final state interactions and ± 0.009 GeV due to LEP energy uncertainty.

⁵ ABBIENDI 06 use direct reconstruction of the kinematics of $W^+W^- \rightarrow q\bar{q}\ell\nu\ell$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events. The result quoted here is obtained combining this mass value with the results using $W^+W^- \rightarrow \nu_\ell\ell\nu_\ell$ events in the energy range 183–207

Gauge & Higgs Boson Particle Listings

W

GeV (ABBIENDI 03c) and the dependence of the WW production cross-section on m_W at threshold. The systematic error includes ± 0.009 GeV due to the uncertainty on the LEP beam energy.

- ⁶ACHARD 06 use direct reconstruction of the kinematics of $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events in the C.M. energy range 189–209 GeV. The result quoted here is obtained combining this mass value with those obtained from a direct W mass reconstruction at 172 and 183 GeV and with those from the dependence of the WW production cross-section on m_W at 161 and 172 GeV (ACCIARRI 99).
- ⁷SCHAEEL 06 use direct reconstruction of the kinematics of $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events in the C.M. energy range 183–209 GeV. The result quoted here is obtained combining this mass value with those obtained from the dependence of the W pair production cross-section on m_W at 161 and 172 GeV (BARATE 97 and BARATE 97s respectively). The systematic error includes ± 0.009 GeV due to possible effects of final state interactions in the $q\bar{q}q\bar{q}$ channel and ± 0.009 GeV due to the uncertainty on the LEP beam energy.
- ⁸ABAZOV 02D improve the measurement of the W -boson mass including $W \rightarrow e\nu_e$ events in which the electron is close to a boundary of a central electromagnetic calorimeter module. Properly combining the results obtained by fitting $m_T(W)$, $p_T(e)$, and $p_T(\nu)$, this sample provides a mass value of 80.574 ± 0.405 GeV. The value reported here is a combination of this measurement with all previous $D0$ W -boson mass measurements.
- ⁹AFFOLDER 01E fit the transverse mass spectrum of 30115 $W \rightarrow e\nu_e$ events ($M_W = 80.473 \pm 0.065 \pm 0.092$ GeV) and of 14740 $W \rightarrow \mu\nu_\mu$ events ($M_W = 80.465 \pm 0.100 \pm 0.103$ GeV) obtained in the run IB (1994–95). Combining the electron and muon results, accounting for correlated uncertainties, yields $M_W = 80.470 \pm 0.089$ GeV. They combine this value with their measurement of ABE 95P reported in run IA (1992–93) to obtain the quoted value.
- ¹⁰AALTONEN 07F obtain high purity $W \rightarrow e\nu_e$ and $W \rightarrow \mu\nu_\mu$ candidate samples totaling 63,964 and 51,128 events respectively. The W mass value quoted above is derived by simultaneously fitting the transverse mass and the lepton, and neutrino p_T distributions.
- ¹¹AKTAS 06 fit the Q^2 dependence ($300 < Q^2 < 30,000$ GeV²) of the charged-current differential cross section with a propagator mass. The first error is experimental and the second corresponds to uncertainties due to input parameters and model assumptions.
- ¹²CHEKA NOV 02c fit the Q^2 dependence ($200 < Q^2 < 60000$ GeV²) of the charged-current differential cross sections with a propagator mass fit. The last error is due to the uncertainty on the probability density functions.
- ¹³BREITWEG 00D fit the Q^2 dependence ($200 < Q^2 < 22500$ GeV²) of the charged-current differential cross sections with a propagator mass fit. The last error is due to the uncertainty on the probability density functions.
- ¹⁴ALITTI 92B result has two contributions to the systematic error (± 0.83); one (± 0.81) cancels in m_W/m_Z and one (± 0.17) is noncancelling. These were added in quadrature. We choose the ALITTI 92B value without using the LEP m_Z value, because we perform our own combined fit.
- ¹⁵There are two contributions to the systematic error (± 0.84): one (± 0.81) which cancels in m_W/m_Z and one (± 0.21) which is non-cancelling. These were added in quadrature.
- ¹⁶ABE 89i systematic error dominated by the uncertainty in the absolute energy scale.
- ¹⁷ALBAJAR 89 result is from a total sample of 299 $W \rightarrow e\nu$ events.
- ¹⁸ALBAJAR 89 result is from a total sample of 67 $W \rightarrow \mu\nu$ events.
- ¹⁹ALBAJAR 89 result is from $W \rightarrow \tau\nu$ events.

W WIDTH

The W width listed here corresponds to the width parameter in a Breit-Wigner distribution with mass-dependent width. To obtain the world average, common systematic uncertainties between experiments are properly taken into account. The LEP-2 average W width based on published results is 2.196 ± 0.083 GeV [CERN-PH-EP/2006-042]. The combined Tevatron data yields an average W width of 2.046 ± 0.049 GeV [FERMILAB-TM-2460-E].

OUR FIT uses these average LEP and Tevatron width values and combines them assuming no correlations.

- ²³ABAZOV 09AK obtain this result fitting the high-end tail (100–200 GeV) of the transverse mass spectrum in $W \rightarrow e\nu$ decays.
- ²⁴AALTONEN 08B obtain this result fitting the high-end tail (90–200 GeV) of the transverse mass spectrum in semileptonic $W \rightarrow e\nu_e$ and $W \rightarrow \mu\nu_\mu$ decays.
- ²⁵ABDALLAH 08A use direct reconstruction of the kinematics of $W^+W^- \rightarrow q\bar{q}\ell\nu$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events. The systematic error includes ± 0.065 GeV due to final state interactions.
- ²⁶ABBIENDI 06 use direct reconstruction of the kinematics of $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events. The systematic error includes ± 0.003 GeV due to the uncertainty on the LEP beam energy.
- ²⁷ACHARD 06 use direct reconstruction of the kinematics of $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events in the C.M. energy range 189–209 GeV. The result quoted here is obtained combining this value of the width with the result obtained from a direct W mass reconstruction at 172 and 183 GeV (ACCIARRI 99).
- ²⁸SCHAEEL 06 use direct reconstruction of the kinematics of $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events. The systematic error includes ± 0.05 GeV due to possible effects of final state interactions in the $q\bar{q}q\bar{q}$ channel and ± 0.01 GeV due to the uncertainty on the LEP beam energy.
- ²⁹ABAZOV 02E obtain this result fitting the high-end tail (90–200 GeV) of the transverse-mass spectrum in semileptonic $W \rightarrow e\nu_e$ decays.
- ³⁰AFFOLDER 00M fit the high transverse mass (100–200 GeV) $W \rightarrow e\nu_e$ and $W \rightarrow \mu\nu_\mu$ events to obtain $\Gamma(W) = 2.04 \pm 0.11(\text{stat}) \pm 0.09(\text{syst})$ GeV. This is combined with the earlier CDF measurement (ABE 95c) to obtain the quoted result.
- ³¹ABBOTT 00B measure $R = 10.43 \pm 0.27$ for the $W \rightarrow e\nu_e$ decay channel. They use the SM theoretical predictions for $\sigma(W)/\sigma(Z)$ and $\Gamma(W \rightarrow e\nu_e)$ and the world average for $\Gamma(Z \rightarrow e^+e^-)$. The value quoted here is obtained combining this result (2.169 ± 0.070 GeV) with that of ABBOTT 99H.
- ³²ABE 95W measured $R = 10.90 \pm 0.32 \pm 0.29$. They use $m_W = 80.23 \pm 0.18$ GeV, $\sigma(W)/\sigma(Z) = 3.35 \pm 0.03$, $\Gamma(W \rightarrow e\nu) = 225.9 \pm 0.9$ MeV, $\Gamma(Z \rightarrow e^+e^-) = 83.98 \pm 0.18$ MeV, and $\Gamma(Z) = 2.4969 \pm 0.0038$ GeV.
- ³³ALITTI 92 measured $R = 10.4 +0.7 -0.6 \pm 0.3$. The values of $\sigma(Z)$ and $\sigma(W)$ come from $O(\alpha_s^2)$ calculations using $m_W = 80.14 \pm 0.27$ GeV, and $m_Z = 91.175 \pm 0.021$ GeV along with the corresponding value of $\sin^2\theta_W = 0.2274$. They use $\sigma(W)/\sigma(Z) = 3.26 \pm 0.07 \pm 0.05$ and $\Gamma(Z) = 2.487 \pm 0.010$ GeV.
- ³⁴ALBAJAR 91 measured $R = 9.5 +1.1 -1.0$ (stat. + syst.). $\sigma(W)/\sigma(Z)$ is calculated in QCD at the parton level using $m_W = 80.18 \pm 0.28$ GeV and $m_Z = 91.172 \pm 0.031$ GeV along with $\sin^2\theta_W = 0.2322 \pm 0.0014$. They use $\sigma(W)/\sigma(Z) = 3.23 \pm 0.05$ and $\Gamma(Z) = 2.498 \pm 0.020$ GeV. This measurement is obtained combining both the electron and muon channels.

W+ DECAY MODES

W^- modes are charge conjugates of the modes below.

Mode	Fraction (Γ_i/Γ)	Confidence level
Γ_1 $\ell^+\nu$	[a] (10.80 ± 0.09) %	
Γ_2 $e^+\nu$	(10.75 ± 0.13) %	
Γ_3 $\mu^+\nu$	(10.57 ± 0.15) %

This represents the width for the decay of the W boson into a charged particle with momentum below detectability, $p < 200$ MeV.				
VALUE (MeV)	DOCUMENT ID	TECN	COMMENT	
$30^{+52}_{-48} \pm 33$	35 BARATE	99i ALEP	$E_{\text{cm}}^{ee} = 161+172+183$ GeV	
• • • We do not use the following data for averages, fits, limits, etc. • • •				
	36 BARATE	99L ALEP	$E_{\text{cm}}^{ee} = 161+172+183$ GeV	
35 BARATE 99i measure this quantity using the dependence of the total cross section σ_{WW} upon a change in the total width. The fit is performed to the WW measured cross sections at 161, 172, and 183 GeV. This partial width is < 139 MeV at 95%CL.				
36 BARATE 99L use W -pair production to search for effectively invisible W decays, tagging with the decay of the other W boson to Standard Model particles. The partial width for effectively invisible decay is < 27 MeV at 95%CL.				

W BRANCHING RATIOS

Overall fits are performed to determine the branching ratios of the W . LEP averages on $W \rightarrow e\nu_e$, $W \rightarrow \mu\nu_\mu$, and $W \rightarrow \tau\nu_\tau$, and their correlations are first obtained by combining results from the four experiments taking properly into account the common systematics. The procedure is described in the note LEPEWWG/XSEC/2001-02, 30 March 2001, at <http://lepewwg.web.cern.ch/LEPEWWG/lepww/4f/PDG01>. The LEP average values so obtained, using published data, are given in the note LEPEWWG/XSEC/2005-01 accessible at <http://lepewwg.web.cern.ch/LEPEWWG/lepww/4f/PDG05/>. These results, together with results from the $p\bar{p}$ colliders are then used in fits to obtain the world average W branching ratios. A first fit determines three individual leptonic branching ratios, $B(W \rightarrow e\nu_e)$, $B(W \rightarrow \mu\nu_\mu)$, and $B(W \rightarrow \tau\nu_\tau)$. This fit has a $\chi^2=7.9$ for 9 degrees of freedom. The correlation coefficients between the branching fractions are 0.08 ($e-\mu$), -0.21 ($e-\tau$), -0.14 ($\mu-\tau$). A second fit assumes lepton universality and determines the leptonic branching ratio $B(W \rightarrow \ell\nu_\ell)$ and the hadronic branching ratio is derived as $B(W \rightarrow \text{hadrons}) = 1-3B(W \rightarrow \ell\nu)$. This fit has a $\chi^2=15.5$ for 11 degrees of freedom.

The LEP $W \rightarrow \ell\nu$ data are obtained by the Collaborations using individual leptonic channels and are, therefore, not included in the overall fits to avoid double counting.

Note: The LEP combination including the new OPAL results, ABBIENDI 07A, could not be performed in time for this Review. Thus, the OUR FIT values quoted below use the previous OPAL results as in ABBIENDI,G 00.

42 ABBOTT 00D measure $\sigma_{W\ell} \times B(W \rightarrow \tau\nu_\tau) = 2.22 \pm 0.09 \pm 0.10 \pm 0.10$ nb. Using the ABBOTT 00B result $\sigma_{W\ell} \times B(W \rightarrow e\nu_e) = 2.31 \pm 0.01 \pm 0.05 \pm 0.10$ nb, they quote the ratio of the couplings from which we derive this measurement.

43 ABE 92E use two procedures for selecting $W \rightarrow \tau\nu_\tau$ events. The missing E_T trigger leads to $132 \pm 14 \pm 8$ events and the τ trigger to $47 \pm 9 \pm 4$ events. Proper statistical and systematic correlations are taken into account to arrive at $\sigma_B(W \rightarrow \tau\nu) = 2.05 \pm 0.27$ nb. Combined with ABE 91C result on $\sigma_B(W \rightarrow e\nu)$, ABE 92E quote a ratio of the couplings from which we derive this measurement.

44 This measurement is derived by us from the ratio of the couplings of ALITTI 92F.

19.23 ± 0.74	56 ABREU	98C	DLPH	$E_{cm}^{ee} = 172$ GeV

⁵³ ABBIENDI 06A measure $\langle N_{\text{charged}} \rangle = 38.74 \pm 0.12 \pm 0.26$ when both W bosons decay hadronically and $\langle N_{\text{charged}} \rangle = 19.39 \pm 0.11 \pm 0.09$ when one W boson decays semileptonically. The value quoted here is obtained under the assumption that there is no color reconnection between W bosons; the value is a weighted average taking into account correlations in the systematic uncertainties.

⁵⁴ ABREU,P 00F measure $\langle N_{\text{charged}} \rangle = 39.12 \pm 0.33 \pm 0.36$ and $38.11 \pm 0.57 \pm 0.44$ in the fully hadronic final states at 189 and 183 GeV respectively, and $\langle N_{\text{charged}} \rangle = 19.49 \pm 0.31 \pm 0.27$ and $19.78 \pm 0.49 \pm 0.43$ in the semileptonic final states. The value quoted is a weighted average without assuming any correlations.

⁵⁵ ABBIENDI 99N use the final states $W^+W^- \rightarrow q\bar{q}\ell\bar{\nu}_\ell$ to derive this value.

⁵⁶ ABREU 98C combine results from both the fully hadronic as well semileptonic WW final states after demonstrating that the W decay charged multiplicity is independent of the topology within errors.

TRIPLE GAUGE COUPLINGS (TGC'S)

Revised March 2012 by M.W. Grunewald (U. Ghent) and A. Gurtu (King Abdulaziz University).

Fourteen independent couplings, 7 each for ZWW and γWW , completely describe the VWW vertices within the most general framework of the electroweak Standard Model (SM) consistent with Lorentz invariance and $U(1)$ gauge invariance. Of each of the 7 TGC's, 3 conserve C and P individually, 3 violate CP , and one TGC violates C and P individually while conserving CP . Assumption of C and P conservation and electromagnetic gauge invariance reduces the independent VWW couplings to five: one common set [1,2] is $(\kappa_\gamma, \kappa_Z, \lambda_\gamma, \lambda_Z, g_1^Z)$, where $\kappa_\gamma = \kappa_Z = g_1^Z = 1$ and $\lambda_\gamma = \lambda_Z = 0$ in the Standard Model at the tree level. The parameters κ_Z and λ_Z are related to the other three due to constraints

of gauge invariance as follows: $\kappa_Z = g_1^Z - (\kappa_\gamma - 1) \tan^2 \theta_W$ and $\lambda_Z = \lambda_\gamma$, where θ_W is the weak mixing angle. The W magnetic dipole moment, μ_W , and the W electric quadrupole moment, q_W , are expressed as $\mu_W = e(1 + \kappa_\gamma + \lambda_\gamma)/2M_W$ and $q_W = -e(\kappa_\gamma - \lambda_\gamma)/M_W^2$.

Precision measurements of suitable observables at LEP1 has already led to an exploration of much of the TGC parameter space. At LEP2, the VWW coupling arises in W -pair production via s -channel exchange, or in single W production via the radiation of a virtual photon off the incident e^+ or e^- . At the Tevatron and the LHC, hard-photon bremsstrahlung off a produced W or Z signals the presence of a triple-gauge vertex. In order to extract the value of one TGC, the others are generally kept fixed to their SM values.

While most analyses use the above gauge constraints in the extraction of TGCs, one analysis of W -pair events also determines the real and imaginary parts of all 14 couplings using unconstrained single-parameter fits [3]. The results are consistent.

⁵⁷ ABDALLAH 10 use data on the final states $e^+e^- \rightarrow jj\ell\nu, jjjj, jjX, \ell X$, at center-of-mass energies between 189-209 GeV at LEP2, where $j = \text{jet}$, $\ell = \text{lepton}$, and X represents missing momentum. The fit is carried out keeping all other parameters fixed at their SM values.

⁵⁸ SCHAEEL 05A study single-photon, single- W , and WW -pair production from 183 to 209 GeV. The result quoted here is derived from the WW -pair production sample. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.

⁵⁹ ABBIENDI 04D combine results from W^+W^- in all decay channels. Only CP -conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $0.923 < g_1^Z < 1.054$.

⁶⁰ ACHARD 04D study WW -pair production, single- W production and single-photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained from the WW -pair production sample including data from 161 to 183 GeV, ACCIARRI 99Q. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.

⁶¹ ABAZOV 11 study the $p\bar{p} \rightarrow 3\ell\nu$ process arising in WZ production. They observe 34 WZ candidates with an estimated background of 6 events. An analysis of the p_T spectrum of the Z boson leads to a 95% C.L. limit of $0.944 < g_1^Z < 1.154$, for a form factor $\Lambda = 2$ TeV.

- ⁶² AALTONEN 10K study $p\bar{p} \rightarrow W^+W^-$ with $W \rightarrow e/\mu\nu$. The p_T of the leading (second) lepton is required to be > 20 (10) GeV. The final number of events selected is 654 of which 320 ± 47 are estimated to be background. The 95% C.L. interval is $0.76 < g_1^Z < 1.34$ for $\Lambda = 1.5$ TeV and $0.78 < g_1^Z < 1.30$ for $\Lambda = 2$ TeV.
- ⁶³ ABAZOV 09AD study the $p\bar{p} \rightarrow \ell\nu 2$ jet process arising in WW and WZ production. They select 12,473 (14,392) events in the electron (muon) channel with an expected di-boson signal of 436 (527) events. The results on the anomalous couplings are derived from an analysis of the p_T spectrum of the 2-jet system and quoted at 68% C.L. and for a form factor of 2 TeV. This measurement is not used for obtaining the mean as it is for a specific form factor. The 95% confidence interval is $0.88 < g_1^Z < 1.20$.
- ⁶⁴ ABAZOV 09AJ study the $p\bar{p} \rightarrow 2\ell\nu$ process arising in WW production. They select 100 events with an expected WW signal of 65 events. An analysis of the p_T spectrum of the two charged leptons leads to 95% C.L. limits of $0.86 < g_1^Z < 1.3$, for a form factor $\Lambda = 2$ TeV.
- ⁶⁵ ABDALLAH 08c determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \rightarrow W^+W^- \rightarrow (qq)(\ell\nu)$, where $\ell = e$ or μ . Values of all other couplings are fixed to their standard model values.
- ⁶⁶ ABAZOV 07z set limits on anomalous TGCs using the measured cross section and $p_T(Z)$ distribution in WZ production with both the W and the Z decaying leptonically into electrons and muons. Setting the other couplings to their standard model values, the 95% C.L. limit for a form factor scale $\Lambda = 2$ TeV is $0.86 < g_1^Z < 1.35$.
- ⁶⁷ ABAZOV 05s study $p\bar{p} \rightarrow WZ$ production with a subsequent trilepton decay to $\ell\nu\ell'\bar{\nu}$ (ℓ and $\ell' = e$ or μ). Three events (estimated background 0.71 ± 0.08 events) with WZ decay characteristics are observed from which they derive limits on the anomalous WWZ couplings. The 95% C.L. limit for a form factor scale $\Lambda = 1.5$ TeV is $0.51 < g_1^Z < 1.66$, fixing λ_Z and κ_Z to their Standard Model values.
- ⁶⁸ ABREU 01i combine results from e^+e^- interactions at 189 GeV leading to W^+W^- and $W\nu_e$ final states with results from ABREU 99L at 183 GeV. The 95% confidence interval is $0.84 < g_1^Z < 1.13$.
- ⁶⁹ ABBOTT 99i perform a simultaneous fit to the $W\gamma$, $WW \rightarrow$ dilepton, $WW/WZ \rightarrow e\nu jj$, $WW/WZ \rightarrow \mu\nu jj$, and $WZ \rightarrow$ trilepton data samples. For $\Lambda = 2.0$ TeV, the 95%CL limits are $0.63 < g_1^Z < 1.57$, fixing λ_Z and κ_Z to their Standard Model values, and assuming Standard Model values for the $WW\gamma$ couplings.

 κ_γ

OUR FIT below is obtained by combining the measurements taking into account properly the common systematic errors (see LEPEWWG/TGC/2005-01 at <http://lepewwg.web.cern.ch/LEPEWWG/lepww/tgc/>).

		70 ABDALLAH	10	use data on the final states $e^+e^- \rightarrow jj\ell\nu, jjjj, jjX, \ell X$, at center-of-mass energies between 189–209 GeV at LEP2, where $j =$ jet, $\ell =$ lepton, and X represents missing momentum. The fit is carried out keeping all other parameters fixed at their SM values.
		71 SCHAEEL	05A	study single-photon, single- W , and WW -pair production from 183 to 209 GeV. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.
		72 ABBIENDI	04D	combine results from W^+W^- in all decay channels. Only CP -conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $0.73 < \kappa_\gamma < 1.07$.
		73 ACHARD	04D	study W^+W^- production, single- W production and single-photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained including data from 161 to 183 GeV, ACCIARRI 99q. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.
		74 ABAZOV	11AC	study $W\gamma$ production in $p\bar{p}$ collisions at 1.96 TeV, with the W decay products containing an electron or a muon. They select 196 (363) events in the electron (muon) mode, with a SM expectation of 190 (372) events. A likelihood fit to the photon E_T spectrum above 15 GeV yields at 95% C.L. the result: $0.6 < \kappa_\gamma < 1.4$ for a formfactor $\Lambda = 2$ TeV.

- ⁷⁵ CHATRCHYAN 11M study $W\gamma$ production in pp collisions at $\sqrt{s} = 7$ TeV using 36 pb^{-1} pp data with the W decaying to electron and muon. The total cross section is measured for photon transverse energy $E_T^\gamma > 10$ GeV and spatial separation from charged leptons in the plane of pseudo rapidity and azimuthal angle $\Delta R(\ell, \gamma) > 0.7$. The number of candidate (background) events is 452 (228 ± 21) for the electron channel and 520 (277 ± 25) for the muon channel. Setting other couplings to their standard model value, they derive a 95% CL limit of $-0.11 < \kappa_\gamma < 2.04$.
- ⁷⁶ AALTONEN 10K study $p\bar{p} \rightarrow W^+W^-$ with $W \rightarrow e/\mu\nu$. The p_T of the leading (second) lepton is required to be > 20 (10) GeV. The final number of events selected is 654 of which 320 ± 47 are estimated to be background. The 95% C.L. interval is $0.37 < \kappa_\gamma < 1.72$ for $\Lambda = 1.5$ TeV and $0.43 < \kappa_\gamma < 1.65$ for $\Lambda = 2$ TeV.
- ⁷⁷ AARON 09B study single- W production in ep collisions at 0.3 TeV C.M. energy. They select 53 $W \rightarrow e/\mu$ events with a standard model expectation of 54.1 ± 7.4 events. Fitting the transverse momentum spectrum of the hadronic recoil system they obtain a 95% C.L. limit of $-3.7 < \kappa_\gamma < -1.5$ or $0.3 < \kappa_\gamma < 1.5$, where the ambiguity is due to the quadratic dependence of the cross section to the coupling parameter.
- ⁷⁸ ABAZOV 09AD study the $p\bar{p} \rightarrow \ell\nu 2$ jet process arising in WW and WZ production. They select 12,473 (14,392) events in the electron (muon) channel with an expected di-boson signal of 436 (527) events. The results on the anomalous couplings are derived from an analysis of the p_T spectrum of the 2-jet system and quoted at 68% C.L. and for a form factor of 2 TeV. This measurement is not used for obtaining the mean as it is for a specific form factor. The 95% confidence interval is $0.56 < \kappa_\gamma < 1.55$.
- ⁷⁹ ABAZOV 09AJ study the $p\bar{p} \rightarrow 2\ell\nu$ process arising in WW production. They select 100 events with an expected WW signal of 65 events. An analysis of the p_T spectrum of the two charged leptons leads to 95% C.L. limits of $0.46 < \kappa_\gamma < 1.83$, for a form factor $\Lambda = 2$ TeV.
- ⁸⁰ ABAZOV 08R use 0.7 fb^{-1} $p\bar{p}$ data at $\sqrt{s} = 1.96$ TeV to select 263 $W\gamma + X$ events, of which 187 constitute signal, with the W decaying into an electron or a muon, which is required to be well separated from a photon with $E_T > 9$ GeV. A likelihood fit to the photon E_T spectrum yields a 95% CL limit $0.49 < \kappa_\gamma < 1.51$ with other couplings fixed to their Standard Model values.
- ⁸¹ ABDALLAH 08c determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \rightarrow W^+W^- \rightarrow (qq)(\ell\nu)$, where $\ell = e$ or μ . Values of all other couplings are fixed to their standard model values.
- ⁸² AALTONEN 07L set limits on anomalous TGCs using the $p_T(W)$ distribution in WW and WZ production with the W decaying to an electron or muon and the Z to 2 jets. Setting other couplings to their standard model value, the 95% C.L. limits are $0.54 < \kappa_\gamma < 1.39$ for a form factor scale $\Lambda = 1.5$ TeV.
- ⁸³ ABAZOV 06H study $p\bar{p} \rightarrow WW$ production with a subsequent decay $WW \rightarrow e^+\nu_e e^-\bar{\nu}_e$, $WW \rightarrow e^+\nu_e \mu^+\bar{\nu}_\mu$ or $WW \rightarrow \mu^+\nu_\mu \mu^-\bar{\nu}_\mu$. The 95% C.L. limit for a form factor scale $\Lambda = 1$ TeV is $-0.05 < \kappa_\gamma < 2.29$, fixing $\lambda_\gamma = 0$. With the assumption that the $WW\gamma$ and WWZ couplings are equal the 95% C.L. one-dimensional limit ($\Lambda = 2$ TeV) is $0.68 < \kappa < 1.45$.
- ⁸⁴ ABAZOV 05i perform a likelihood fit to the photon E_T spectrum of $W\gamma + X$ events, where the W decays to an electron or muon which is required to be well separated from the photon. For $\Lambda = 2.0$ TeV the 95% CL limits are $0.12 < \kappa_\gamma < 1.96$. In the fit λ_γ is kept fixed to its Standard Model value.
- ⁸⁵ ABREU 01i combine results from e^+e^- interactions at 189 GeV leading to W^+W^- , $W\nu_e$, and $\nu\bar{\nu}$ final states with results from ABREU 99L at 183 GeV. The 95% confidence interval is $0.87 < \kappa_\gamma < 1.68$.
- ⁸⁶ BREITWEG 00 search for W production in events with large hadronic p_T . For $p_T > 20$ GeV, the upper limit on the cross section gives the 95%CL limit $-3.7 < \kappa_\gamma < 2.5$ (for $\lambda_\gamma = 0$).
- ⁸⁷ ABBOTT 99i perform a simultaneous fit to the $W\gamma$, $WW \rightarrow$ dilepton, $WW/WZ \rightarrow e\nu jj$, $WW/WZ \rightarrow \mu\nu jj$, and $WZ \rightarrow$ trilepton data samples. For $\Lambda = 2.0$ TeV, the 95%CL limits are $0.75 < \kappa_\gamma < 1.39$.

 λ_γ

OUR FIT below is obtained by combining the measurements taking into account properly the common systematic errors (see LEPEWWG/TGC/2005-01 at <http://lepewwg.web.cern.ch/LEPEWWG/lepww/tgc/>).

W

- 88** ABDALLAH 10 use data on the final states $e^+e^- \rightarrow jj\ell\nu, jjjj, jjX, \ell X$, at center-of-mass energies between 189–209 GeV at LEP2, where $j = \text{jet}$, $\ell = \text{lepton}$, and X represents missing momentum. The fit is carried out keeping all other parameters fixed at their SM values.
- 89** SCHAE 05A study single-photon, single- W , and WW -pair production from 183 to 209 GeV. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.
- 90** ABBIENDI 04D combine results from W^+W^- in all decay channels. Only CP -conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $-0.13 < \lambda_\gamma < 0.01$.
- 91** ACHARD 04D study WW -pair production, single- W production and single-photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained including data from 161 to 183 GeV, ACCIARRI 99Q. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.
- 92** ABAZOV 11AC study $W\gamma$ production in $p\bar{p}$ collisions at 1.96 TeV, with the W decay products containing an electron or a muon. They select 196 (363) events in the electron (muon) mode, with a SM expectation of 190 (372) events. A likelihood fit to the photon E_T spectrum above 15 GeV yields at 95% C.L. the result: $-0.08 < \lambda_\gamma < 0.07$ for a form factor $\Lambda = 2$ TeV.
- 93** CHATRCHYAN 11M study $W\gamma$ production in pp collisions at $\sqrt{s} = 7$ TeV using 36 pb $^{-1}$ pp data with the W decaying to electron and muon. The total cross section is measured for photon transverse energy $E_T^\gamma > 10$ GeV and spatial separation from charged leptons in the plane of pseudo rapidity and azimuthal angle $\Delta R(\ell, \gamma) > 0.7$. The number of candidate (background) events is 452 (228 ± 21) for the electron channel and 520 (277 ± 25) for the muon channel. Setting other couplings to their standard model value, they derive a 95% CL limit of $-0.18 < \lambda_\gamma < 0.17$.
- 94** AARON 09B study single- W production in $e p$ collisions at 0.3 TeV C.M. energy. They select 53 $W \rightarrow e/\mu$ events with a standard model expectation of 54.1 ± 7.4 events. Fitting the transverse momentum spectrum of the hadronic recoil system they obtain a 95% C.L. limit of $-2.5 < \lambda_\gamma < 2.5$.
- 95** ABAZOV 09AD study the $p\bar{p} \rightarrow \ell\nu 2\text{jet}$ process arising in WW and WZ production. They select 12,473 (14,392) events in the electron (muon) channel with an expected di-boson signal of 436 (527) events. The results on the anomalous couplings are derived from an analysis of the p_T spectrum of the 2-jet system and quoted at 68% C.L. and for a form factor of 2 TeV. This measurement is not used for obtaining the mean as it is for a specific form factor. The 95% confidence interval is $-0.10 < \lambda_\gamma < 0.11$.
- 96** ABAZOV 09AJ study the $p\bar{p} \rightarrow 2\ell 2\nu$ process arising in WW production. They select 100 events with an expected WW signal of 65 events. An analysis of the p_T spectrum of the two charged leptons leads to 95% C.L. limits of $-0.14 < \lambda_\gamma < 0.18$, for a form factor $\Lambda = 2$ TeV.
- 97** ABAZOV 08R use 0.7 fb $^{-1}$ $p\bar{p}$ data at $\sqrt{s} = 1.96$ TeV to select 263 $W\gamma + X$ events, of which 187 constitute signal, with the W decaying into an electron or a muon, which is required to be well separated from a photon with $E_T > 9$ GeV. A likelihood fit to the photon E_T spectrum yields a 95% CL limit $-0.12 < \lambda_\gamma < 0.13$ with other couplings fixed to their Standard Model values.
- 98** ABDALLAH 08C determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \rightarrow W^+W^- \rightarrow (qq)(\ell\nu)$, where $\ell = e$ or μ . Values of all other couplings are fixed to their standard model values.
- 99** AALTONEN 07L set limits on anomalous TGCs using the $p_T(W)$ distribution in WW and WZ production with the W decaying to an electron or muon and the Z to 2 jets. Setting other couplings to their standard model value, the 95% C.L. limits are $-0.18 < \lambda_\gamma < 0.17$ for a form factor scale $\Lambda = 1.5$ TeV.
- 100** ABAZOV 06H study $p\bar{p} \rightarrow WW$ production with a subsequent decay $WW \rightarrow e^+\nu_e e^-\bar{\nu}_e, WW \rightarrow e^\pm\nu_e\mu^\mp\nu_\mu$ or $WW \rightarrow \mu^+\nu_\mu\mu^-\bar{\nu}_\mu$. The 95% C.L. limit for a form factor scale $\Lambda = 1$ TeV is $-0.97 < \lambda_\gamma < 1.04$, fixing $\kappa_\gamma=1$. With the assumption that the $WW\gamma$ and WWZ couplings are equal the 95% C.L. one-dimensional limit ($\Lambda = 2$ TeV) is $-0.29 < \lambda_\gamma < 0.30$.
- 101** ABAZOV 05J perform a likelihood fit to the photon E_T spectrum of $W\gamma + X$ events, where the W decays to an electron or muon which is required to be well separated from the photon. For $\Lambda = 2.0$ TeV the 95% CL limits are $-0.20 < \lambda_\gamma < 0.20$. In the fit κ_γ is kept fixed to its Standard Model value.
- 102** ABREU 01I combine results from e^+e^- interactions at 189 GeV leading to W^+W^- , $W\nu_\mu$, and $\nu\bar{\nu}\gamma$ final states with results from ABREU 99L at 183 GeV. The 95% confidence interval is $-0.11 < \lambda_\gamma < 0.23$.
- 103** BREITWEG 00 search for W production in events with large hadronic p_T . For $p_T > 20$ GeV, the upper limit on the cross section gives the 95%CL limit $-3.2 < \lambda_\gamma < 3.2$ for κ_γ fixed to its Standard Model value.
- 104** ABBOTT 99I perform a simultaneous fit to the $W\gamma, WW \rightarrow \text{dilepton}, WW/WZ \rightarrow e\nu jj, WW/WZ \rightarrow \mu\nu jj$, and $WZ \rightarrow \text{trilepton}$ data samples. For $\Lambda = 2.0$ TeV, the 95%CL limits are $-0.18 < \lambda_\gamma < 0.19$.

 κ_Z

This coupling is CP -conserving (C - and P -separately conserving).

- 105** ACHARD 04D study WW -pair production, single- W production and single-photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained using the WW -pair production sample. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.
- 106** ABAZOV 11 study the $p\bar{p} \rightarrow 3\ell\nu$ process arising in WZ production. They observe 34 WZ candidates with an estimated background of 6 events. An analysis of the p_T spectrum of the Z boson leads to a 95% C.L. limit of $0.600 < \kappa_Z < 1.675$, for a form factor $\Lambda = 2$ TeV.

- 107** ABAZOV 06H study $p\bar{p} \rightarrow WW$ production with a subsequent decay $WW \rightarrow e^+\nu_e e^-\bar{\nu}_e, WW \rightarrow e^\pm\nu_e\mu^\mp\nu_\mu$ or $WW \rightarrow \mu^+\nu_\mu\mu^-\bar{\nu}_\mu$. The 95% C.L. limit for a form factor scale $\Lambda = 2$ TeV is $0.55 < \kappa_Z < 1.55$, fixing $\lambda_Z=0$. With the assumption that the $WW\gamma$ and WWZ couplings are equal the 95% C.L. one-dimensional limit ($\Lambda = 2$ TeV) is $0.68 < \kappa < 1.45$.
- 108** ABAZOV 05S study $p\bar{p} \rightarrow WZ$ production with a subsequent trilepton decay to $\ell\nu\ell'\bar{\nu}'$ (ℓ and $\ell' = e$ or μ). Three events (estimated background 0.71 ± 0.08 events) with WZ decay characteristics are observed from which they derive limits on the anomalous WWZ couplings. The 95% CL limit for a form factor scale $\Lambda = 1$ TeV is $-1.0 < \kappa_Z < 3.4$, fixing λ_Z and g_1^Z to their Standard Model values.

 λ_Z

W ANOMALOUS MAGNETIC MOMENT

The full magnetic moment is given by $\mu_W = e(1+\kappa+\lambda)/2m_W$. In the Standard Model, at tree level, $\kappa=1$ and $\lambda=0$. Some papers have defined $\Delta\kappa = 1-\kappa$ and assume that $\lambda=0$. Note that the electric quadrupole moment is given by $-e(\kappa-\lambda)/m_W^2$. A description of the parameterization of these moments and additional references can be found in HAGIWARA 87 and BAUR 88. The parameter Λ appearing in the theoretical limits below is a regularization cutoff which roughly corresponds to the energy scale where the structure of the W boson becomes manifest.

- 127 ABREU 01i combine results from e^+e^- interactions at 189 GeV leading to W^+W^- , $W\nu_e$, and $\nu\bar{\nu}\gamma$ final states with results from ABREU 99L at 183 GeV to determine Δg_{T}^Z , $\Delta\kappa_\gamma$, and λ_γ . $\Delta\kappa_\gamma$ and λ_γ are simultaneously floated in the fit to determine μ_W .
- 128 ABE 95c report $-1.3 < \kappa < 3.2$ for $\lambda=0$ and $-0.7 < \lambda < 0.7$ for $\kappa=1$ in $p\bar{p} \rightarrow e\nu_e\gamma X$ and $\mu\nu_\mu\gamma X$ at $\sqrt{s} = 1.8$ TeV.
- 129 ALITTI 92c measure $\kappa = 1^{+2.6}_{-2.2}$ and $\lambda = 0^{+1.7}_{-1.8}$ in $p\bar{p} \rightarrow e\nu\gamma + X$ at $\sqrt{s} = 630$ GeV. At 95%CL they report $-3.5 < \kappa < 5.9$ and $-3.6 < \lambda < 3.5$.
- 130 SAMUEL 92 use preliminary CDF and UA2 data and find $-2.4 < \kappa < 3.7$ at 96%CL and $-3.1 < \kappa < 4.2$ at 95%CL respectively. They use data for $W\gamma$ production and radiative W decay.
- 131 SAMUEL 91 use preliminary CDF data for $p\bar{p} \rightarrow W\gamma X$ to obtain $-11.3 \leq \Delta\kappa \leq 10.9$. Note that their $\kappa = 1 - \Delta\kappa$.
- 132 GRIFOLS 88 uses deviation from ρ parameter to set limit $\Delta\kappa \lesssim 65 (M_W^2/\Lambda^2)$.
- 133 GROTCHE 87 finds the limit $-37 < \Delta\kappa < 73.5$ (90% CL) from the experimental limits on $e^+e^- \rightarrow \nu\bar{\nu}\gamma$ assuming three neutrino generations and $-19.5 < \Delta\kappa < 56$ for four generations. Note their $\Delta\kappa$ has the opposite sign as our definition.

- 134 VANDERBIJ 87 uses existing limits to the photon structure to obtain $|\Delta\kappa| < 33 (m_W/\Lambda)$. In addition VANDERBIJ 87 discusses problems with using the ρ parameter of the Standard Model to determine $\Delta\kappa$.
- 135 GRAU 85 uses the muon anomaly to derive a coupled limit on the anomalous magnetic dipole and electric quadrupole (λ) moments $1.05 > \Delta\kappa \ln(\Lambda/m_W) + \lambda/2 > -2.77$. In the Standard Model $\lambda = 0$.
- 136 SUZUKI 85 uses partial-wave unitarity at high energies to obtain $|\Delta\kappa| \lesssim 190 (m_W/\Lambda)^2$. From the anomalous magnetic moment of the muon, SUZUKI 85 obtains $|\Delta\kappa| \lesssim 2.2/\ln(\Lambda/m_W)$. Finally SUZUKI 85 uses deviations from the ρ parameter and obtains a very qualitative, order-of-magnitude limit $|\Delta\kappa| \lesssim 150 (m_W/\Lambda)^4$ if $|\Delta\kappa| \ll 1$.
- 137 HERZOG 84 consider the contribution of W -boson to muon magnetic moment including anomalous coupling of $WW\gamma$. Obtain a limit $-1 < \Delta\kappa < 3$ for $\Lambda \gtrsim 1$ TeV.

ANOMALOUS W/Z QUARTIC COUPLINGS

Revised March 2012 by M.W. Grünewald (U. Ghent) and A. Gurtu (King Abdulaziz University).

The Standard Model quartic couplings, $WWWW$, $WWZZ$, $WWZ\gamma$, $WW\gamma\gamma$, and $ZZ\gamma\gamma$ lead to negligible effects at LEP energies, while they are important at a TeV Linear Collider. Outside the Standard Model framework, possible quartic couplings, a_0, a_c, a_n , are expressed in terms of the following dimension-6 operators [1,2];

$$L_6^0 = -\frac{e^2}{16\Lambda^2} a_0 F^{\mu\nu} F_{\mu\nu} \vec{W}^\alpha \cdot \vec{W}_\alpha$$

$$L_6^c = -\frac{e^2}{16\Lambda^2} a_c F^{\mu\alpha} F_{\mu\beta} \vec{W}^\beta \cdot \vec{W}_\alpha$$

$$L_6^n = -i\frac{e^2}{16\Lambda^2} a_n \epsilon_{ijk} W_{\mu\alpha}^{(i)} W_\nu^{(j)} W^{(k)\alpha} F^{\mu\nu}$$

$$\tilde{L}_6^0 = -\frac{e^2}{16\Lambda^2} \tilde{a}_0 F^{\mu\nu} \tilde{F}_{\mu\nu} \vec{W}^\alpha \cdot \vec{W}_\alpha$$

$$\tilde{L}_6^n = -i\frac{e^2}{16\Lambda^2} \tilde{a}_n \epsilon_{ijk} W_{\mu\alpha}^{(i)} W_\nu^{(j)} W^{(k)\alpha} \tilde{F}^{\mu\nu}$$

where F, W are photon and W fields, L_6^0 and L_6^c conserve C, P separately (\tilde{L}_6^0 conserves only C) and generate anomalous $W^+W^-\gamma\gamma$ and $ZZ\gamma\gamma$ couplings, L_6^n violates CP (\tilde{L}_6^n violates both C and P) and generates an anomalous $W^+W^-Z\gamma$ coupling, and Λ is an energy scale for new physics. For the $ZZ\gamma\gamma$ coupling the CP -violating term represented by L_6^n does not contribute. These couplings are assumed to be real and to vanish at tree level in the Standard Model.

Within the same framework as above, a more recent description of the quartic couplings [3] treats the anomalous parts of the $WW\gamma\gamma$ and $ZZ\gamma\gamma$ couplings separately leading to two sets parameterized as a_0^V/Λ^2 and a_c^V/Λ^2 , where $V = W$ or Z .

At LEP the processes studied in search of these quartic couplings are $e^+e^- \rightarrow WW\gamma$, $e^+e^- \rightarrow \gamma\gamma\nu\bar{\nu}$, and $e^+e^- \rightarrow Z\gamma\gamma$ and limits are set on the quantities $a_0^W/\Lambda^2, a_c^W/\Lambda^2, a_n/\Lambda^2$. The characteristics of the first process depend on all the three couplings whereas those of the latter two depend only on the two CP -conserving couplings. The sensitive measured variables are the cross sections for these processes as well as the energy and angular distributions of the photon and recoil mass to the photon pair.

• • • We do not use the following data for averages, fits, limits, etc. • • •

- 138 ABBIENDI 04b select $187 e^+ e^- \rightarrow W^+ W^- \gamma$ events in the C.M. energy range 180–209 GeV, where $E_\gamma > 2.5 \text{ GeV}$, the photon has a polar angle $|\cos\theta_\gamma| < 0.975$ and is well isolated from the nearest jet and charged lepton, and the effective masses of both fermion-antifermion systems agree with the W mass within $3\Gamma_W$. The measured differential cross section as a function of the photon energy and photon polar angle is used to extract the 95% CL limits: $-0.020 \text{ GeV}^{-2} < a_0^W/\Lambda^2 < 0.020 \text{ GeV}^{-2}$, $-0.053 \text{ GeV}^{-2} < a_c^W/\Lambda^2 < 0.037 \text{ GeV}^{-2}$ and $-0.16 \text{ GeV}^{-2} < a_n/\Lambda^2 < 0.15 \text{ GeV}^{-2}$.
- 139 ABBIENDI 04L select $20 e^+ e^- \rightarrow \nu\bar{\nu}\gamma\gamma$ acoplanar events in the energy range 180–209 GeV and $176 e^+ e^- \rightarrow q\bar{q}\gamma\gamma$ events in the energy range 130–209 GeV. These samples are used to constrain possible anomalous $W^+ W^- \gamma\gamma$ and $Z Z \gamma\gamma$ quartic couplings. Further combining with the $W^+ W^- \gamma$ sample of ABBIENDI 04b the following one-parameter 95% CL limits are obtained: $-0.007 < a_0^Z/\Lambda^2 < 0.023 \text{ GeV}^{-2}$, $-0.029 < a_c^Z/\Lambda^2 < 0.029 \text{ GeV}^{-2}$, $-0.020 < a_0^W/\Lambda^2 < 0.020 \text{ GeV}^{-2}$, $-0.052 < a_c^W/\Lambda^2 < 0.037 \text{ GeV}^{-2}$.
- 140 In the CM energy range 183 to 209 GeV HEISTER 04a select $30 e^+ e^- \rightarrow \nu\bar{\nu}\gamma\gamma$ events with two acoplanar, high energy and high transverse momentum photons. The photon-photon acoplanarity is required to be $> 5^\circ$, $E_\gamma/\sqrt{s} > 0.025$ (the more energetic photon having energy $> 0.2\sqrt{s}$), $p_{T,\gamma}/E_{\text{beam}} > 0.05$ and $|\cos\theta_\gamma| < 0.94$. A likelihood fit to the photon energy and recoil missing mass yields the following one-parameter 95% CL limits: $-0.012 < a_0^Z/\Lambda^2 < 0.019 \text{ GeV}^{-2}$, $-0.041 < a_c^Z/\Lambda^2 < 0.044 \text{ GeV}^{-2}$, $-0.060 < a_0^W/\Lambda^2 < 0.055 \text{ GeV}^{-2}$, $-0.099 < a_c^W/\Lambda^2 < 0.093 \text{ GeV}^{-2}$.
- 141 ABDALLAH 03i select $122 e^+ e^- \rightarrow W^+ W^- \gamma$ events in the C.M. energy range 189–209 GeV, where $E_\gamma > 5 \text{ GeV}$, the photon has a polar angle $|\cos\theta_\gamma| < 0.95$ and is well isolated from the nearest charged fermion. A fit to the photon energy spectra yields $a_c/\Lambda^2 = 0.000 \pm 0.019 \text{ GeV}^{-2}$, $a_0/\Lambda^2 = -0.004 \pm 0.018 \text{ GeV}^{-2}$, $\bar{a}_0/\Lambda^2 = -0.007 \pm 0.019 \text{ GeV}^{-2}$, $a_n/\Lambda^2 = -0.09 \pm 0.16 \text{ GeV}^{-2}$, and $\bar{a}_n/\Lambda^2 = +0.05 \pm 0.15 \text{ GeV}^{-2}$, keeping the other parameters fixed to their Standard Model values (0). The 95% CL limits are: $-0.063 \text{ GeV}^{-2} < a_c/\Lambda^2 < +0.032 \text{ GeV}^{-2}$, $-0.020 \text{ GeV}^{-2} < a_0/\Lambda^2 < +0.020 \text{ GeV}^{-2}$, $-0.020 \text{ GeV}^{-2} < \bar{a}_0/\Lambda^2 < +0.020 \text{ GeV}^{-2}$, $-0.18 \text{ GeV}^{-2} < a_n/\Lambda^2 < +0.14 \text{ GeV}^{-2}$, $-0.16 \text{ GeV}^{-2} < \bar{a}_n/\Lambda^2 < +0.17 \text{ GeV}^{-2}$.
- 142 ACHARD 02f select $86 e^+ e^- \rightarrow W^+ W^- \gamma$ events at 192–207 GeV, where $E_\gamma > 5 \text{ GeV}$ and the photon is well isolated. They also select 43 acoplanar $e^+ e^- \rightarrow \nu\bar{\nu}\gamma\gamma$ events in this energy range, where the photon energies are $> 5 \text{ GeV}$ and $> 1 \text{ GeV}$ and the photon polar angles are between 14° and 166° . All these 43 events are in the recoil mass region corresponding to the Z (75–110 GeV). Using the shape and normalization of the photon spectra in the $W^+ W^- \gamma$ events, and combining with the 42 event sample from 189 GeV data (ACCIARRI 00T), they obtain: $a_0/\Lambda^2 = 0.000 \pm 0.010 \text{ GeV}^{-2}$, $a_c/\Lambda^2 = -0.013 \pm 0.023 \text{ GeV}^{-2}$, and $a_n/\Lambda^2 = -0.002 \pm 0.076 \text{ GeV}^{-2}$. Further combining the analyses of $W^+ W^- \gamma$ events with the low recoil mass region of $\nu\bar{\nu}\gamma\gamma$ events (including samples collected at 183 + 189 GeV), they obtain the following one-parameter 95% CL limits: $-0.015 \text{ GeV}^{-2} < a_0/\Lambda^2 < 0.015 \text{ GeV}^{-2}$, $-0.048 \text{ GeV}^{-2} < a_c/\Lambda^2 < 0.026 \text{ GeV}^{-2}$, and $-0.14 \text{ GeV}^{-2} < a_n/\Lambda^2 < 0.13 \text{ GeV}^{-2}$.

THE Z BOSON

Revised March 2009 by M. Grünwald (U. College Dublin and U. Ghent), and A. Gurtu (Tata Inst.).

Precision measurements at the Z-boson resonance using electron-positron colliding beams began in 1989 at the SLC and at LEP. During 1989–95, the four LEP experiments (ALEPH, DELPHI, L3, OPAL) made high-statistics studies of the production and decay properties of the Z. Although the SLD experiment at the SLC collected much lower statistics, it was able to match the precision of LEP experiments in determining

the effective electroweak mixing angle $\sin^2\bar{\theta}_W$ and the rates of Z decay to b - and c -quarks, owing to availability of polarized electron beams, small beam size, and stable beam spot.

The Z -boson properties reported in this section may broadly be categorized as:

- The standard ‘lineshape’ parameters of the Z consisting of its mass, M_Z , its total width, Γ_Z , and its partial decay widths, $\Gamma(\text{hadrons})$, and $\Gamma(\ell\bar{\ell})$ where $\ell = e, \mu, \tau, \nu$;
- Z asymmetries in leptonic decays and extraction of Z couplings to charged and neutral leptons;
- The b - and c -quark-related partial widths and charge asymmetries which require special techniques;
- Determination of Z decay modes and the search for modes that violate known conservation laws;
- Average particle multiplicities in hadronic Z decay;
- Z anomalous couplings.

The effective vector and axial-vector coupling constants describing the Z -to-fermion coupling are also measured in $p\bar{p}$ and ep collisions at the Tevatron and at HERA. The corresponding cross-section formulae are given in Section 39 (Cross-section formulae for specific processes) and Section 16 (Structure Functions) in this *Review*. In this minireview, we concentrate on the measurements in e^+e^- collisions at LEP and SLC.

The standard ‘lineshape’ parameters of the Z are determined from an analysis of the production cross sections of these final states in e^+e^- collisions. The $Z \rightarrow \nu\bar{\nu}(\gamma)$ state is identified directly by detecting single photon production and indirectly by subtracting the visible partial widths from the total width. Inclusion in this analysis of the forward-backward asymmetry of charged leptons, $A_{FB}^{(0,\ell)}$, of the τ polarization, $P(\tau)$, and its forward-backward asymmetry, $P(\tau)^{fb}$, enables the separate determination of the effective vector (\bar{g}_V) and axial vector (\bar{g}_A) couplings of the Z to these leptons and the ratio (\bar{g}_V/\bar{g}_A), which is related to the effective electroweak mixing angle $\sin^2\bar{\theta}_W$ (see the ‘‘Electroweak Model and Constraints on New Physics’’ review).

Determination of the b - and c -quark-related partial widths and charge asymmetries involves tagging the b and c quarks for which various methods are employed: requiring the presence of a high momentum prompt lepton in the event with high transverse momentum with respect to the accompanying jet; impact parameter and lifetime tagging using precision vertex measurement with high-resolution detectors; application of neural-network techniques to classify events as b or non- b on a statistical basis using event-shape variables; and using the presence of a charmed meson (D/D^*) or a kaon as a tag.

Z-parameter determination

LEP was run at energy points on and around the Z mass (88–94 GeV) constituting an energy ‘scan.’ The shape of the cross-section variation around the Z peak can be described by a Breit-Wigner *ansatz* with an energy-dependent

total width [1–3]. The **three** main properties of this distribution, viz., the **position** of the peak, the **width** of the distribution, and the **height** of the peak, determine respectively the values of M_Z , Γ_Z , and $\Gamma(e^+e^-) \times \Gamma(f\bar{f})$, where $\Gamma(e^+e^-)$ and $\Gamma(f\bar{f})$ are the electron and fermion partial widths of the Z . The quantitative determination of these parameters is done by writing analytic expressions for these cross sections in terms of the parameters, and fitting the calculated cross sections to the measured ones by varying these parameters, taking properly into account all the errors. Single-photon exchange (σ_γ^0) and γ - Z interference ($\sigma_{\gamma Z}^0$) are included, and the large ($\sim 25\%$) initial-state radiation (ISR) effects are taken into account by convoluting the analytic expressions over a ‘Radiator Function’ [1–5] $H(s, s')$. Thus for the process $e^+e^- \rightarrow f\bar{f}$:

$$\sigma_f(s) = \int H(s, s') \sigma_f^0(s') ds' \quad (1)$$

$$\sigma_f^0(s) = \sigma_Z^0 + \sigma_\gamma^0 + \sigma_{\gamma Z}^0 \quad (2)$$

$$\sigma_Z^0 = \frac{12\pi}{M_Z^2} \frac{\Gamma(e^+e^-)\Gamma(f\bar{f})}{\Gamma_Z^2} \frac{s \Gamma_Z^2}{(s - M_Z^2)^2 + s^2 \Gamma_Z^2 / M_Z^2} \quad (3)$$

$$\sigma_\gamma^0 = \frac{4\pi\alpha^2(s)}{3s} Q_f^2 N_c^f \quad (4)$$

$$\sigma_{\gamma Z}^0 = -\frac{2\sqrt{2}\alpha(s)}{3} (Q_f G_F N_c^f \mathcal{G}_V^e \mathcal{G}_V^f) \times \frac{(s - M_Z^2) M_Z^2}{(s - M_Z^2)^2 + s^2 \Gamma_Z^2 / M_Z^2} \quad (5)$$

where Q_f is the charge of the fermion, $N_c^f = 3$ for quarks and 1 for leptons, and \mathcal{G}_V^f is the vector coupling of the Z to the fermion-antifermion pair $f\bar{f}$.

Since $\sigma_{\gamma Z}^0$ is expected to be much less than σ_Z^0 , the LEP Collaborations have generally calculated the interference term in the framework of the Standard Model. This fixing of $\sigma_{\gamma Z}^0$ leads to a tighter constraint on M_Z , and consequently a smaller error on its fitted value. It is possible to relax this constraint and carry out the fit within the S-matrix framework, which is briefly described in the next section.

In the above framework, the QED radiative corrections have been explicitly taken into account by convoluting over the ISR and allowing the electromagnetic coupling constant to run [6]: $\alpha(s) = \alpha/(1 - \Delta\alpha)$. On the other hand, weak radiative corrections that depend upon the assumptions of the electroweak theory and on the values of M_{top} and M_{Higgs} are accounted for by **absorbing them into the couplings**, which are then called the *effective* couplings \mathcal{G}_V and \mathcal{G}_A (or alternatively the effective parameters of the \star scheme of Kennedy and Lynn [7].)

\mathcal{G}_V^f and \mathcal{G}_A^f are complex numbers with small imaginary parts. As experimental data does not allow simultaneous extraction of both real and imaginary parts of the effective couplings, the convention $g_A^f = \text{Re}(\mathcal{G}_A^f)$ and $g_V^f = \text{Re}(\mathcal{G}_V^f)$ is used and the imaginary parts are added in the fitting code [4].

Defining

$$A_f = 2 \frac{g_V^f \cdot g_A^f}{(g_V^f)^2 + (g_A^f)^2} \quad (6)$$

Gauge & Higgs Boson Particle Listings

Z

the lowest-order expressions for the various lepton-related asymmetries on the Z pole are [8–10] $A_{FB}^{(0,\ell)} = (3/4)A_e A_f$, $P(\tau) = -A_\tau$, $P(\tau)^{fb} = -(3/4)A_e$, $A_{LR} = A_e$. The full analysis takes into account the energy-dependence of the asymmetries. Experimentally A_{LR} is defined as $(\sigma_L - \sigma_R)/(\sigma_L + \sigma_R)$, where $\sigma_{L(R)}$ are the $e^+e^- \rightarrow Z$ production cross sections with left- (right)-handed electrons.

The definition of the partial decay width of the Z to $f\bar{f}$ includes the effects of QED and QCD final-state corrections, as well as the contribution due to the imaginary parts of the couplings:

$$\Gamma(f\bar{f}) = \frac{G_F M_Z^3}{6\sqrt{2}\pi} N_c^f \left(|G_A^f|^2 R_A^f + |G_V^f|^2 R_V^f \right) + \Delta_{ew/QCD} \quad (7)$$

where R_V^f and R_A^f are radiator factors to account for final state QED and QCD corrections, as well as effects due to nonzero fermion masses, and $\Delta_{ew/QCD}$ represents the non-factorizable electroweak/QCD corrections.

S-matrix approach to the Z

While most experimental analyses of LEP/SLC data have followed the ‘Breit-Wigner’ approach, an alternative S-matrix-based analysis is also possible. The Z , like all unstable particles, is associated with a complex pole in the S matrix. The pole position is process-independent and gauge-invariant. The mass, \bar{M}_Z , and width, $\bar{\Gamma}_Z$, can be defined in terms of the pole in the energy plane via [11–14]

$$\bar{s} = \bar{M}_Z^2 - i\bar{M}_Z\bar{\Gamma}_Z \quad (8)$$

leading to the relations

$$\begin{aligned} \bar{M}_Z &= M_Z / \sqrt{1 + \Gamma_Z^2/M_Z^2} \\ &\approx M_Z - 34.1 \text{ MeV} \end{aligned} \quad (9)$$

$$\begin{aligned} \bar{\Gamma}_Z &= \Gamma_Z / \sqrt{1 + \Gamma_Z^2/M_Z^2} \\ &\approx \Gamma_Z - 0.9 \text{ MeV} . \end{aligned} \quad (10)$$

The L3 and OPAL Collaborations at LEP (ACCIARRI 00Q and ABBIENDI 04G) have analyzed their data using the S-matrix approach as defined in Eq. (8), in addition to the conventional one. They observe a downward shift in the Z mass as expected.

Handling the large-angle e^+e^- final state

Unlike other $f\bar{f}$ decay final states of the Z , the e^+e^- final state has a contribution not only from the s -channel but also from the t -channel and s - t interference. The full amplitude is not amenable to fast calculation, which is essential if one has to carry out minimization fits within reasonable computer time. The usual procedure is to calculate the non- s channel part of the cross section separately using the Standard Model programs ALIBABA [15] or TOPAZ0 [16], with the measured value of M_{top} , and $M_{\text{Higgs}} = 150$ GeV, and add it to the s -channel cross section calculated as for other channels. This leads to two additional sources of error in the analysis: firstly,

the theoretical calculation in ALIBABA itself is known to be accurate to $\sim 0.5\%$, and secondly, there is uncertainty due to the error on M_{top} and the unknown value of M_{Higgs} (100–1000 GeV). These errors are propagated into the analysis by including them in the systematic error on the e^+e^- final state. As these errors are common to the four LEP experiments, this is taken into account when performing the LEP average.

Errors due to uncertainty in LEP energy determination [17–22]

The systematic errors related to the LEP energy measurement can be classified as:

- The absolute energy scale error;
- Energy-point-to-energy-point errors due to the non-linear response of the magnets to the exciting currents;
- Energy-point-to-energy-point errors due to possible higher-order effects in the relationship between the dipole field and beam energy;
- Energy reproducibility errors due to various unknown uncertainties in temperatures, tidal effects, corrector settings, RF status, *etc.*

Precise energy calibration was done outside normal data-taking using the resonant depolarization technique. Run-time energies were determined every 10 minutes by measuring the relevant machine parameters and using a model which takes into account all the known effects, including leakage currents produced by trains in the Geneva area and the tidal effects due to gravitational forces of the Sun and the Moon. The LEP Energy Working Group has provided a covariance matrix from the determination of LEP energies for the different running periods during 1993–1995 [17].

Choice of fit parameters

The LEP Collaborations have chosen the following primary set of parameters for fitting: M_Z , Γ_Z , σ_{hadron}^0 , $R(\text{lepton})$, $A_{FB}^{(0,\ell)}$, where $R(\text{lepton}) = \Gamma(\text{hadrons})/\Gamma(\text{lepton})$, $\sigma_{\text{hadron}}^0 = 12\pi\Gamma(e^+e^-)\Gamma(\text{hadrons})/M_Z^2\Gamma_Z^2$. With a knowledge of these fitted parameters and their covariance matrix, any other parameter can be derived. The main advantage of these parameters is that they form a physics motivated set of parameters with much reduced correlations.

Thus, the most general fit carried out to cross section and asymmetry data determines the **nine parameters**: M_Z , Γ_Z , σ_{hadron}^0 , $R(e)$, $R(\mu)$, $R(\tau)$, $A_{FB}^{(0,e)}$, $A_{FB}^{(0,\mu)}$, $A_{FB}^{(0,\tau)}$. Assumption of lepton universality leads to a **five-parameter fit** determining M_Z , Γ_Z , σ_{hadron}^0 , $R(\text{lepton})$, $A_{FB}^{(0,\ell)}$.

Combining results from LEP and SLC experiments

With a steady increase in statistics over the years and improved understanding of the common systematic errors between LEP experiments, the procedures for combining results have evolved continuously [23]. The Line Shape Sub-group of the LEP Electroweak Working Group investigated the effects of these common errors, and devised a combination procedure

for the precise determination of the Z parameters from LEP experiments. Using these procedures, this note also gives the results after combining the final parameter sets from the four experiments, and these are the results quoted as the fit results in the Z listings below. Transformation of variables leads to values of derived parameters like partial decay widths and branching ratios to hadrons and leptons. Finally, transforming the LEP combined nine parameter set to $(M_Z, \Gamma_Z, \sigma_{\text{hadron}}^{\circ}, g_A^f, g_V^f, f = e, \mu, \tau)$ using the average values of lepton asymmetry parameters (A_e, A_μ, A_τ) as constraints, leads to the best fitted values of the vector and axial-vector couplings (g_V, g_A) of the charged leptons to the Z .

Brief remarks on the handling of common errors and their magnitudes are given below. The identified common errors are those coming from

- (a) LEP energy-calibration uncertainties, and
- (b) the theoretical uncertainties in (i) the luminosity determination using small angle Bhabha scattering, (ii) estimating the non-s channel contribution to large angle Bhabha scattering, (iii) the calculation of QED radiative effects, and (iv) the parametrization of the cross section in terms of the parameter set used.

Common LEP energy errors

All the collaborations incorporate in their fit the full LEP energy error matrix as provided by the LEP energy group for their intersection region [17]. The effect of these errors is separated out from that of other errors by carrying out fits with energy errors scaled up and down by $\sim 10\%$ and redoing the fits. From the observed changes in the overall error matrix, the covariance matrix of the common energy errors is determined. Common LEP energy errors lead to uncertainties on M_Z , Γ_Z , and $\sigma_{\text{hadron}}^{\circ}$ of 1.7, 1.2 MeV, and 0.011 nb, respectively.

Common luminosity errors

BHLUMI 4.04 [24] is used by all LEP collaborations for small-angle Bhabha scattering leading to a common uncertainty in their measured cross sections of 0.061% [25]. BHLUMI does not include a correction for production of light fermion pairs. OPAL explicitly corrects for this effect and reduces their luminosity uncertainty to 0.054%, which is taken fully correlated with the other experiments. The other three experiments among themselves have a common uncertainty of 0.061%.

Common non-s channel uncertainties

The same standard model programs ALIBABA [15] and TOPAZ0 [16] are used to calculate the non-s channel contribution to the large angle Bhabha scattering [26]. As this contribution is a function of the Z mass, which itself is a variable in the fit, it is parametrized as a function of M_Z by each collaboration to properly track this contribution as M_Z varies in the fit. The common errors on R_e and $A_{FB}^{(0,e)}$ are 0.024 and 0.0014 respectively, and are correlated between them.

Common theoretical uncertainties: QED

There are large initial-state photon and fermion pair radiation effects near the Z resonance, for which the best currently

available evaluations include contributions up to $\mathcal{O}(\alpha^3)$. To estimate the remaining uncertainties, different schemes are incorporated in the standard model programs ZFITTER [5], TOPAZ0 [16], and MIZA [27]. Comparing the different options leads to error estimates of 0.3 and 0.2 MeV on M_Z and Γ_Z respectively, and of 0.02% on $\sigma_{\text{hadron}}^{\circ}$.

Common theoretical uncertainties: parametrization of lineshape and asymmetries

To estimate uncertainties arising from ambiguities in the model-independent parametrization of the differential cross-section near the Z resonance, results from TOPAZ0 and ZFITTER were compared by using ZFITTER to fit the cross sections and asymmetries calculated using TOPAZ0. The resulting uncertainties on M_Z , Γ_Z , $\sigma_{\text{hadron}}^{\circ}$, $R(\text{lepton})$, and $A_{FB}^{(0,\ell)}$ are 0.1 MeV, 0.1 MeV, 0.001 nb, 0.004, and 0.0001 respectively.

Thus, the overall theoretical errors on M_Z , Γ_Z , $\sigma_{\text{hadron}}^{\circ}$ are 0.3 MeV, 0.2 MeV, and 0.008 nb respectively; on each $R(\text{lepton})$ is 0.004 and on each $A_{FB}^{(0,\ell)}$ is 0.0001. Within the set of three $R(\text{lepton})$'s and the set of three $A_{FB}^{(0,\ell)}$'s, the respective errors are fully correlated.

All the theory-related errors mentioned above utilize Standard Model programs which need the Higgs mass and running electromagnetic coupling constant as inputs; uncertainties on these inputs will also lead to common errors. All LEP collaborations used the same set of inputs for Standard Model calculations: $M_Z = 91.187$ GeV, the Fermi constant $G_F = (1.16637 \pm 0.00001) \times 10^{-5}$ GeV⁻² [28], $\alpha^{(5)}(M_Z) = 1/128.877 \pm 0.090$ [29], $\alpha_s(M_Z) = 0.119$ [30], $M_{\text{top}} = 174.3 \pm 5.1$ GeV [30] and $M_{\text{Higgs}} = 150$ GeV. The only observable effect, on M_Z , is due to the variation of M_{Higgs} between 100–1000 GeV (due to the variation of the γ/Z interference term which is taken from the Standard Model): M_Z changes by +0.23 MeV per unit change in $\log_{10} M_{\text{Higgs}}/\text{GeV}$, which is not an error but a correction to be applied once M_{Higgs} is determined. The effect is much smaller than the error on M_Z (± 2.1 MeV).

Methodology of combining the LEP experimental results

The LEP experimental results actually used for combination are slightly modified from those published by the experiments (which are given in the Listings below). This has been done in order to facilitate the procedure by making the inputs more consistent. These modified results are given explicitly in [23]. The main differences compared to the published results are (a) consistent use of ZFITTER 6.23 and TOPAZ0 (the published ALEPH results used ZFITTER 6.10); (b) use of the combined energy-error matrix, which makes a difference of 0.1 MeV on the M_Z and Γ_Z for L3 only as at that intersection the RF modeling uncertainties are the largest.

Thus, nine-parameter sets from all four experiments with their covariance matrices are used together with all the common errors correlations. A grand covariance matrix, V , is constructed and a combined nine-parameter set is obtained by

Gauge & Higgs Boson Particle Listings

Z

minimizing $\chi^2 = \Delta^T V^{-1} \Delta$, where Δ is the vector of residuals of the combined parameter set to the results of individual experiments. Imposing lepton universality in the combination results in the combined five parameter set.

Study of $Z \rightarrow b\bar{b}$ and $Z \rightarrow c\bar{c}$

In the sector of c - and b -physics, the LEP experiments have measured the ratios of partial widths $R_b = \Gamma(Z \rightarrow b\bar{b})/\Gamma(Z \rightarrow \text{hadrons})$, and $R_c = \Gamma(Z \rightarrow c\bar{c})/\Gamma(Z \rightarrow \text{hadrons})$, and the forward-backward (charge) asymmetries $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$. The SLD experiment at SLC has measured the ratios R_c and R_b and, utilizing the polarization of the electron beam, was able to obtain the final state coupling parameters A_b and A_c from a measurement of the left-right forward-backward asymmetry of b - and c -quarks. The high precision measurement of R_c at SLD was made possible owing to the small beam size and very stable beam spot at SLC, coupled with a highly precise CCD pixel detector. Several of the analyses have also determined other quantities, in particular the semileptonic branching ratios, $B(b \rightarrow \ell^-)$, $B(b \rightarrow c \rightarrow \ell^+)$, and $B(c \rightarrow \ell^+)$, the average time-integrated $B^0\bar{B}^0$ mixing parameter $\bar{\chi}$ and the probabilities for a c -quark to fragment into a D^+ , a D_s , a D^{*+} , or a charmed baryon. The latter measurements do not concern properties of the Z boson, and hence they do not appear in the Listing below. However, for completeness, we will report at the end of this minireview their values as obtained fitting the data contained in the Z section. All these quantities are correlated with the electroweak parameters, and since the mixture of b hadrons is different from the one at the $\Upsilon(4S)$, their values might differ from those measured at the $\Upsilon(4S)$.

All the above quantities are correlated to each other since:

- Several analyses (for example the lepton fits) determine more than one parameter simultaneously;
- Some of the electroweak parameters depend explicitly on the values of other parameters (for example R_b depends on R_c);
- Common tagging and analysis techniques produce common systematic uncertainties.

The LEP Electroweak Heavy Flavour Working Group has developed [31] a procedure for combining the measurements taking into account known sources of correlation. The combining procedure determines fourteen parameters: the six parameters of interest in the electroweak sector, R_b , R_c , $A_{FB}^{b\bar{b}}$, $A_{FB}^{c\bar{c}}$, A_b and A_c and, in addition, $B(b \rightarrow \ell^-)$, $B(b \rightarrow c \rightarrow \ell^+)$, $B(c \rightarrow \ell^+)$, $\bar{\chi}$, $f(D^+)$, $f(D_s)$, $f(c_{\text{baryon}})$ and $P(c \rightarrow D^{*+}) \times B(D^{*+} \rightarrow \pi^+ D^0)$, to take into account their correlations with the electroweak parameters. Before the fit both the peak and off-peak asymmetries are translated to the common energy $\sqrt{s} = 91.26$ GeV using the predicted energy-dependence from ZFITTER [5].

Summary of the measurements and of the various kinds of analysis

The measurements of R_b and R_c fall into two classes. In the first, named single-tag measurement, a method for selecting

b and c events is applied and the number of tagged events is counted. A second technique, named double-tag measurement, has the advantage that the tagging efficiency is directly derived from the data thereby reducing the systematic error on the measurement.

The measurements in the b - and c -sector can be essentially grouped in the following categories:

- Lifetime (and lepton) double-tagging measurements of R_b . These are the most precise measurements of R_b and obviously dominate the combined result. The main sources of systematics come from the charm contamination and from estimating the hemisphere b -tagging efficiency correlation;
- Analyses with $D/D^{*\pm}$ to measure R_c . These measurements make use of several different tagging techniques (inclusive/exclusive double tag, exclusive double tag, reconstruction of all weakly decaying charmed states) and no assumptions are made on the energy-dependence of charm fragmentation;
- A measurement of R_c using single leptons and assuming $B(b \rightarrow c \rightarrow \ell^+)$;
- Lepton fits which use hadronic events with one or more leptons in the final state to measure the asymmetries $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$. Each analysis usually gives several other electroweak parameters. The dominant sources of systematics are due to lepton identification, to other semileptonic branching ratios and to the modeling of the semileptonic decay;
- Measurements of $A_{FB}^{b\bar{b}}$ using lifetime tagged events with a hemisphere charge measurement. These measurements dominate the combined result;
- Analyses with $D/D^{*\pm}$ to measure $A_{FB}^{c\bar{c}}$ or simultaneously $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$;
- Measurements of A_b and A_c from SLD, using several tagging methods (lepton, kaon, D/D^* , and vertex mass). These quantities are directly extracted from a measurement of the left-right forward-backward asymmetry in $c\bar{c}$ and $b\bar{b}$ production using a polarized electron beam.

Averaging procedure

All the measurements are provided by the LEP and SLD Collaborations in the form of tables with a detailed breakdown of the systematic errors of each measurement and its dependence on other electroweak parameters.

The averaging proceeds via the following steps:

- Define and propagate a consistent set of external inputs such as branching ratios, hadron lifetimes, fragmentation models *etc.* All the measurements are checked to ensure that all use a common set of assumptions (for instance, since the QCD corrections for the forward-backward asymmetries are strongly dependent on the experimental conditions, the data are corrected before combining);

- Form the full (statistical and systematic) covariance matrix of the measurements. The systematic correlations between different analyses are calculated from the detailed error breakdown in the measurement tables. The correlations relating several measurements made by the same analysis are also used;
- Take into account any explicit dependence of a measurement on the other electroweak parameters. As an example of this dependence, we illustrate the case of the double-tag measurement of R_b , where c -quarks constitute the main background. The normalization of the charm contribution is not usually fixed by the data and the measurement of R_b depends on the assumed value of R_c , which can be written as:

$$R_b = R_b^{\text{meas}} + a(R_c) \frac{(R_c - R_c^{\text{used}})}{R_c}, \quad (11)$$

where R_b^{meas} is the result of the analysis which assumed a value of $R_c = R_c^{\text{used}}$ and $a(R_c)$ is the constant which gives the dependence on R_c ;

- Perform a χ^2 minimization with respect to the combined electroweak parameters.

After the fit the average peak asymmetries $A_{FB}^{c\bar{c}}$ and $A_{FB}^{b\bar{b}}$ are corrected for the energy shift from 91.26 GeV to M_Z and for QED (initial state radiation), γ exchange, and γZ interference effects, to obtain the corresponding pole asymmetries $A_{FB}^{0,c}$ and $A_{FB}^{0,b}$.

This averaging procedure, using the fourteen parameters described above, and applied to the data contained in the Z particle listing below, gives the following results (where the last 8 parameters do not depend directly on the Z):

$$R_b^0 = 0.21629 \pm 0.00066$$

$$R_c^0 = 0.1721 \pm 0.0030$$

$$A_{FB}^{0,b} = 0.0992 \pm 0.0016$$

$$A_{FB}^{0,c} = 0.0707 \pm 0.0035$$

$$A_b = 0.923 \pm 0.020$$

$$A_c = 0.670 \pm 0.027$$

$$B(b \rightarrow \ell^-) = 0.1071 \pm 0.0022$$

$$B(b \rightarrow c \rightarrow \ell^+) = 0.0801 \pm 0.0018$$

$$B(c \rightarrow \ell^+) = 0.0969 \pm 0.0031$$

$$\bar{\chi} = 0.1250 \pm 0.0039$$

$$f(D^+) = 0.235 \pm 0.016$$

$$f(D_s) = 0.126 \pm 0.026$$

$$P(c_{\text{baryon}}) = 0.093 \pm 0.022$$

$$P(c \rightarrow D^{*+}) \times B(D^{*+} \rightarrow \pi^+ D^0) = 0.1622 \pm 0.0048$$

Among the non-electroweak observables, the B semileptonic branching fraction $B(b \rightarrow \ell^-)$ is of special interest, since the dominant error source on this quantity is the dependence on the semileptonic decay model for $b \rightarrow \ell^-$, with $\Delta B(b \rightarrow \ell^-)_{b \rightarrow \ell^- \text{-model}} = 0.0012$. Extensive studies have been made to understand the size of this error. Among the electroweak quantities, the quark asymmetries with leptons depend also on the semileptonic decay model, while the asymmetries using other methods usually do not. The fit implicitly requires that the different methods give consistent results and this effectively constrains the decay model, and thus reduces in principle the error from this source in the fit result.

To obtain a conservative estimate of the modelling error, the above fit has been repeated removing all asymmetry measurements. The results of the fit on B-decay related observables are [23]: $B(b \rightarrow \ell^-) = 0.1069 \pm 0.0022$, with $\Delta B(b \rightarrow \ell^-)_{b \rightarrow \ell^- \text{-model}} = 0.0013$, $B(b \rightarrow c \rightarrow \ell^+) = 0.0802 \pm 0.0019$ and $\bar{\chi} = 0.1259 \pm 0.0042$.

Z MASS

OUR FIT is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). The fit is performed using the Z mass and width, the Z hadronic pole cross section, the ratios of hadronic to leptonic partial widths, and the Z pole forward-backward lepton asymmetries. This set is believed to be most free of correlations.

The Z-boson mass listed here corresponds to the mass parameter in a Breit-Wigner distribution with mass dependent width. The value is 34 MeV greater than the real part of the position of the pole (in the energy-squared plane) in the Z-boson propagator. Also the LEP experiments have generally assumed a fixed value of the $\gamma - Z$ interferences term based on the standard model. Keeping this term as free parameter leads to a somewhat larger error on the fitted Z mass. See ACCIARRI 00q and ABBIENDI 04g for a detailed investigation of both these issues.

91.74 ± 0.28 ± 0.93	156	⁹ ALITTI	92B UA2	$E_{cm}^{pp} = 630$ GeV
90.9 ± 0.3 ± 0.2	188	¹⁰ ABE	89C CDF	$E_{cm}^{pp} = 1.8$ TeV
91.14 ± 0.12	480	¹¹ ABRAMS	89B MRK2	$E_{cm}^{ee} = 89-93$ GeV
93.1 ± 1.0 ± 3.0	24	¹² ALBAJAR	89 UA1	$E_{cm}^{pp} = 546,630$ GeV

¹ ABBIENDI 01A error includes approximately 2.3 MeV due to statistics and 1.8 MeV due to LEP energy uncertainty.

² The error includes 1.6 MeV due to LEP energy uncertainty.

³ The error includes 1.8 MeV due to LEP energy uncertainty.

⁴ BARATE 00C error includes approximately 2.4 MeV due to statistics, 0.2 MeV due to experimental systematics, and 1.7 MeV due to LEP energy uncertainty.

⁵ ABBIENDI 04G obtain this result using the S-matrix formalism for a combined fit to their cross section and asymmetry data at the Z peak and their data at 130–209 GeV. The authors have corrected the measurement for the 34 MeV shift with respect to the Breit-Wigner fits.

⁶ ACHARD 04C select $e^+e^- \rightarrow Z\gamma$ events with hard initial-state radiation. Z decays to $q\bar{q}$ and muon pairs are considered. The fit results obtained in the two samples are found consistent to each other and combined considering the uncertainty due to ISR modelling as fully correlated.

⁷ ACCIARRI 00q interpret the s-dependence of the cross sections and lepton forward-backward asymmetries in the framework of the S-matrix formalism. They fit to their cross section and asymmetry data at high energies, using the results of S-matrix fits to Z-peak data (ACCIARRI 00c) as constraints. The 130–189 GeV data constrains the γ/Z interference term. The authors have corrected the measurement for the 34.1 MeV shift with respect to the Breit-Wigner fits. The error contains a contribution of ± 2.3 MeV due to the uncertainty on the γ/Z interference.

⁸ MIYABAYASHI 95 combine their low energy total hadronic cross-section measurement with the ACTON 93d data and perform a fit using an S-matrix formalism. As expected, this result is below the mass values obtained with the standard Breit-Wigner parametrization.

⁹ Enters fit through W/Z mass ratio given in the W Particle Listings. The ALITTI 92b systematic error (± 0.93) has two contributions: one (± 0.92) cancels in m_W/m_Z and one (± 0.12) is noncancelling. These were added in quadrature.

¹⁰ First error of ABE 89 is combination of statistical and systematic contributions; second is mass scale uncertainty.

¹¹ ABRAMS 89B uncertainty includes 35 MeV due to the absolute energy measurement.

¹² ALBAJAR 89 result is from a total sample of 33 $Z \rightarrow e^+e^-$ events.

Z WIDTH

OUR FIT is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06).

2.7 ± 2.0 ± 1.0	25	²² ANSARI	87 UA2	$E_{cm}^{pp} = 546,630$ GeV

¹³ ABBIENDI 01A error includes approximately 3.6 MeV due to statistics, 1 MeV due to event selection systematics, and 1.3 MeV due to LEP energy uncertainty.

¹⁴ The error includes 1.2 MeV due to LEP energy uncertainty.

¹⁵ The error includes 1.3 MeV due to LEP energy uncertainty.

¹⁶ BARATE 00C error includes approximately 3.8 MeV due to statistics, 0.9 MeV due to experimental systematics, and 1.3 MeV due to LEP energy uncertainty.

¹⁷ ABBIENDI 04G obtain this result using the S-matrix formalism for a combined fit to their cross section and asymmetry data at the Z peak and their data at 130–209 GeV. The authors have corrected the measurement for the 1 MeV shift with respect to the Breit-Wigner fits.

¹⁸ ACCIARRI 00q interpret the s-dependence of the cross sections and lepton forward-backward asymmetries in the framework of the S-matrix formalism. They fit to their

cross section and asymmetry data at high energies, using the results of S-matrix fits to Z-peak data (ACCIARRI 00c) as constraints. The 130–189 GeV data constrains the γ/Z interference term. The authors have corrected the measurement for the 0.9 MeV shift with respect to the Breit-Wigner fits.

- ¹⁹ ABREU 96R obtain this value from a study of the interference between initial and final state radiation in the process $e^+e^- \rightarrow Z \rightarrow \mu^+\mu^-$.
- ²⁰ ABRAMS 89B uncertainty includes 50 MeV due to the miniSAM background subtraction error.
- ²¹ ALBAJAR 89 result is from a total sample of 33 $Z \rightarrow e^+e^-$ events.
- ²² Quoted values of ANSARI 87 are from direct fit. Ratio of Z and W production gives either $\Gamma(Z) < (1.09 \pm 0.07) \times \Gamma(W)$, CL = 90% or $\Gamma(Z) = (0.82^{+0.19}_{-0.14} \pm 0.06) \times \Gamma(W)$. Assuming Standard-Model value $\Gamma(W) = 2.65$ GeV then gives $\Gamma(Z) < 2.89 \pm 0.19$ or $= 2.17^{+0.50}_{-0.37} \pm 0.16$.

$\Gamma((u\bar{u} + c\bar{c})/2)/\Gamma(\text{hadrons})$

Γ_7/Γ_6

This quantity is the branching ratio of $Z \rightarrow$ "up-type" quarks to $Z \rightarrow$ hadrons. Except ACKERSTAFF 97T the values of $Z \rightarrow$ "up-type" and $Z \rightarrow$ "down-type" branchings are extracted from measurements of $\Gamma(\text{hadrons})$, and $\Gamma(Z \rightarrow \gamma + \text{jets})$ where γ is a high-energy (>5 or 7 GeV) isolated photon. As the experiments use different procedures and slightly different values of M_Z , $\Gamma(\text{hadrons})$ and α_S in their extraction procedures, our average has to be taken with caution.

VALUE	DOCUMENT ID	TECN	COMMENT

• • • We do not use the following data for averages, fits, limits, etc. • • •

0.1623 ± 0.0085 ± 0.0209 49 ABREU 95D DLPH $E_{\text{cm}}^{\text{ee}} = 88\text{--}94$ GeV

44 ABE 05F use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $c\bar{c}$ events using a double tag method. The single c -tag is obtained with a neural network trained to perform flavor discrimination using as input several signatures (corrected secondary vertex mass, vertex decay length, multiplicity and total momentum of the neural network and R_C is extracted from a simultaneous fit to the count rates of the 4 different tags. The quoted systematic error includes an uncertainty of ± 0.0006 due to the uncertainty on R_b .

45 ABREU 00 obtain this result properly combining the measurement from the D^{*+} production rate ($R_C = 0.1610 \pm 0.0104 \pm 0.0077 \pm 0.0043$ (BR)) with that from the overall charm counting ($R_C = 0.1692 \pm 0.0047 \pm 0.0063 \pm 0.0074$ (BR)) in $c\bar{c}$ events. The systematic error includes an uncertainty of ± 0.0054 due to the uncertainty on the charmed hadron branching fractions.

46 BARATE 00B use exclusive decay modes to independently determine the quantities $R_C \times f(c \rightarrow X)$, $X = D^0, D^+, D_s^+$, and A_c . Estimating $R_C \times f(c \rightarrow \Xi_c / \Omega_c) = 0.0034$, they simply sum over all the charm decays to obtain $R_C = 0.1738 \pm 0.0047 \pm 0.0088 \pm 0.0075$ (BR). This is combined with all previous ALEPH measurements (BARATE 98T and BUSKULIC 94G, $R_C = 0.1681 \pm 0.0054 \pm 0.0062$) to obtain the quoted value.

47 ACKERSTAFF 98E use an inclusive/exclusive double tag. In one jet $D^{*\pm}$ mesons are exclusively reconstructed in several decay channels and in the opposite jet a slow pion (opposite charge inclusive $D^{*\pm}$) tag is used. The b content of this sample is measured by the simultaneous detection of a lepton in one jet and an inclusively reconstructed $D^{*\pm}$ meson in the opposite jet. The systematic error includes an uncertainty of ± 0.006 due to the external branching ratios.

48 ALEXANDER 96R obtain this value via direct charm counting, summing the partial contributions from D^0, D^+, D_s^+ , and Λ_c^+ , and assuming that strange-charmed baryons account for the 15% of the Λ_c^+ production. An uncertainty of ± 0.005 due to the uncertainties in the charm hadron branching ratios is included in the overall systematics.

49 ABREU 95D perform a maximum likelihood fit to the combined p and p_T distributions of single and dilepton samples. The second error includes an uncertainty of ± 0.0124 due to models and branching ratios.

 $R_b = \Gamma(b\bar{b})/\Gamma(\text{hadrons})$ Γ_{10}/Γ_6

OUR FIT is obtained by a simultaneous fit to several c - and b -quark measurements as explained in the note “The Z boson” and ref. LEP-SLC 06.

The Standard Model predicts $R_b = 0.21581$ for $m_t = 174.3$ GeV and $M_H = 150$ GeV.

0.219 ± 0.006 ± 0.005 56 BUSKULIC 94G ALEP $E_{\text{cm}}^{\text{ee}} = 88\text{--}94$ GeV

0.251 ± 0.049 ± 0.030 57 JACOBSEN 91 MRK2 $E_{\text{cm}}^{\text{ee}} = 91$ GeV

50 ABE 05F use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $b\bar{b}$ events using a double tag method. The single b -tag is obtained with a neural network trained to perform flavor discrimination using as input several signatures (corrected secondary vertex mass, vertex decay length, multiplicity and total momentum of the hemisphere; the key tag is obtained requiring the secondary vertex corrected mass to be above the D -meson mass). ABE 05F obtain $R_b = 0.21604 \pm 0.00098 \pm 0.00074$ where the systematic error includes an uncertainty of ± 0.00012 due to the uncertainty on R_C . The value reported here is obtained properly combining with ABE 98D. The quoted systematic error includes an uncertainty of ± 0.00012 due to the uncertainty on R_C .

51 ACCIARRI 00 obtain this result using a double-tagging technique, with a high p_T lepton tag and an impact parameter tag in opposite hemispheres.

52 ABBIENDI 99B tag $Z \rightarrow b\bar{b}$ decays using leptons and/or separated decay vertices. The b -tagging efficiency is measured directly from the data using a double-tagging technique.

53 ABREU 99B obtain this result combining in a multivariate analysis several tagging methods (impact parameter and secondary vertex reconstruction, complemented by event shape variables). For R_C different from its Standard Model value of 0.172, R_b varies as $-0.024 \times (R_C - 0.172)$.

54 BARATE 97F combine the lifetime-mass hemisphere tag (BARATE 97E) with event shape information and lepton tag to identify $Z \rightarrow b\bar{b}$ candidates. They further use c - and u d -selection tags to identify the background. For R_C different from its Standard Model value of 0.172, R_b varies as $-0.019 \times (R_C - 0.172)$.

55 ABREU 95D perform a maximum likelihood fit to the combined p and p_T distributions of single and dilepton samples. The second error includes an uncertainty of ± 0.0023 due to models and branching ratios.

56 BUSKULIC 94G perform a simultaneous fit to the p and p_T spectra of both single and dilepton events.

57 JACOBSEN 91 tagged $b\bar{b}$ events by requiring coincidence of ≥ 3 tracks with significant impact parameters using vertex detector. Systematic error includes lifetime and decay uncertainties (± 0.014).

58 ABBIENDI 01G use a sample of four-jet events from hadronic Z decays. To enhance the $b\bar{b}b\bar{b}$ signal, at least three of the four jets are required to have a significantly detached secondary vertex.

59 ABREU 99U force hadronic Z decays into 3 jets to use all the available phase space and require a b tag for every jet. This decay mode includes primary and secondary 4b production, e.g. from gluon splitting to $b\bar{b}$.

0.024 ± 0.005 ± 0.006	⁹⁵ ALEXANDER	96R	OPAL $E_{\text{cm}}^{\text{e}} = 88-94$ GeV
0.021 ± 0.003 ± 0.005	⁹⁶ BUSKULIC	96Y	ALEP $E_{\text{cm}}^{\text{e}} = 88-94$ GeV

⁹⁵ ALEXANDER 96R measure $R_b \times f(b \rightarrow \Lambda_c^+ X) \times B(\Lambda_c^+ \rightarrow p K^- \pi^+) = (0.122 \pm 0.023 \pm 0.010)\%$ in hadronic Z decays; the value quoted here is obtained using our best value $B(\Lambda_c^+ \rightarrow p K^- \pi^+) = (5.0 \pm 1.3)\%$. The first error is the total experiment's error and the second error is the systematic error due to the branching fraction uncertainty.

⁹⁶ BUSKULIC 96Y obtain the production fraction of Λ_c^+ baryons in hadronic Z decays $f(b \rightarrow \Lambda_c^+ X) = 0.110 \pm 0.014 \pm 0.006$ using $B(\Lambda_c^+ \rightarrow p K^- \pi^+) = (4.4 \pm 0.6)\%$; we have rescaled using our best value $B(\Lambda_c^+ \rightarrow p K^- \pi^+) = (5.0 \pm 1.3)\%$ obtaining $f(b \rightarrow \Lambda_c^+ X) = 0.097 \pm 0.013 \pm 0.025$ where the first error is their total experiment's error and the second error is the systematic error due to the branching fraction uncertainty. The value quoted here is obtained multiplying this production fraction by our value of $R_b = \Gamma(b\bar{b})/\Gamma(\text{hadrons})$.

 $\Gamma(\Xi_c^0 X)/\Gamma(\text{hadrons})$ Γ_{41}/Γ_6

• • • We do not use the following data for averages, fits, limits, etc. • • •

seen ⁹⁷ ABDALLAH 05c DLPH $E_{\text{cm}}^{\text{e}} = 88-94$ GeV
⁹⁷ ABDALLAH 05c searched for the charmed strange baryon Ξ_c^0 in the decay channel $\Xi_c^0 \rightarrow \Xi^- \pi^+ (\Xi^- \rightarrow \Lambda \pi^-)$. The production rate is measured to be $f_{\Xi_c^0} \times B(\Xi_c^0 \rightarrow \Xi^- \pi^+) = (4.7 \pm 1.4 \pm 1.1) \times 10^{-4}$ per hadronic Z decay.

 $\Gamma(\Xi_b X)/\Gamma(\text{hadrons})$ Γ_{42}/Γ_6

Here Ξ_b is used as a notation for the strange b -baryon states Ξ_b^- and Ξ_b^0 .

VALUE	DOCUMENT ID	TECN	COMMENT
-------	-------------	------	---------

• • • We do not use the following data for averages, fits, limits, etc. • • •

seen ⁹⁸ ABDALLAH 05c DLPH $E_{\text{cm}}^{\text{e}} = 88-94$ GeV
 seen ⁹⁹ BUSKULIC 96T ALEP $E_{\text{cm}}^{\text{e}} = 88-94$ GeV
 seen ¹⁰⁰ ABREU 95v DLPH $E_{\text{cm}}^{\text{e}} = 88-94$ GeV

⁹⁸ ABDALLAH 05c searched for the beauty strange baryon Ξ_b in the inclusive semileptonic decay channel $\Xi_b \rightarrow \Xi^- \ell^+ \nu_\ell X$. Evidence for the Ξ_b production is seen from the observation of Ξ^\pm production accompanied by a lepton of the same sign. From the excess of "right-sign" pairs $\Xi^\pm \ell^\mp$ compared to "wrong-sign" pairs $\Xi^\mp \ell^\pm$ the production rate is measured to be $B(b \rightarrow \Xi_b) \times B(\Xi_b \rightarrow \Xi^- \ell^+ X) = (3.0 \pm 1.0 \pm 0.3) \times 10^{-4}$ per lepton species, averaged over electrons and muons.

⁹⁹ BUSKULIC 96T investigate Ξ -lepton correlations and find a significant excess of "right-sign" pairs $\Xi^\pm \ell^\mp$ compared to "wrong-sign" pairs $\Xi^\mp \ell^\pm$. This excess is interpreted as evidence for Ξ_b semileptonic decay. The measured product branching ratio is $B(b \rightarrow \Xi_b) \times B(\Xi_b \rightarrow X_c X \ell^+ \nu_\ell) \times B(X_c \rightarrow \Xi^- X') = (5.4 \pm 1.1 \pm 0.8) \times 10^{-4}$ per lepton species, averaged over electrons and muons, with X_c a charmed baryon.

¹⁰⁰ ABREU 95v observe an excess of "right-sign" pairs $\Xi^\pm \ell^\mp$ compared to "wrong-sign" pairs $\Xi^\mp \ell^\pm$ in jets: this excess is interpreted as evidence for the beauty strange baryon Ξ_b production, with $\Xi_b \rightarrow \Xi^- \ell^+ \nu_\ell X$. They find that the probability for this signal to come from non b -baryon decays is less than 5×10^{-4} and that Λ_b decays can account for less than 10% of these events. The Ξ_b production rate is then measured to be $B(b \rightarrow \Xi_b) \times B(\Xi_b \rightarrow \Xi^- \ell^+ X) = (5.9 \pm 2.1 \pm 1.0) \times 10^{-4}$ per lepton species, averaged over electrons and muons.

 $\Gamma(b\text{-baryon } X)/\Gamma(\text{hadrons})$ Γ_{43}/Γ_6

"OUR EVALUATION" is obtained using our current values for $f(b \rightarrow b\text{-baryon})$ and $R_b = \Gamma(b\bar{b})/\Gamma(\text{hadrons})$. We calculate $\Gamma(b\text{-baryon } X)/\Gamma(\text{hadrons}) = R_b \times f(b \rightarrow b\text{-baryon})$. The decay fraction $f(b \rightarrow b\text{-baryon})$ was provided by the Heavy Flavor Averaging Group (HFAG, http://www.slac.stanford.edu/xorg/hfag/osc/PDG_2009).

VALUE	DOCUMENT ID	TECN	COMMENT
0.0197 ± 0.0032 OUR EVALUATION			
0.0221 ± 0.0015 ± 0.0058	¹⁰¹ BARATE	98v	ALEP $E_{\text{cm}}^{\text{e}} = 88-94$ GeV

¹⁰¹ BARATE 98v use the overall number of identified protons in b -hadron decays to measure $f(b \rightarrow b\text{-baryon}) = 0.102 \pm 0.007 \pm 0.027$. They assume $\text{BR}(b\text{-baryon} \rightarrow p X) = (58 \pm 6)\%$ and $\text{BR}(B_s^0 \rightarrow p X) = (8.0 \pm 4.0)\%$. The value quoted here is obtained multiplying this production fraction by our value of $R_b = \Gamma(b\bar{b})/\Gamma(\text{hadrons})$.

Z HADRONIC POLE CROSS SECTION

OUR FIT is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). This quantity is defined as

$$\sigma_h^0 = \frac{12\pi}{M_Z^2} \frac{\Gamma(e^+e^-)\Gamma(\text{hadrons})}{\Gamma_Z^2}$$

It is one of the parameters used in the Z lineshape fit.

126 ABBIENDI 01A error includes approximately 0.031 due to statistics, 0.033 due to event selection systematics, 0.029 due to uncertainty in luminosity measurement, and 0.011 due to LEP energy uncertainty.

127 BARATE 00c error includes approximately 0.030 due to statistics, 0.026 due to experimental systematics, and 0.025 due to uncertainty in luminosity measurement.

Z VECTOR COUPLINGS

These quantities are the effective vector couplings of the Z to charged leptons. Their magnitude is derived from a measurement of the Z lineshape and the forward-backward lepton asymmetries as a function of energy around the Z mass. The relative sign among the vector to axial-vector couplings is obtained from a measurement of the Z asymmetry parameters, A_{e^+} , A_{μ^+} , and A_{τ^+} . By convention the sign of g_A^e is fixed to be negative (and opposite to that of g_V^e obtained using ν_e scattering measurements). For the light quarks, the sign of the couplings is assigned consistently with this assumption. The fit values quoted below correspond to global nine- or five-parameter fits to lineshape, lepton forward-backward asymmetry, and A_{e^+} , A_{μ^+} , and A_{τ^+} measurements. See the note "The Z boson" and ref. LEP-SLC 06 for details. Where $p\bar{p}$ and $e p$ data is quoted, OUR FIT value corresponds to a weighted average of this with the LEP/SLD fit result.

Z AXIAL-VECTOR COUPLINGS

These quantities are the effective axial-vector couplings of the Z to charged leptons. Their magnitude is derived from a measurement of the Z lineshape and the forward-backward lepton asymmetries as a function of energy around the Z mass. The relative sign among the vector to axial-vector couplings is obtained from a measurement of the Z asymmetry parameters, A_e , A_μ , and A_τ . By convention the sign of g_A^e is fixed to be negative (and opposite to that of g^{*e} obtained using ν_e scattering measurements). For the light quarks, the sign of the couplings is assigned consistently with this assumption. The fit values quoted below correspond to global nine- or five-parameter fits to lineshape, lepton forward-backward asymmetry, and A_e , A_μ , and A_τ measurements. See the note "The Z boson" and ref. LEP-SLC 06 for details. Where $p\bar{p}$ and $e p$ data is quoted, OUR FIT value corresponds to a weighted average of this with the LEP/SLD fit result.

¹⁶⁸ VILAIN 94 derive this value from their value of $g^{\nu\mu}$ and their ratio $g^{\nu e}/g^{\nu\mu} = 1.05^{+0.15}_{-0.18}$.

$g^{\nu\mu}$

VALUE	DOCUMENT ID	TECN	COMMENT
0.502 ± 0.017	169 VILAIN 94	CHM2	From $\nu_\mu e$ scattering

¹⁶⁹ VILAIN 94 derive this value from their measurement of the couplings $g_A^{e\nu\mu} = -0.503 \pm 0.017$ and $g_V^{e\nu\mu} = -0.035 \pm 0.017$ obtained from $\nu_\mu e$ scattering. We have re-evaluated this value using the current PDG values for g_A^e and g_V^e .

Z ASYMMETRY PARAMETERS

For each fermion-antifermion pair coupling to the Z these quantities are defined as

$$A_f = \frac{2g_V^f g_A^f}{(g_V^f)^2 + (g_A^f)^2}$$

where g_V^f and g_A^f are the effective vector and axial-vector couplings. For their relation to the various lepton asymmetries see the note "The Z boson" and ref. LEP-SLC 06.

A_e

Using polarized beams, this quantity can also be measured as $(\sigma_L - \sigma_R)/(\sigma_L + \sigma_R)$, where σ_L and σ_R are the e^+e^- production cross sections for Z bosons produced with left-handed and right-handed electrons respectively.

A_c

This quantity is directly extracted from a measurement of the left-right forward-backward asymmetry in $c\bar{c}$ production at SLC using polarized electron beam. This double asymmetry eliminates the dependence on the Z- e - e coupling parameter A_e . OUR FIT is obtained by a simultaneous fit to several c - and b -quark measurements as explained in the note "The Z boson" and ref. LEP-SLC 06.

VALUE	DOCUMENT ID	TECN	COMMENT
0.670 ± 0.027 OUR FIT			

0.6712 ± 0.0224 ± 0.0157 183 ABE 05 SLD $E_{\text{cm}}^{\text{ee}} = 91.24 \text{ GeV}$

• • • We do not use the following data for averages, fits, limits, etc. • • •

0.583 ± 0.055 ± 0.055 184 ABE 02G SLD $E_{\text{cm}}^{\text{ee}} = 91.24 \text{ GeV}$

0.688 ± 0.041 185 ABE 01c SLD $E_{\text{cm}}^{\text{ee}} = 91.25 \text{ GeV}$

¹⁸³ ABE 05 use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $c\bar{c}$ events tagging on the invariant mass of reconstructed secondary decay vertices. The charge of the underlying c -quark is obtained with an algorithm that takes into account the net charge of the vertex as well as the charge of tracks emanating from the vertex and identified as kaons. This yields (9970 events) $A_c = 0.6747 \pm 0.0290 \pm 0.0233$. Taking into account all correlations with earlier results reported in ABE 02G and ABE 01c, they obtain the quoted overall SLD result.

¹⁸⁴ ABE 02c tag b and c quarks through their semileptonic decays into electrons and muons. A maximum likelihood fit is performed to extract simultaneously A_b and A_c .

¹⁸⁵ ABE 01c tag $Z \rightarrow c\bar{c}$ events using two techniques: exclusive reconstruction of D^{*+}, D^+ and D^0 mesons and the soft pion tag for $D^{*+} \rightarrow D^0 \pi^+$. The large background from D mesons produced in $b\bar{b}$ events is separated efficiently from the signal using precision vertex information. When combining the A_c values from these two samples, care is taken to avoid double counting of events common to the two samples, and common systematic errors are properly taken into account.

A_b

This quantity is directly extracted from a measurement of the left-right forward-backward asymmetry in $b\bar{b}$ production at SLC using polarized electron beam. This double asymmetry eliminates the dependence on the Z- e - e coupling parameter A_e . OUR FIT is obtained by a simultaneous fit to several c - and b -quark measurements as explained in the note "The Z boson" and ref. LEP-SLC 06.

Gauge & Higgs Boson Particle Listings

Z

- 186 ABE 05 use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $b\bar{b}$ events tagging on the invariant mass of reconstructed secondary decay vertices. The charge of the underlying b -quark is obtained with an algorithm that takes into account the net charge of the vertex as well as the charge of tracks emanating from the vertex and identified as kaons. This yields (25917 events) $A_b = 0.9173 \pm 0.0184 \pm 0.0173$. Taking into account all correlations with earlier results reported in ABE 03F, ABE 02g and ABE 99L, they obtain the quoted overall SLD result.
- 187 ABE 03F obtain an enriched sample of $b\bar{b}$ events tagging on the invariant mass of a 3-dimensional topologically reconstructed secondary decay. The charge of the underlying b quark is obtained using a self-calibrating track-charge method. For the 1996–1998 data sample they measure $A_b = 0.906 \pm 0.022 \pm 0.023$. The value quoted here is obtained combining the above with the result of ABE 98I (1993–1995 data sample).
- 188 ABE 02g tag b and c quarks through their semileptonic decays into electrons and muons. A maximum likelihood fit is performed to extract simultaneously A_b and A_c .
- 189 ABE 99L obtain an enriched sample of $b\bar{b}$ events tagging with an inclusive vertex mass cut. For distinguishing b and \bar{b} quarks they use the charge of identified K^\pm .

TRANSVERSE SPIN CORRELATIONS IN $Z \rightarrow \tau^+ \tau^-$

The correlations between the transverse spin components of $\tau^+ \tau^-$ produced in Z decays may be expressed in terms of the vector and axial-vector couplings:

$$C_{TT} = \frac{|g_A^\tau|^2 - |g_V^\tau|^2}{|g_A^\tau|^2 + |g_V^\tau|^2}$$

$$C_{TN} = -2 \frac{|g_A^\tau||g_V^\tau|}{|g_A^\tau|^2 + |g_V^\tau|^2} \sin(\Phi_{g_V^\tau} - \Phi_{g_A^\tau})$$

C_{TT} refers to the transverse-transverse (within the collision plane) spin correlation and C_{TN} refers to the transverse-normal (to the collision plane) spin correlation.

The longitudinal τ polarization P_τ ($= -A_\tau$) is given by:

$$P_\tau = -2 \frac{|g_A^\tau||g_V^\tau|}{|g_A^\tau|^2 + |g_V^\tau|^2} \cos(\Phi_{g_V^\tau} - \Phi_{g_A^\tau})$$

Here Φ is the phase and the phase difference $\Phi_{g_V^\tau} - \Phi_{g_A^\tau}$ can be obtained using both the measurements of C_{TN} and P_τ .

FORWARD-BACKWARD $e^+ e^- \rightarrow f\bar{f}$ CHARGE ASYMMETRIES

These asymmetries are experimentally determined by tagging the respective lepton or quark flavor in $e^+ e^-$ interactions. Details of heavy flavor (c - or b -quark) tagging at LEP are described in the note on "The Z boson" and ref. LEP-SLC 06. The Standard Model predictions for LEP data have been (re)computed using the ZFITTER package (version 6.36) with input parameters $M_Z = 91.187$ GeV, $M_{top} = 174.3$ GeV, $M_{Higgs} = 150$ GeV, $\alpha_s = 0.119$, $\alpha^{(5)}(M_Z) = 1/128.877$ and the Fermi constant $G_F = 1.16637 \times 10^{-5}$ GeV⁻² (see the note on "The Z boson" for references). For non-LEP data the Standard Model predictions are as given by the authors of the respective publications.

$A_{FB}^{(0,e)}$ CHARGE ASYMMETRY IN $e^+ e^- \rightarrow e^+ e^-$

OUR FIT is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). For the Z peak, we report the pole asymmetry defined by $(3/4)A_e^2$ as determined by the nine-parameter fit to cross-section and lepton forward-backward asymmetry data.

1.88 ± 0.34	1.57	91.2	192 BARATE	00C ALEP

- 191 ABBIENDI 01A error includes approximately 0.38 due to statistics, 0.16 due to event selection systematics, and 0.18 due to the theoretical uncertainty in t -channel prediction.
- 192 BARATE 00c error includes approximately 0.31 due to statistics, 0.06 due to experimental systematics, and 0.13 due to the theoretical uncertainty in t -channel prediction.

$A_{FB}^{(0,\mu)}$ CHARGE ASYMMETRY IN $e^+ e^- \rightarrow \mu^+ \mu^-$

OUR FIT is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). For the Z peak, we report the pole asymmetry defined by $(3/4)A_e A_\mu$ as determined by the nine-parameter fit to cross-section and lepton forward-backward asymmetry data.

204 BARATE 00c error includes approximately 0.15 due to statistics, 0.04 due to experimental systematics, and 0.02 due to the theoretical uncertainty in t-channel prediction.

$A_{FB}^{(0,u)}$ CHARGE ASYMMETRY IN $e^+e^- \rightarrow u\bar{u}$

ASYMMETRY (%)	STD. MODEL	\sqrt{s} (GeV)	DOCUMENT ID	TECN
4.0 ± 6.7 ± 2.8	7.2	91.2	205 ACKERSTAFF 97T	OPAL

205 ACKERSTAFF 97T measure the forward-backward asymmetry of various fast hadrons made of light quarks. Then using SU(2) isospin symmetry and flavor independence for down and strange quarks authors solve for the different quark types.

$A_{FB}^{(0,s)}$ CHARGE ASYMMETRY IN $e^+e^- \rightarrow s\bar{s}$

The s-quark asymmetry is derived from measurements of the forward-backward asymmetry of fast hadrons containing an s quark.

ASYMMETRY (%)	STD. MODEL	\sqrt{s} (GeV)	DOCUMENT ID	TECN
9.8 ± 1.1 OUR AVERAGE				
10.08 ± 1.13 ± 0.40	10.1	91.2	206 ABREU 00b	DLPH
6.8 ± 3.5 ± 1.1	10.1	91.2	207 ACKERSTAFF 97T	OPAL

206 ABREU 00b tag the presence of an s quark requiring a high-momentum-identified charged kaon. The s-quark pole asymmetry is extracted from the charged-kaon asymmetry taking the expected d- and u-quark asymmetries from the Standard Model and using the measured values for the c- and b-quark asymmetries.

207 ACKERSTAFF 97T measure the forward-backward asymmetry of various fast hadrons made of light quarks. Then using SU(2) isospin symmetry and flavor independence for down and strange quarks authors solve for the different quark types. The value reported here corresponds then to the forward-backward asymmetry for "down-type" quarks.

$A_{FB}^{(0,c)}$ CHARGE ASYMMETRY IN $e^+e^- \rightarrow c\bar{c}$

OUR FIT, which is obtained by a simultaneous fit to several c- and b-quark measurements as explained in the note "The Z boson" and ref. LEP-SLC 06, refers to the Z pole asymmetry. The experimental values, on the other hand, correspond to the measurements carried out at the respective energies.

215 ABDALLAH 05 obtain an enriched samples of $b\bar{b}$ events using lifetime information. The quark (or antiquark) charge is determined with a neural network using the secondary vertex charge, the jet charge and particle identification.

216 ABDALLAH 04F tag b- and c-quarks using semileptonic decays combined with charge flow information from the hemisphere opposite to the lepton. Enriched samples of $c\bar{c}$ and $b\bar{b}$ events are obtained using lifetime information.

Gauge & Higgs Boson Particle Listings

Z

- 217 ABBIENDI 03P tag heavy flavors using events with one or two identified leptons. This allows the simultaneous fitting of the b and c quark forward-backward asymmetries as well as the average B^0 - \bar{B}^0 mixing.
- 218 ABBIENDI 02i tag $Z^0 \rightarrow b\bar{b}$ decays using a combination of secondary vertex and lepton tags. The sign of the b -quark charge is determined using an inclusive tag based on jet, vertex, and kaon charges.
- 219 HEISTER 02H measure simultaneously b and c quark forward-backward asymmetries using their semileptonic decays to tag the quark charge. The flavor separation is obtained with a discriminating multivariate analysis.
- 220 HEISTER 01D tag $Z \rightarrow b\bar{b}$ events using the impact parameters of charged tracks complemented with information from displaced vertices, event shape variables, and lepton identification. The b -quark direction and charge is determined using the hemisphere charge method along with information from fast kaon tagging and charge estimators of primary and secondary vertices. The change in the quoted value due to variation of A_{FB}^C and R_b is given as $+0.103 (A_{FB}^C - 0.0651) - 0.440 (R_b - 0.21585)$.
- 221 ABREU 99Y tag $Z \rightarrow b\bar{b}$ and $Z \rightarrow c\bar{c}$ events by an exclusive reconstruction of several D meson decay modes (D^{*+} , D^0 , and D^+ with their charge-conjugate states).
- 222 ACCIARRI 99D tag $Z \rightarrow b\bar{b}$ events using high p and p_T leptons. The analysis determines simultaneously a mixing parameter $\chi_b = 0.1192 \pm 0.0068 \pm 0.0051$ which is used to correct the observed asymmetry.
- 223 ACCIARRI 98u tag $Z \rightarrow b\bar{b}$ events using lifetime and measure the jet charge using the hemisphere charge.
- 224 ALEXANDER 97C identify the b and c events using a D/D^* tag.

CHARGE ASYMMETRY IN $e^+e^- \rightarrow q\bar{q}$

Summed over five lighter flavors.

Experimental and Standard Model values are somewhat event-selection dependent. Standard Model expectations contain some assumptions on B^0 - \bar{B}^0 mixing and on other electroweak parameters.

ANOMALOUS $Z\gamma$, $Z\gamma\gamma$, AND ZZV COUPLINGS

Revised March 2012 by M.W. Gr unewald (U. Ghent) and A. Gurtu (King Abdulaziz University).

In on-shell $Z\gamma$ production, deviations from the Standard Model for the $Z\gamma\gamma^*$ and $Z\gamma Z^*$ couplings may be described in terms of 8 parameters, h_i^V ($i = 1, 4; V = \gamma, Z$) [1]. The parameters h_i^γ describe the $Z\gamma\gamma^*$ couplings and the parameters h_i^Z the $Z\gamma Z^*$ couplings. In this formalism h_1^V and h_2^V lead to CP -violating and h_3^V and h_4^V to CP -conserving effects. All these anomalous contributions to the cross section increase rapidly with center-of-mass energy. In order to ensure unitarity, these parameters are usually described by a form-factor representation, $h_i^V(s) = h_{i0}^V / (1 + s/\Lambda^2)^n$, where Λ is the energy scale for the manifestation of a new phenomenon and n is a sufficiently large power. By convention one uses $n = 3$ for $h_{1,3}^V$ and $n = 4$ for $h_{2,4}^V$. Usually limits on h_i^V 's are put assuming some value of Λ , sometimes ∞ .

In on-shell ZZ production, deviations from the Standard Model for the $ZZ\gamma^*$ and ZZZ^* couplings may be described by

means of four anomalous couplings f_i^V ($i = 4, 5; V = \gamma, Z$) [2]. As above, the parameters f_i^γ describe the $ZZ\gamma^*$ couplings and the parameters f_i^Z the ZZZ^* couplings. The anomalous couplings f_5^V lead to violation of C and P symmetries while f_4^V introduces CP violation. Also here, formfactors depending on a scale Λ are used.

All these couplings h_i^V and f_i^V are zero at tree level in the Standard Model; they are measured in e^+e^- , $p\bar{p}$ and pp collisions at LEP, Tevatron and LHC.

233 ABBIENDI, G	00C	OPAL	
234 ABBOTT 98M	D0		
235 ABREU 98K	DLPH		

- 227 AALTONEN 11s study $Z\gamma$ events in $p\bar{p}$ interactions at $\sqrt{s} = 1.96$ TeV with integrated luminosity 5.1 fb^{-1} for $Z \rightarrow e^+e^-/\mu^+\mu^-$ and 4.9 fb^{-1} for $Z \rightarrow \nu\bar{\nu}$. For the charged lepton case, the two leptons must be of the same flavor with the transverse momentum/energy of one > 20 GeV and the other > 10 GeV. The isolated photon must have $E_T > 50$ GeV. They observe 91 events with 87.2 ± 7.8 events expected from standard model processes. For the $\nu\bar{\nu}$ case they require solitary photons with $E_T > 25$ GeV and missing $E_T > 25$ GeV and observe 85 events with standard model expectation of 85.9 ± 5.6 events. Taking the form factor $\Lambda = 1.5$ TeV they derive 95% C.L. limits as $|h_3^{\gamma, Z}| < 0.022$ and $|h_4^{\gamma, Z}| < 0.0009$.

- 228 CHATRCHYAN 11M study $Z\gamma$ production in $p\bar{p}$ collisions at $\sqrt{s} = 7$ TeV using 36 pb^{-1} $p\bar{p}$ data, where the Z decays to e^+e^- or $\mu^+\mu^-$. The total cross sections are measured for photon transverse energy $E_T^\gamma > 10$ GeV and spatial separation from charged leptons in the plane of pseudo rapidity and azimuthal angle $\Delta R(\ell, \gamma) > 0.7$ with the dilepton invariant mass requirement of $M_{\ell\ell} > 50$ GeV. The number of $e^+e^- \gamma$ and $\mu^+\mu^- \gamma$ candidates is 81 and 90 with estimated backgrounds of 20.5 ± 2.5 and 27.3 ± 3.2 events respectively. The 95% CL limits for $Z\gamma\gamma$ couplings are $-0.05 < h_3^Z < 0.06$ and $-0.0005 < h_4^Z < 0.0005$, and for $Z\gamma\gamma$ couplings are $-0.07 < h_3^\gamma < 0.07$ and $-0.0005 < h_4^\gamma < 0.0006$.

- 229 ABAZOV 09L study $Z\gamma$, $Z \rightarrow \nu\bar{\nu}$ production in $p\bar{p}$ collisions at 1.96 TeV C.M. energy. They select 51 events with a photon of transverse energy E_T^γ larger than 90 GeV, with an expected background of 17 events. Based on the photon E_T spectrum and including also Z decays to charged leptons (from ABAZOV 07M), the following 95% CL limits are reported: $|h_{30}^Z| < 0.033$, $|h_{40}^Z| < 0.0017$, $|h_{30}^\gamma| < 0.033$, $|h_{40}^\gamma| < 0.0017$.

- 230 ABAZOV 07M use 968 $p\bar{p} \rightarrow e^+e^-/\mu^+\mu^- \gamma X$ candidates, at 1.96 TeV center of mass energy, to tag $p\bar{p} \rightarrow Z\gamma$ events by requiring $E_T(\gamma) > 7$ GeV, lepton-gamma separation $\Delta R_{\ell\gamma} > 0.7$, and di-lepton invariant mass > 30 GeV. The cross section is in agreement with the SM prediction. Using these $Z\gamma$ events they obtain 95% C.L. limits on each h_i^V , keeping all others fixed at their SM values. They report: $-0.083 < h_{30}^Z < 0.082$, $-0.0053 < h_{40}^Z < 0.0054$, $-0.085 < h_{30}^\gamma < 0.084$, $-0.0053 < h_{40}^\gamma < 0.0054$, for the form factor scale $\Lambda = 1.2$ TeV.

- 231 Using data collected at $\sqrt{s} = 183$ – 208 , ABDALLAH 07C select 1,877 $e^+e^- \rightarrow Z\gamma$ events with $Z \rightarrow q\bar{q}$ or $\nu\bar{\nu}$, 171 $e^+e^- \rightarrow ZZ$ events with $Z \rightarrow q\bar{q}$ or lepton pair (except an explicit τ pair), and 74 $e^+e^- \rightarrow Z\gamma^*$ events with a $q\bar{q}\mu^+\mu^-$ or $q\bar{q}e^+e^-$ signature, to derive 95% CL limits on h_i^V . Each limit is derived with other parameters set to zero. They report: $-0.23 < h_1^Z < 0.23$, $-0.30 < h_2^Z < 0.16$, $-0.14 < h_1^\gamma < 0.14$, $-0.049 < h_3^\gamma < 0.044$.

- 232 ACHARD 04H select 3515 $e^+e^- \rightarrow Z\gamma$ events with $Z \rightarrow q\bar{q}$ or $\nu\bar{\nu}$ at $\sqrt{s} = 189$ – 209 GeV to derive 95% CL limits on h_i^V . For deriving each limit the other parameters are fixed at zero. They report: $-0.153 < h_1^Z < 0.141$, $-0.087 < h_2^Z < 0.079$, $-0.220 <$

- $h_1^Z < 0.112$, $-0.068 < h_4^Z < 0.148$, $-0.057 < h_1^\gamma < 0.057$, $-0.050 < h_2^\gamma < 0.023$, $-0.059 < h_3^\gamma < 0.004$, $-0.004 < h_4^\gamma < 0.042$.
- 233 ABBIENDI, G 00c study $e^+e^- \rightarrow Z\gamma$ events (with $Z \rightarrow q\bar{q}$ and $Z \rightarrow \nu\bar{\nu}$) at 189 GeV to obtain the central values (and 95% CL limits) of these couplings: $h_1^Z = 0.000 \pm 0.100$ ($-0.190, 0.190$), $h_2^Z = 0.000 \pm 0.068$ ($-0.128, 0.128$), $h_3^Z = -0.074^{+0.102}_{-0.103}$ ($-0.269, 0.119$), $h_4^Z = 0.046 \pm 0.068$ ($-0.084, 0.175$), $h_1^\gamma = 0.000 \pm 0.061$ ($-0.115, 0.115$), $h_2^\gamma = 0.000 \pm 0.041$ ($-0.077, 0.077$), $h_3^\gamma = -0.080^{+0.039}_{-0.041}$ ($-0.164, -0.006$), $h_4^\gamma = 0.064^{+0.033}_{-0.030}$ ($+0.007, +0.134$). The results are derived assuming that only one coupling at a time is different from zero.
- 234 ABBOTT 98M study $p\bar{p} \rightarrow Z\gamma + X$, with $Z \rightarrow e^+e^-, \mu^+\mu^-, \bar{\nu}\nu$ at 1.8 TeV, to obtain 95% CL limits at $\Lambda = 750$ GeV: $|h_{30}^Z| < 0.36$, $|h_{40}^Z| < 0.05$ (keeping $h_1^Z = 0$), and $|h_{30}^\gamma| < 0.37$, $|h_{40}^\gamma| < 0.05$ (keeping $h_1^\gamma = 0$). Limits on the CP -violating couplings are $|h_{20}^Z| < 0.36$, $|h_{20}^\gamma| < 0.05$ (keeping $h_1^Z = 0$), and $|h_{10}^\gamma| < 0.37$, $|h_{20}^\gamma| < 0.05$ (keeping $h_1^\gamma = 0$).
- 235 ABREU 98k determine a 95% CL upper limit on $\sigma(e^+e^- \rightarrow \gamma + \text{invisible particles}) < 2.5$ pb using 161 and 172 GeV data. This is used to set 95% CL limits on $|h_{30}^\gamma| < 0.8$ and $|h_{30}^Z| < 1.3$, derived at a scale $\Lambda = 1$ TeV and with $n=3$ in the form factor representation.

 f_1^V

Combining the LEP results properly taking into account the correlations the following 95% CL limits are derived (CERN-PH-EP/2005-051 or hep-ex/0511027):

$$\begin{aligned} -0.30 < f_4^Z < +0.30, & \quad -0.34 < f_5^Z < +0.38, \\ -0.17 < f_4^\gamma < +0.19, & \quad -0.32 < f_5^\gamma < +0.36. \end{aligned}$$

VALUE	DOCUMENT ID	TECN	COMMENT
••• We do not use the following data for averages, fits, limits, etc. •••			
	236 SCHAEEL	09 ALEP	$E_{cm}^{ee} = 192\text{--}209$ GeV

- 236 Using data collected in the center of mass energy range 192–209 GeV, SCHAEEL 09 select 318 $e^+e^- \rightarrow ZZ$ events with 319.4 expected from the standard model. Using this data they derive the following 95% CL limits: $-0.321 < f_4^Z < 0.318$, $-0.534 < f_4^\gamma < 0.534$, $-0.724 < f_5^Z < 0.733$, $-1.194 < f_5^\gamma < 1.190$.
- 237 ABAZOV 08k search for ZZ and $Z\gamma^*$ events with 1 fb^{-1} $p\bar{p}$ data at $\sqrt{s} = 1.96$ TeV in (e^+e^-) , $(\mu\mu)$, $(\mu\mu)$, (e^+e^-) final states requiring the lepton pair masses to be > 30 GeV. They observe 1 event, which is consistent with an expected signal of 1.71 ± 0.15 events and a background of 0.13 ± 0.03 events. From this they derive the following limits, for a form factor (Λ) value of 1.2 TeV: $-0.28 < f_{40}^Z < 0.28$, $-0.31 < f_{50}^Z < 0.29$, $-0.26 < f_{40}^\gamma < 0.26$, $-0.30 < f_{50}^\gamma < 0.28$.
- 238 Using data collected at $\sqrt{s} = 183\text{--}208$ GeV, ABDALLAH 07c select 171 $e^+e^- \rightarrow ZZ$ events with $Z \rightarrow q\bar{q}$ or lepton pair (except an explicit τ pair), and 74 $e^+e^- \rightarrow Z\gamma^*$ events with a $q\bar{q}\mu^+\mu^-$ or $q\bar{q}e^+e^-$ signature, to derive 95% CL limits on f_1^V . Each limit is derived with other parameters set to zero. They report: $-0.40 < f_4^Z < 0.42$, $-0.38 < f_5^Z < 0.62$, $-0.23 < f_4^\gamma < 0.25$, $-0.52 < f_5^\gamma < 0.48$.
- 239 ABBIENDI 04c study ZZ production in e^+e^- collisions in the C.M. energy range 190–209 GeV. They select 340 events with an expected background of 180 events. Including the ABBIENDI 00N data at 183 and 189 GeV (118 events with an expected background of 65 events) they report the following 95% CL limits: $-0.45 < f_4^Z < 0.58$, $-0.94 < f_5^Z < 0.25$, $-0.32 < f_4^\gamma < 0.33$, and $-0.71 < f_5^\gamma < 0.59$.
- 240 ACHARD 03d study Z -boson pair production in e^+e^- collisions in the C.M. energy range 200–209 GeV. They select 549 events with an expected background of 432 events. Including the ACCIARRI 99g and ACCIARRI 99o data (183 and 189 GeV respectively, 286 events with an expected background of 241 events) and the 192–202 GeV ACCIARRI 01i results (656 events, expected background of 512 events), they report the following 95% CL limits: $-0.48 \leq f_4^Z \leq 0.46$, $-0.36 \leq f_5^Z \leq 1.03$, $-0.28 \leq f_4^\gamma \leq 0.28$, and $-0.40 \leq f_5^\gamma \leq 0.47$.

ANOMALOUS W/Z QUARTIC COUPLINGS

Revised March 2012 by M.W. Grinewald (U. Ghent) and A. Gurtu (King Abdulaziz University).

The Standard Model quartic couplings, $WWWW$, $WWZZ$, $WWZ\gamma$, $WW\gamma\gamma$, and $ZZ\gamma\gamma$ lead to negligible effects at LEP energies, while they are important at a TeV Linear Collider. Outside the Standard Model framework, possible quartic couplings, a_0, a_c, a_n , are expressed in terms of the following dimension-6 operators [1,2];

$$\begin{aligned} L_6^0 &= -\frac{e^2}{16\Lambda^2} a_0 F^{\mu\nu} F_{\mu\nu} \vec{W}^\alpha \cdot \vec{W}^\alpha \\ L_6^c &= -\frac{e^2}{16\Lambda^2} a_c F^{\mu\alpha} F_{\mu\beta} \vec{W}^\beta \cdot \vec{W}^\alpha \end{aligned}$$

$$\begin{aligned} L_6^n &= -i\frac{e^2}{16\Lambda^2} a_n \epsilon_{ijk} W_{\mu\alpha}^{(i)} W_\nu^{(j)} W^{(k)\alpha} F^{\mu\nu} \\ \tilde{L}_6^0 &= -\frac{e^2}{16\Lambda^2} \tilde{a}_0 F^{\mu\nu} \tilde{F}_{\mu\nu} \vec{W}^\alpha \cdot \vec{W}^\alpha \\ \tilde{L}_6^n &= -i\frac{e^2}{16\Lambda^2} \tilde{a}_n \epsilon_{ijk} W_{\mu\alpha}^{(i)} W_\nu^{(j)} W^{(k)\alpha} \tilde{F}^{\mu\nu} \end{aligned}$$

where F, W are photon and W fields, L_6^0 and L_6^c conserve C , P separately (\tilde{L}_6^0 conserves only C) and generate anomalous $W^+W^-\gamma\gamma$ and $ZZ\gamma\gamma$ couplings, L_6^n violates CP (\tilde{L}_6^n violates both C and P) and generates an anomalous $W^+W^-Z\gamma$ coupling, and Λ is an energy scale for new physics. For the $ZZ\gamma\gamma$ coupling the CP -violating term represented by L_6^n does not contribute. These couplings are assumed to be real and to vanish at tree level in the Standard Model.

Within the same framework as above, a more recent description of the quartic couplings [3] treats the anomalous parts of the $WW\gamma\gamma$ and $ZZ\gamma\gamma$ couplings separately leading to two sets parameterized as a_0^V/Λ^2 and a_c^V/Λ^2 , where $V = W$ or Z .

At LEP the processes studied in search of these quartic couplings are $e^+e^- \rightarrow WW\gamma$, $e^+e^- \rightarrow \gamma\gamma\nu\bar{\nu}$, and $e^+e^- \rightarrow Z\gamma\gamma$ and limits are set on the quantities a_0^W/Λ^2 , a_c^W/Λ^2 , a_n/Λ^2 . The characteristics of the first process depend on all the three couplings whereas those of the latter two depend only on the two CP -conserving couplings. The sensitive measured variables are the cross sections for these processes as well as the energy and angular distributions of the photon and recoil mass to the photon pair.

I. Introduction

Understanding the mechanism that breaks electroweak symmetry and generates the masses of the known elementary particles¹ is one of the most fundamental problems in particle physics. The Higgs mechanism [1] provides a general framework to explain the observed masses of the W^\pm and Z gauge bosons by means of charged and neutral Goldstone bosons that are manifested as the longitudinal components of the gauge bosons. These Goldstone bosons are generated by the underlying dynamics of electroweak symmetry breaking (EWSB). However, the fundamental dynamics of the electroweak symmetry breaking are unknown. There are two main classes of

theories proposed in the literature, those with weakly coupled dynamics—such as in the Standard Model (SM) [2]—and those with strongly coupled dynamics; both classes are summarized below.

In the SM, the electroweak interactions are described by a gauge field theory based on the $SU(2)_L \times U(1)_Y$ symmetry group. The Higgs mechanism posits a self-interacting complex doublet of scalar fields, and renormalizable interactions are arranged such that the neutral component of the scalar doublet acquires a vacuum expectation value $v \approx 246$ GeV, which sets the scale of EWSB. Three massless Goldstone bosons are generated, which are absorbed to give masses to the W^\pm and Z gauge bosons. The remaining component of the complex doublet becomes the Higgs boson—a new fundamental scalar particle. The masses of all fermions are also a consequence of EWSB since the Higgs doublet is postulated to couple to the fermions through Yukawa interactions. If the Higgs boson mass m_H is below ~ 180 GeV, all fields remain weakly interacting up to the Planck scale, M_{Pl} .

The validity of the SM as an effective theory describing physics up to the Planck scale is questionable, however, because of the following “naturalness” argument. All fermion masses and dimensionless couplings are logarithmically sensitive to the scale Λ at which new physics becomes relevant. In contrast, scalar squared masses are quadratically sensitive to Λ . Thus, the observable SM Higgs mass has the following form:

$$m_H^2 = m_{H_0}^2 + \frac{kg^2\Lambda^2}{16\pi^2},$$

where m_{H_0} is a fundamental parameter of the theory. The second term is a one-loop correction in which g is an electroweak coupling and k is a constant, presumably of $\mathcal{O}(1)$, that is calculable within the low-energy effective theory. The two contributions arise from independent sources and one would not expect that the observable Higgs boson mass is significantly smaller than either of the two terms. Hence, if the scale of new physics Λ is much larger than the electroweak scale, unnatural cancellations must occur to remove the quadratic dependence of the Higgs boson mass on this large energy scale and to give a Higgs boson mass of order of the electroweak scale, as required from unitarity constraints [3,4], and as preferred by precision measurements of electroweak observables [5]. Most relevantly, recent results from direct Higgs searches at the Tevatron [6] and, in particular, at the LHC [7–10] strongly constrain the SM Higgs boson mass to be in the range 114–129 GeV, in excellent agreement with the indirect predictions from electroweak precision data. Thus, the SM is expected to be embedded in a more fundamental theory which will stabilize the hierarchy between the electroweak scale and the Planck scale in a natural way. A theory of that type would usually predict the onset of new physics at scales of the order of, or just above, the electroweak scale. Theorists strive to construct models of new physics that keep the successful features of the SM while curing its shortcomings, such as the absence of a dark matter candidate or a

¹ In the case of neutrinos, it is possible that the Higgs mechanism plays a role but is not entirely responsible for the generation of their observed masses.

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

detailed explanation of the observed baryon asymmetry of the universe.

In the weakly-coupled approach to electroweak symmetry breaking, supersymmetric (SUSY) extensions of the SM provide a possible explanation for the stability of the electroweak energy scale in the presence of quantum corrections [11,12]. These theories predict at least five Higgs particles [13]. The properties of the lightest Higgs scalar often resemble those of the SM Higgs boson, with a mass that is predicted to be less than 135 GeV [14] in the simplest supersymmetric model². Additional neutral and charged Higgs bosons are also predicted. Moreover, low-energy supersymmetry with a supersymmetry breaking scale of order 1 TeV allows for grand unification of the electromagnetic, weak and strong gauge interactions in a consistent way, strongly supported by the prediction of the electroweak mixing angle at low energy scales, with an accuracy at the percent level [22,23].

Alternatively new strong interactions near the TeV scale can induce strong breaking of the electroweak symmetry [24]. “Little Higgs” models have been proposed in which the scale of the new strong interactions is pushed up above 10 TeV [25–27], and the lightest Higgs scalar resembles the weakly-coupled SM Higgs boson.

Another approach to electroweak symmetry breaking has been explored in which extra space dimensions beyond the usual $3 + 1$ dimensional space-time are introduced [28] with characteristic sizes of the fundamental Planck scale of order $(1 \text{ TeV})^{-1}$. In such scenarios, the mechanisms for electroweak symmetry breaking are inherently extra-dimensional and the resulting Higgs phenomenology can depart significantly from SM predictions [27,29].

Both in the framework of supersymmetric theories and in the strongly coupled dynamic approach there have been many studies based on effective theory approaches [18,20,21,30,31] that prove useful in exploring departures from the SM Higgs phenomenology in a more model independent way.

Prior to 1989, when the e^+e^- collider LEP at CERN came into operation, searches were sensitive only to Higgs bosons with masses of a few GeV and below [32]. In the LEP 1 phase, the collider operated at center-of-mass energies close to M_Z . During the LEP 2 phase, the energy was increased in steps, reaching 209 GeV in the year 2000 before the final shutdown. The combined data of the four LEP experiments, ALEPH, DELPHI, L3, and OPAL, were sensitive to neutral

² Larger values of the mass of the lightest Higgs boson, up to about 250 GeV, can be obtained in non-minimal SUSY extensions of the SM [15–21]. However, if the LHC’s indications of a light Higgs boson are confirmed, the main motivation for non-minimal SUSY extensions would be to obtain a Higgs boson mass in the 120–130 GeV mass range without demanding heavy top quark superpartners, and thereby avoid the so-called little hierarchy problem.

Higgs bosons with masses up to about 115 GeV and to charged Higgs bosons with masses up to about 90 GeV [33,34].

The search for the Higgs boson continued at the Tevatron $p\bar{p}$ collider, which operated at a center-of-mass energy of 1.96 TeV until its shutdown in the Fall of 2011. The two experiments, CDF and DØ, each collected approximately 10 fb^{-1} of data with the capability to probe a SM Higgs boson mass in the 90–185 GeV range. The combination of the results from CDF and DØ shows an excess of data events with respect to the background estimation in the mass range $115 \text{ GeV} < m_H < 135 \text{ GeV}$. The global significance for such an excess anywhere in the full mass range is approximately 2.2 standard deviations. The excess is concentrated in the $H \rightarrow b\bar{b}$ channel, although the results in the $H \rightarrow W^+W^-$ channel are also consistent with the possible presence of a low-mass Higgs boson. Other neutral and charged Higgs particles postulated in most theories beyond the SM are also searched for at the Tevatron. The Tevatron Higgs results are discussed in more detail later in this review. The final results are expected to be available by the end of 2012.

Searches for Higgs bosons are ongoing at the LHC pp collider. These searches have much higher sensitivity than the Tevatron searches and cover masses up to several hundred GeV. At present both LHC experiments, ATLAS and CMS, have searched for a SM Higgs boson produced mainly through gluon fusion, and decaying dominantly into gauge boson pairs. The initial results are compatible with the presence of a SM-like Higgs boson with a mass in the range 114–129 GeV, with most of the remaining mass values up to at least 500 GeV being excluded at the 95% C.L. by both experiments. Both LHC experiments observe small excesses, predominantly in the $\gamma\gamma$ and ZZ modes, which could be compatible with a Higgs boson with a mass near 125 GeV but are not yet conclusive. These results are discussed in more detail later in this review. If a signal is confirmed, the next step is to understand the precise nature of such a particle by scrutinizing the coupling strengths in the different production and decay channels. Searches are also conducted by both LHC collaborations for Higgs bosons produced via vector boson fusion and in association with a W or a Z boson. Decays to $b\bar{b}$ and $\tau^+\tau^-$ are searched for in addition to the more experimentally distinct boson pair signatures. With additional data, these searches will constrain the production rates and decay branching ratios of the Higgs boson. An exciting time lies ahead in the case of the discovery of a Higgs boson since we would need to understand its nature and the underlying new physics that might be related to it. Beyond a discovery, precision measurements will be crucial to completely understand the mechanism of electroweak symmetry breaking.

II. The Standard Model (SM) Higgs Boson

In the SM, the Higgs boson mass is given by $m_H = \sqrt{\lambda/2} v$, where λ is the Higgs self-coupling parameter and v is the vacuum expectation value of the Higgs field, $v = (\sqrt{2}G_F)^{-1/2} \approx$

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

246 GeV, fixed by the Fermi coupling G_F , which is determined with a precision of 0.6 ppm from muon decay measurements [35]. Since λ is presently unknown, the value of the SM Higgs boson mass m_H cannot be predicted. However, besides the upper bound on the Higgs boson mass from unitarity constraints [3,4], additional theoretical arguments place approximate upper and lower bounds on m_H [36]. There is an upper bound based on the perturbativity of the theory up to the scale Λ at which the SM breaks down, and a lower bound derived from the stability of the Higgs potential. If m_H is too large, then the Higgs self-coupling diverges at some scale Λ below the Planck scale. If m_H is too small, then the Higgs potential develops a second (global) minimum at a large value of the magnitude of the scalar field of order Λ . New physics must enter at a scale Λ or below, so that the global minimum of the theory corresponds to the observed $SU(2)_L \times U(1)_Y$ broken vacuum with $v = 246$ GeV. Given a value of Λ , one can compute the minimum and maximum allowed Higgs boson masses. Conversely, the value of m_H itself can provide an important constraint on the scale up to which the SM remains successful as an effective theory. In particular, a Higgs boson with mass in the range $130 \text{ GeV} \lesssim m_H \lesssim 180 \text{ GeV}$ would be consistent with an effective SM description that survives all the way to the Planck scale. For smaller Higgs mass values, the stability of our universe prefers new physics at a lower scale. The lower bound on m_H can be reduced to about 115 GeV [37] if one allows for the electroweak vacuum to be metastable, with a lifetime greater than the age of the universe. The main uncertainties in the stability and perturbativity bounds come from the uncertainties in the value of α_s and the top quark mass. As can be inferred from Fig. 1 [38], taking these uncertainties into account, a Higgs boson mass of about 125 GeV is close to the boundary of a SM that is consistent up to the Planck scale, and a SM that is unstable with a slow tunneling rate.

Figure 1: Renormalization group evolution of the Higgs self coupling λ , for $m_H = 124$ GeV (left) and $m_H = 126$ GeV (right), for the central values of m_t and α_s (solid curves), as well as for variations of m_t (dashed curves) and α_s (dotted curves). For negative values of λ , the lifetime of the SM vacuum due to quantum tunneling at zero temperature is longer than the age of the universe as long as λ remains above the region shaded in red. From Ref. 38.

The SM Higgs couplings to fundamental fermions are proportional to the fermion masses, and the couplings to bosons are proportional to the squares of the boson masses. In particular, the SM Higgs boson is a CP -even scalar, and its couplings to gauge bosons, Higgs bosons and fermions are given by:

$$g_{Hf\bar{f}} = \frac{m_f}{v}, \quad g_{HVV} = \frac{2m_V^2}{v}, \quad g_{HHVV} = \frac{2m_V^2}{v^2}$$

$$g_{HHH} = \frac{3m_H^2}{v}, \quad g_{HHHH} = \frac{3m_H^2}{v^2}$$

where $V = W^\pm$ or Z . In Higgs boson production and decay processes, the dominant mechanisms involve the coupling of the H to the W^\pm , Z and/or the third generation quarks and leptons. The Higgs boson's coupling to gluons, is induced at leading order by a one-loop graph in which the H couples to a virtual $t\bar{t}$ pair. Likewise, the Higgs boson's coupling to photons is also generated via loops, although in this case the one-loop graph with a virtual W^+W^- pair provides the dominant contribution [13]. Reviews of the SM Higgs boson's properties and phenomenology, with an emphasis on the impact of loop corrections to the Higgs boson decay rates and cross sections, can be found in Refs. [39–45].

The main Higgs boson production cross sections at an e^+e^- collider are the Higgs-strahlung process $e^+e^- \rightarrow ZH$ [4,46], and the WW fusion process [47] $e^+e^- \rightarrow \bar{\nu}_e\nu_e W^*W^* \rightarrow \bar{\nu}_e\nu_e H$. As center-of-mass energy \sqrt{s} is increased, the cross-section for the Higgs-strahlung process decreases as s^{-1} and is dominant at low energies, while the cross-section for the WW fusion process grows as $\ln(s/m_H^2)$ and dominates at high energies [48,49,50]. The ZZ fusion mechanism, $e^+e^- \rightarrow e^+e^- Z^*Z^* \rightarrow e^+e^- H$, also contributes to Higgs boson production, with a cross-section suppressed by an order of magnitude with respect to that of WW fusion. The process $e^+e^- \rightarrow t\bar{t}H$ [51,52] can become relevant for large $\sqrt{s} \simeq 800$ GeV for SM Higgs masses in the experimentally preferred region. For a more detailed discussion of Higgs production properties at lepton colliders see for example Refs. [44] and [45], and references therein.

At high-energy hadron colliders, the Higgs boson production mechanism with the largest cross section is $gg \rightarrow H + X$. This process is known at next-to-next-to-leading order (NNLO) in QCD, in the large top-mass limit, and at NLO in QCD for arbitrary top mass [53]. The NLO QCD corrections approximately double the leading-order prediction, and the NNLO corrections add approximately 50% to the NLO prediction. NLO electroweak corrections range between 0 and 6% of the LO term [54]. Mixed QCD-electroweak corrections $O(\alpha\alpha_s)$ are computed in Ref. [55]. In addition, soft-gluon contributions to the cross sections have been resummed at next-to-leading logarithmic (NLL), NNLL and partial NNNLL accuracy [56]. Updated predictions for the gluon fusion cross sections at NNLO or through soft-gluon resummation up to next-to-next-to-leading logarithmic accuracy (NNLL), and two-loop electroweak effects can be found in Refs. [55,57]. A better

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

perturbative convergence is achieved by resumming the enhanced contributions arising from the analytic continuation of the gluon form factor [58]. Updated predictions to compute the gluon fusion cross sections at NNNLL in renormalization group improved perturbation theory and incorporating two-loop electroweak effects can be found in Ref. [59]. Some search strategies look for Higgs boson production in association with jets. In the heavy top quark mass limit, the Higgs boson production cross section in association with one jet is considered in Refs. [60–63] and in association with two jets in Refs. [64,65].

The other relevant Higgs boson production mechanisms at the Tevatron and the LHC are associated production with W and Z gauge bosons and vector boson fusion, and at a significantly smaller rate, the associated production with top quark pairs. The cross sections for the associated production processes $q\bar{q} \rightarrow W^\pm H + X$ and $q\bar{q} \rightarrow ZH + X$ [66,67,68] are known at NNLO for the QCD corrections and at NLO for the electroweak corrections [69,70]. The residual uncertainty is less than 5%. For the vector boson fusion processes $qq \rightarrow qqH + X$, corrections to the production cross section are known at NNLO in QCD and at NLO for the electroweak corrections and the remaining theoretical uncertainties in the inclusive cross section are approximately 2% [71], but are larger if jets are required or vetoed [43]. The cross section for the associated production process $t\bar{t}H$ has been calculated at NLO in QCD [72], while the bottom fusion Higgs boson production cross section is known at NNLO in the case of five quark flavors [69,73,74]. The cross sections for the production of SM Higgs bosons are summarized in Fig. 2 for $p\bar{p}$ collisions at the Tevatron, and in Fig. 3 for pp collisions at $\sqrt{s} = 7$ TeV at the LHC [75,76]. Ref. [75] also includes cross sections computed at $\sqrt{s} = 8$ TeV, which are relevant for data collected in 2012.

The branching ratios for the most relevant decay modes of the SM Higgs boson as functions of m_H , including the most recent theoretical uncertainties, are shown in Fig. 4. The total decay width as function of m_H is shown in Fig. 5. Details of these calculations can be found in Refs. [40–44]. For Higgs boson masses below 135 GeV, decays to fermion pairs dominate; the decay $H \rightarrow b\bar{b}$ has the largest branching ratio and the decay $H \rightarrow \tau^+\tau^-$ is about an order of magnitude smaller. For these low masses, the total decay width is less than 10 MeV. For Higgs boson masses above 135 GeV, the W^+W^- decay dominates (below the W^+W^- threshold, one of the W bosons is virtual) with an important contribution from $H \rightarrow ZZ$, and the decay width rises rapidly, reaching about 1 GeV at $m_H = 200$ GeV and 100 GeV at $m_H = 500$ GeV. Above the $t\bar{t}$ threshold, the branching ratio into $t\bar{t}$ pairs increases rapidly as a function of the Higgs boson mass, reaching a maximum of about 20% at $m_H \sim 450$ GeV. Higgs boson decays into pairs of gluons, pairs of photons, and $Z\gamma$ are induced at one loop level. Higgs boson decay into a pair of photons is particularly relevant for the discovery potential of the LHC for a low-mass Higgs boson. In

spite of the small expected signal rate, the reconstructed mass resolution provides a way to separate signal from background, a means to calibrate the background rate with a signal-free sample of events, and a precise measurement of m_H once a signal is identified.

Figure 2: SM Higgs boson production cross sections for $p\bar{p}$ collisions at 1.96 TeV, including theoretical uncertainties [53,70–72].

Figure 3: SM Higgs boson production cross sections for pp collisions at 7 TeV, including theoretical uncertainties [76].

II.1. Indirect Constraints on the SM Higgs Boson

Indirect experimental bounds for the SM Higgs boson mass are obtained from fits to precision measurements of electroweak observables. The Higgs boson contributes to the W^\pm and Z vacuum polarization through loop effects, leading to a logarithmic sensitivity of the ratio of the W^\pm and Z gauge boson masses on the Higgs boson mass. A global fit to the precision electroweak data accumulated in the last two decades at LEP, SLC, the Tevatron, and elsewhere, gives $m_H = 94^{+29}_{-24}$ GeV, or

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

Figure 4: Branching ratios for the main decays of the SM Higgs boson, including theoretical uncertainties [40–44].

Figure 5: The total decay width of the SM Higgs boson, shown as a function of m_H [76].

$m_H < 152$ GeV at 95% C.L. [5]. The top quark contributes to the W^\pm boson vacuum polarization through loop effects that depend quadratically on the top mass, which plays an important role in the global fit. A top quark mass of 173.2 ± 0.9 GeV [77] and a W^\pm boson mass of 80.385 ± 0.015 GeV [5] were used.

II.2. Searches for the SM Higgs Boson at LEP

The principal mechanism for producing the SM Higgs boson in e^+e^- collisions at LEP energies is Higgs-strahlung in the s -channel, $e^+e^- \rightarrow HZ$. The Z boson in the final state is either

virtual (LEP 1), or on mass shell (LEP 2). At LEP energies, SM Higgs boson production via W^+W^- and ZZ fusion in the t -channel has a small cross section. The sensitivity of the LEP searches to the Higgs boson depends on the center-of-mass energy, \sqrt{s} . For $m_H < \sqrt{s} - M_Z$, the cross section is of order 1 pb or more, while for $m_H > \sqrt{s} - M_Z$, the cross section is smaller by at least an order of magnitude.

During the LEP 1 phase, the ALEPH, DELPHI, L3 and OPAL collaborations analyzed over 17 million Z decays and set lower bounds of approximately 65 GeV on the mass of the SM Higgs boson [78]. At LEP 2, substantial data samples were collected at center-of-mass energies up to 209 GeV. Data recorded at each center-of-mass energy were studied independently and the results from the four LEP experiments were then combined. The CL_s method [79] was used to compute the observed and expected limits on the Higgs boson production cross section as functions of the Higgs boson mass considered, and from that a lower bound on m_H was derived.

Higgs bosons with mass above $2m_\tau$ were searched for in four final state topologies: The four-jet topology in which $H \rightarrow b\bar{b}$ and $Z \rightarrow q\bar{q}$; the final states with tau leptons produced in the processes $H \rightarrow \tau^+\tau^-$ where $Z \rightarrow q\bar{q}$, together with the mode $H \rightarrow b\bar{b}$ with $Z \rightarrow \tau^+\tau^-$; the missing energy topology produced mainly in the process $H \rightarrow b\bar{b}$ with $Z \rightarrow \nu\bar{\nu}$, and finally the leptonic states $H \rightarrow b\bar{b}$ with $Z \rightarrow e^+e^-, \mu^+\mu^-$. At LEP 1, only the modes with $Z \rightarrow \ell^+\ell^-$ and $Z \rightarrow \nu\bar{\nu}$ were used because the backgrounds in the other channels were prohibitive. For the data collected at LEP 2, all decay modes were used.

For very light Higgs bosons, with $m_H < 2m_\tau$, the decay modes exploited above are not kinematically allowed, and decays to jets, muon pairs, pion pairs, and lighter particles dominate, depending on m_H . For very low masses, OPAL’s decay-mode independent search [80] for the Bjorken process $e^+e^- \rightarrow S^0Z$, where S^0 denotes a generic neutral scalar particle, provides sensitivity regardless of the branching fractions of the S^0 . This search is based on studies of the recoil mass spectrum in events with $Z \rightarrow e^+e^-$ and $Z \rightarrow \mu^+\mu^-$ decays, and on the final states $Z \rightarrow \nu\bar{\nu}$ and $S^0 \rightarrow e^+e^-$ or photons. Upper bounds on the $e^+e^- \rightarrow ZH$ cross section are obtained for scalar masses between 1 KeV and 100 GeV, and are below 0.05 times the SM prediction for $m_H < 80$ GeV, constraining the coupling of the Higgs boson to the Z .

The combination of the LEP data yields a 95% C.L. lower bound of 114.4 GeV for the mass of the SM Higgs boson [33]. The median limit one would expect to obtain in a large ensemble of identical experiments with no signal present is 115.3 GeV. An excess of data was seen consistent with a Higgs boson of mass $m_H \approx 115$ GeV. The significance of this excess is low, however. It is quantified by the background-only p -value [79], which is the probability to obtain data at least as signal-like as the observed data, assuming a signal is truly absent; a small p -value indicates data that are inconsistent with the background model but are more consistent with a signal model.

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

The background-only p -value for the excess in the LEP data is 9%.

II.3. Searches for the SM Higgs Boson at the Tevatron

As shown in Fig. 2, at the Tevatron, the most important SM Higgs boson production processes are gluon fusion ($gg \rightarrow H$) and Higgs boson production in association with a vector boson ($W^\pm H$ or ZH). Vector boson fusion (VBF) has a smaller cross section, but some search channels are optimized for it. For m_H less than about 135 GeV, the most sensitive analyses search for $W^\pm H$ and ZH with $H \rightarrow b\bar{b}$. The mode $gg \rightarrow H \rightarrow b\bar{b}$ is overwhelmed by the background from the inclusive production of $p\bar{p} \rightarrow b\bar{b} + X$ via the strong interaction. The associated production modes $W^\pm H$ and ZH allow use of the leptonic W and Z decays to purify the signal and reject QCD backgrounds.

The contribution of $H \rightarrow W^*W$ or WW is dominant at higher masses, $m_H > 135$ GeV. Using this decay mode, both the direct ($gg \rightarrow H$) and the associated production ($p\bar{p} \rightarrow W^\pm H$ or ZH) channels are explored, and the results of both Tevatron experiments, CDF and DØ, are combined to maximize the sensitivity to the Higgs boson.

The signal-to-background ratio is much smaller in the Tevatron searches than in the LEP analyses, and the systematic uncertainties on the estimated background rates are typically larger than the signal rates. In order to estimate the background rates in the selected samples more accurately, auxiliary measurements are made in data samples which are expected to be depleted in Higgs boson signal. These auxiliary samples are chosen to maximize the sensitivity to each specific background in turn. Monte Carlo simulations are used to extrapolate these measurements into the Higgs signal regions. The dominant physics backgrounds such as top-pair, diboson, $W^\pm b\bar{b}$, and single top production are estimated by Monte Carlo simulations in this way, i.e., after having been tuned or verified by corresponding measurements in dedicated analyses, thereby reducing the uncertainty on the total background estimate. Nearly all Tevatron analyses use multivariate analysis techniques (MVA's) to further separate signals from backgrounds and to provide the final discriminants whose distributions are used to compute limits, best-fit cross sections and uncertainties, and p -values. Separate MVA's are trained at each m_H in all the different sub-channels.

Both Tevatron experiments have updated their main search analyses to the full analyzable data sample of approximately 10 fb^{-1} . At Higgs boson masses of 150 GeV and below, the searches for associated production, $p\bar{p} \rightarrow W^\pm H, ZH$, are performed in different channels, as follows. The $WH \rightarrow \ell\nu b\bar{b}$ searches [81–85] select events with a charged lepton ($\ell = e$ or μ), large missing transverse energy, and at least two jets, at least one of which must be b -tagged. In order to improve the sensitivity of the searches, events with one b -tag are analyzed separately from those with two, and events with three jets are analyzed separately from those with two jets. Algorithms to identify b jets provide several levels of purity for each jet, and

this serves as another dimension along which to classify events. The quality and the type of the identified lepton also serves to classify events. An event with an isolated, high- p_T track is analyzed as if that track were a lepton, but such events are collected together in different sub-channels. The signals in such categories come from leptons which the detectors failed to reconstruct as leptons, and hadrons from τ lepton decay. The instrumental (“fake-lepton”) backgrounds are higher for these selections, and so samples with well-identified leptons are kept separate from the isolated-track samples.

The $ZH \rightarrow \nu\bar{\nu} b\bar{b}$ searches [86–89] seek events in which no lepton or high- p_T isolated track is found. These searches also accept signals from $WH \rightarrow \ell\nu b\bar{b}$ in which the charged lepton is either not identified or falls outside the detector acceptances. Similar b -tagging categorization is applied to these searches. The $ZH \rightarrow \ell^+\ell^- b\bar{b}$ searches [90–93] seek leptonic decays of the Z boson. These events benefit from the absence of neutrinos, and so missing transverse energy can be interpreted as jet energy mismeasurement, and the jet energies are corrected accordingly, improving the dijet mass resolution. CDF searches for associated production and VBF in the all-hadronic mode, in which the W or the Z decays hadronically, and the H decays to $b\bar{b}$ [94,95].

A cross check of the procedures for searching for the SM Higgs boson in the $WH, ZH \rightarrow b\bar{b}$ channels, their background estimates, and combination procedures, is provided by measurements of $WZ + ZZ$ production in b -tagged final states [96,97], and their combination [98]. In these analyses, the decay $Z \rightarrow b\bar{b}$ mimics the decay $H \rightarrow b\bar{b}$, and WW production is considered a background. The measured cross section is consistent with the SM expectations, giving confidence in the Higgs boson search procedures.

Both Tevatron experiments also search for $H \rightarrow \tau^+\tau^-$ in events with one or more associated jets [99–102]. As the di-tau mass resolution is poor due to the presence of unmeasured neutrinos, the $Z \rightarrow \tau^+\tau^-$ background is large in the absence of the requirement of one or more additional jets, which purifies the sample in associated production and VBF. The process $gg \rightarrow H$ is considered as well, although the uncertainties on $gg \rightarrow H + \text{jets}$ are larger than the inclusive uncertainties.

The decay mode $H \rightarrow \gamma\gamma$ is searched for by both Tevatron collaborations [103–106]. Prompt diphoton production, $\pi^0 \rightarrow \gamma\gamma$, and fake photons are the main backgrounds. The backgrounds have a smoothly varying shape as a function of $m_{\gamma\gamma}$, while the signal mass resolution is of order 3%. All Higgs boson production mechanisms are considered, but the signal-to-background ratio at the Tevatron is not sufficient for this channel to contribute significantly to the SM search. Nonetheless, the searches for $H \rightarrow \gamma\gamma$ provide powerful tests of models with enhanced $\text{BR}(H \rightarrow \gamma\gamma)$, described later.

Another process searched for at the Tevatron is $t\bar{t}H$ production with $H \rightarrow b\bar{b}$ [107,108]. The backgrounds in this channel are low and are dominated by $t\bar{t}b\bar{b}$, but the low signal

See key on page 457

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

production rate and combinatoric ambiguity in assigning jets to the Higgs boson decay reduces the sensitivity.

For Higgs boson masses above 130 GeV, the searches for $H \rightarrow W^+W^- \rightarrow \ell^+\nu\ell^-\bar{\nu}$ [109–114] are the most sensitive. The candidate mass cannot be fully reconstructed in these events due to the presence of two neutrinos, but the lepton angles are correlated due to the scalar nature of the Higgs boson and the $V - A W\ell\nu$ coupling. The process $W^\pm H \rightarrow W^\pm W^+ W^-$ gives rise to like-sign dilepton and trilepton final states which have very low backgrounds [110,115]. CDF also seeks $H \rightarrow ZZ \rightarrow \ell^+\ell^-\ell^+\ell^-$ [116] where $\ell = e$ or μ . The excellent mass resolution and low backgrounds help the sensitivity of the search, but low decay branching ratio for $Z \rightarrow \ell^+\ell^-$ reduces the sensitivity.

Figure 6: Observed and expected 95% C.L. upper limits on the ratios to the SM cross section, as functions of the Higgs boson mass for the combined CDF and D0 analyses [6]. The limits are expressed as a multiple of the SM prediction. The bands indicate the 68% and 95% probability regions where the limits can fluctuate, in the absence of signal. Also shown are the regions excluded by LEP, ATLAS, and CMS.

All of the searches for the SM Higgs boson at the Tevatron are combined together for maximum sensitivity [6,117,118]. The Tevatron combination excludes two ranges in m_H : between 100 GeV and 106 GeV, and between 147 GeV and 179 GeV. An excess of data is seen in the mass range $115 \text{ GeV} < m_H < 135 \text{ GeV}$, as shown in Fig. 6, with a maximum local significance of 2.7 standard deviations (σ), at $m_H = 120 \text{ GeV}$, where the expected local significance for a SM Higgs signal is 2.0 σ . When corrected for the look-elsewhere effect (LEE) [119], which accounts for the possibility of selecting the strongest of the several random excess which may happen in the range $115 \text{ GeV} < m_H < 200 \text{ GeV}$, the global significance of the

excess is 2.2 standard deviations³. The majority of the excess is contributed by the searches for $H \rightarrow b\bar{b}$. The best-fit cross section for Higgs boson production, normalized to the SM production rate, and assuming SM decay branching ratios and SM ratios between the production mechanisms, is shown in Fig. 7.

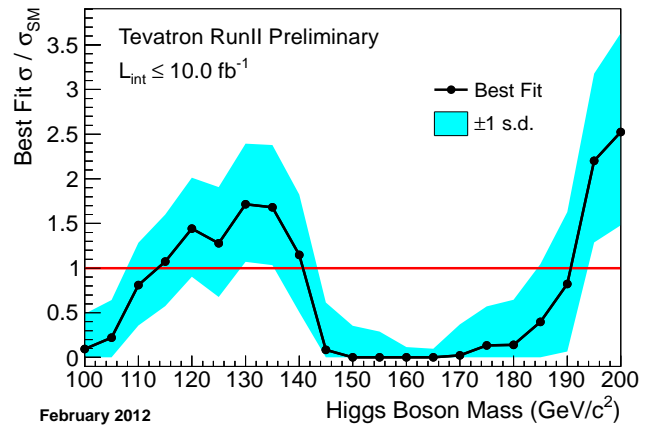

Figure 7: Best-fit cross section for the SM Higgs boson from the combined CDF and D0 searches, normalized to the SM production rates, assuming SM decay branching ratios and the SM ratio between the various production mechanisms [6]. The shaded region shows the 68% C.L. interval, as a function of the mass of the Higgs boson considered. In this fit, negative signal cross sections are not considered.

The channels used at the Tevatron for Higgs boson masses below 130 GeV are different from those dominantly used at the LHC, and thus provide complementary information on the couplings of the Higgs boson to gauge bosons and to b quarks.

II.4. SM Higgs Boson Searches at the LHC

At the LHC, the main production processes are the same as those at the Tevatron, but with a different order of importance: gluon fusion ($gg \rightarrow H$), vector boson fusion (qqH or $q\bar{q}H$) and Higgs boson production in association with a vector boson ($W^\pm H$ or ZH) or with a top-quark pair ($t\bar{t}H$).

The higher center-of-mass energy of 7 TeV (8 TeV in 2012) and the fact that both beams consist of protons has a strong impact on the parton luminosities. The LHC experiments are sensitive to Higgs bosons with much higher masses than the Tevatron experiments. The gg luminosity is also enhanced at the LHC by the beam energy due to the large gluon PDF at lower parton momentum fraction x compared to that at higher x .

A variety of search channels are pursued by the LHC collaborations, ATLAS and CMS, with the channels' relative importances changing due to the branching ratios of the SM Higgs

³ In this Review, we use the phrase “local significance” to indicate a calculation of the significance not corrected for the LEE.

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

boson as functions of m_H . At low masses, $m_H < 120$ GeV, searches for $H \rightarrow \gamma\gamma$ provide the highest sensitivity, with searches for $H \rightarrow b\bar{b}$ and $H \rightarrow \tau^+\tau^-$ contributing as well. For higher masses, $120 \text{ GeV} < m_H < 200 \text{ GeV}$, searches for $H \rightarrow W^+W^- \rightarrow \ell^+\nu\ell^-\nu$ are the most sensitive, with an important contribution from $H \rightarrow ZZ \rightarrow \ell^+\ell^-\ell^+\ell^-$ between 120 GeV and 150 GeV. At even higher masses, up to $m_H = 600$ GeV, the $H \rightarrow ZZ$ searches are the most sensitive.

Both LHC collaborations seek $H \rightarrow W^+W^- \rightarrow \ell^+\nu\ell^-\nu$ production [120–122]. This channel provides high sensitivity for Higgs boson masses for which $\text{BR}(H \rightarrow W^+W^-)$ is large, $m_H > 135$ GeV. The main SM background, nonresonant W^+W^- production, is initiated primarily by $q\bar{q}$ and thus the signal to background ratio benefits at the LHC because of the initial state. The first LHC exclusion of Higgs boson masses was obtained in this search mode. CMS also contributes a search in the mode $W^\pm H \rightarrow W^\pm W^+W^-$ [123] in the trilepton final state. For ATLAS, the fully leptonic decay mode is supplemented with an $H \rightarrow W^+W^- \rightarrow \ell\nu jj$ search [124].

At higher masses, $m_H > 180$ GeV, ATLAS and CMS analyses seeking $H \rightarrow ZZ$ with $ZZ \rightarrow \ell^+\ell^-\ell^+\ell^-$ [125,126], $ZZ \rightarrow \ell^+\ell^-\nu\bar{\nu}$ [127,128], $ZZ \rightarrow \ell^+\ell^-\bar{q}q$ [129,130], and $ZZ \rightarrow \ell^+\ell^-\tau^+\tau^-$ [131] become the most sensitive. A small excess of events in the ATLAS $\ell^+\ell^-\ell^+\ell^-$ channel with reconstructed masses near 125 GeV is seen, with a local significance of ≈ 2 sigma. An excess with similar significance is seen in the CMS $H \rightarrow ZZ \rightarrow 4$ leptons searches at ~ 119 GeV.

ATLAS and CMS seek the process $H \rightarrow \gamma\gamma$ including the four production mechanisms, $gg \rightarrow H$, production in association with a W or Z boson, and VBF [132–134]. Events are divided into categories depending on the reconstructed photon type (barrel calorimeter or endcap), and the presence or absence of additional jets. The reconstructed mass resolution of the selected candidates varies between 1% and 3% depending on the event category and detector. ATLAS observes an excess of events with a local significance of 2.8σ which is maximized at $m_H=126.5$ GeV, while CMS observes an excess of events with a local significance of 2.9σ which is maximized at $m_H=124$ GeV. ATLAS computes the global significance, accounting for the probability of a background fluctuation anywhere in the range $110 \text{ GeV} < m_H < 150 \text{ GeV}$ at least as significant as the observed excess, to be 1.5σ . CMS's global significance is 1.6σ using the same range of m_H .

ATLAS and CMS seek Higgs bosons produced in association with a leptonically decaying vector boson and which decay into $b\bar{b}$ [135,136]. Although these searches benefit from the higher production cross sections at the LHC as compared to the Tevatron, the background cross sections are relatively larger, as a larger fraction of W and Z bosons at the LHC are produced with accompanying jets, some of which contain heavy hadrons. The sensitivity of the searches is maximized by tagging jets containing B hadrons and using MVAs to separate the expected signals from the backgrounds. The achieved sensitivity, in units of the SM production rate, expressed as the 95% exclusion limit

expected in the absence of a signal, varies in the range $110 \text{ GeV} < m_H < 135 \text{ GeV}$ between 2.6 to 5.1 for ATLAS and between 2.7 to 6.7 for CMS. These results are both with 4.7 fb^{-1} of analyzed data. With more data and improved analyses, the LHC will be able to measure the important decay branching ratio to $b\bar{b}$, where currently the Tevatron contributes the most.

Both ATLAS and CMS seek SM Higgs boson decays to $\tau^+\tau^-$ [137–139]. The selected events in these searches are categorized by the number of associated jets, which differentiates signals produced by $gg \rightarrow H$, associated production, and VBF from the backgrounds, which are dominated by $Z \rightarrow \tau^+\tau^-$. The reconstructed di-tau masses are used as the discriminating variables. If the tau pair has a net transverse boost, then the missing transverse energy can be projected unambiguously on the directions of the two tau leptons, and the reconstructed mass resolution is much better than in the case of little transverse boost, in which case the degree to which the neutrino momenta cancel each other is unknown. With 4.7 fb^{-1} of data, ATLAS's expected 95% C.L. limit varies between 3.2 and 7.9 times the SM rate for Higgs bosons with $100 \text{ GeV} < m_H < 150 \text{ GeV}$, and with 4.6 fb^{-1} of data, CMS's expected limits vary between 3.3 and 5.5 times the SM prediction for $110 \text{ GeV} < m_H < 145 \text{ GeV}$. CMS also searches for $WH \rightarrow W\tau^+\tau^-$ [140] with a 95% C.L. sensitivity between 5 and 15 times the SM prediction in the range $100 \text{ GeV} < m_H < 140 \text{ GeV}$ using 4.7 fb^{-1} of data.

Both ATLAS and CMS have combined their SM Higgs boson searches [7–10]. The most recent combination of ATLAS includes the full suite of channels mentioned above. As shown in Fig. 8, ATLAS excludes at the 95% C.L. the mass ranges $110.0 \text{ GeV} < m_H < 117.5 \text{ GeV}$, $118.5 \text{ GeV} < m_H < 122.5 \text{ GeV}$, and $129 \text{ GeV} < m_H < 539 \text{ GeV}$, and expects to exclude, in the absence of a signal, $120 \text{ GeV} < m_H < 555 \text{ GeV}$. ATLAS's local p -values [79], computed with the likelihood ratio test statistic, are shown as functions of the tested m_H in Fig. 9. The local significance is maximal at $m_H = 126$ GeV, with a value of 2.9σ . The global significance is 1.3σ when the interval considered for the LEE correction is $110 \text{ GeV} < m_H < 146 \text{ GeV}$, and becomes 0.5σ for the interval $110 \text{ GeV} < m_H < 600 \text{ GeV}$. The best-fit production cross section as a multiple of the SM prediction is shown in Fig. 10. The excesses seen in the $H \rightarrow \gamma\gamma$ and $H \rightarrow ZZ \rightarrow \ell^+\ell^-\ell^+\ell^-$ searches are somewhat offset by a more background-like outcome in the $H \rightarrow W^+W^-$ searches.

The most recent combination of CMS includes the full suite of channels mentioned above. As shown in Fig. 11, CMS excludes at the 95% C.L. the mass range $127.5 \text{ GeV} < m_H < 600 \text{ GeV}$, and expects to exclude $114.5 \text{ GeV} < m_H < 525 \text{ GeV}$ in the absence of a signal. CMS's local p -values [79], computed using the likelihood ratio test statistic, are shown as functions of the tested m_H in Fig. 12. The local significance is maximal at $m_H = 125$ GeV, with a value of 2.8σ . The global significance becomes 2.1σ (0.8σ) after correcting for LEE in the range $110 \text{ GeV} < m_H < 145 \text{ GeV}$ ($110 \text{ GeV} < m_H < 600 \text{ GeV}$). The best-fit production cross section CMS measures as a multiple of the SM prediction is shown in Fig. 13. A signal-like excess

is seen in the $H \rightarrow \gamma\gamma$ and $H \rightarrow W^+W^-$ searches, but the outcome in the $H \rightarrow ZZ$ search is less signal-like at $m_H = 125$ GeV.

In summary, beyond the region excluded by LEP, the region excluded at 95% C.L. by both ATLAS and CMS extends from

Figure 11: Observed and expected 95% C.L. upper limits on the ratios to the SM cross section, as functions of the Higgs boson mass for the combined CMS analyses [10].

129 GeV to 539 GeV. The observed and expected limits from the two LHC collaborations and the Tevatron are listed in Table 1 for the main channels and the combinations searching for the SM Higgs boson with $m_H = 125$ GeV. The best-fit cross section is close to the SM prediction at the m_H corresponding to the most significant p -value for both LHC experiments. The data samples are not yet large enough to make a significant statement about the balance between the individual channels.

If a SM Higgs boson is discovered, its properties will be studied at the LHC. The decay branching ratios, and more generally, the couplings of the Higgs bosons to fermions and gauge bosons will be constrained by the measurements of the cross sections times branching ratios for the processes searched for above.

The mass of the Higgs boson will be measured by each LHC experiment with a precision of $\sim 0.1\%$, limited by the energy

scale, in the currently allowed low mass range [141,142]. This projection is based on the invariant mass reconstruction from electromagnetic calorimeter objects, using the decays $H \rightarrow \gamma\gamma$ or $H \rightarrow ZZ^* \rightarrow 4\ell$. The precision would be degraded at higher masses because of the larger decay width, but even at $m_H \sim 700$ GeV a precision of 1% on m_H is expected to be achievable. The width of the SM Higgs boson may be too narrow to be

measured directly. The width could be constrained indirectly using partial width measurements [143,144]. For $300 < m_H < 700$ GeV, a direct measurement of the decay width of an SM-like Higgs boson could be performed with a precision of about 6%.

The possibilities for measuring other properties of the Higgs boson, such as its spin, its CP eigenvalue, its couplings to bosons and fermions, and its self-coupling, have been investigated in numerous studies [141,142,145–148]. Given a sufficiently high integrated luminosity (300 fb^{-1}), most of these properties are expected to be accessible to analysis in the favored mass range $114 \text{ GeV} < m_H < 129 \text{ GeV}$. The measurement of Higgs self-couplings, however, may suffer from poor sensitivity at the LHC, although a luminosity upgrade, the so-called Super-LHC, could allow for a more precise measurement. The results of these measurements could either establish the presence of a SM-like Higgs boson or point the way to new physics.

II.5 Models with a Fourth Generation of SM-Like Fermions

The SM Higgs boson production processes and branching ratios presented above are limited to the case of three generations of quarks and leptons. The existence of a fourth generation of fermions is compatible with present experimental bounds and would have direct consequences on the SM Higgs boson production and decay branching ratios [149], and hence on Higgs boson searches at LEP, the Tevatron, and the LHC [150,151]. Current experimental searches bound the fourth generation quark masses to be above the top quark mass [152]. These additional heavy quarks lead to new contributions in the loop-induced couplings of the Higgs boson to gluons and to photons.

See key on page 457

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

In particular, they lead to a strong enhancement of the gluon fusion production rate and of the branching ratio of the Higgs boson decay into a pair of gluons. As a result, the branching ratios of Higgs boson decay to $b\bar{b}$, tau pairs, and pairs of W and Z bosons are reduced, although near $m_H \sim 2M_W$, the decay to a pair of W bosons still nearly saturates the decay width, even with the enhanced gluon decay. Due to a cancellation between the W and heavy fermion contributions, the photon decay channels may be further suppressed. The enhancement of the gluon fusion production rate makes the search channels using Higgs boson decays into tau leptons and W and Z bosons promising for a light Higgs boson. In addition, in the case of a fourth generation Majorana neutrino, exotic signals such as Higgs boson decay into same-sign dileptons may be possible. Interpretations of the experimental searches optimized for a minimal fourth-generation model (SM4) are available from the Tevatron [153] and CMS [10]. CMS excludes the Higgs boson in the SM4 model in the mass range $120 \text{ GeV} < m_H < 600 \text{ GeV}$ at the 95% C.L.

III. Higgs Bosons in the Minimal Supersymmetric Standard Model (MSSM)

Electroweak symmetry breaking driven by a weakly-coupled elementary scalar sector requires a mechanism to explain the smallness of the breaking scale compared with the Planck scale [154]. In addition, within supersymmetric extensions of the SM, the supersymmetry-breaking effects, whose origins may lie at energy scales much larger than 1 TeV, can induce a radiative breaking of the electroweak symmetry due to the effects of the large Higgs-top quark Yukawa coupling [155]. In this way, the electroweak symmetry breaking scale is intimately tied to the scale of supersymmetry breaking masses. Supersymmetry provides an explanation for the stability of the hierarchy of scales, provided that the supersymmetry-breaking masses, in particular those related to the stop sector, are at most in the TeV range [154].

A fundamental theory of supersymmetry breaking is unknown at this time. Nevertheless, one can parameterize the low-energy theory in terms of the most general set of soft supersymmetry-breaking renormalizable operators [156]. The Minimal Supersymmetric extension of the Standard Model (MSSM) [12,157] associates a supersymmetric partner to each gauge boson and chiral fermion of the SM, and provides a realistic model of physics at the weak scale. However, even in this minimal model with the most general set of soft supersymmetry-breaking terms, more than 100 new parameters are introduced [158]. Fortunately, only a subset of these parameters impact the Higgs phenomenology through tree-level and quantum effects. Reviews of the properties and phenomenology of the Higgs bosons of the MSSM can be found for example in Refs. [44] and [159].

The MSSM contains the particle spectrum of a two-Higgs-doublet model (2HDM) extension of the SM and the corresponding supersymmetric partners. Two Higgs doublets, H_u

and H_d , are required to ensure an anomaly-free SUSY extension of the SM and to generate mass for both “up”-type and “down”-type quarks and charged leptons [13]. After the spontaneous breaking of the electroweak symmetry, five physical Higgs particles are left in the spectrum: one charged Higgs pair, H^\pm , one CP -odd scalar, A , and two CP -even states, H and h .

The supersymmetric structure of the theory imposes constraints on the Higgs sector of the model. In particular, the parameters of the Higgs self-interaction are given by the gauge coupling constants. As a result, all Higgs sector parameters at tree level are determined by only two free parameters: the ratio of the H_u and H_d vacuum expectation values, $\tan\beta = v_u/v_d$, with $v_u^2 + v_d^2 \approx (246 \text{ GeV})^2$; and one Higgs boson mass, conventionally chosen to be m_A . The other tree-level Higgs boson masses are then given in terms of these parameters

$$m_{H^\pm}^2 = m_A^2 + M_W^2$$

$$m_{H,h}^2 = \frac{1}{2} \left[m_A^2 + M_Z^2 \pm \sqrt{(m_A^2 + M_Z^2)^2 - 4(M_Z m_A \cos 2\beta)^2} \right]$$

and α is the angle that diagonalizes the CP -even Higgs squared-mass matrix. An important consequence of these mass formulae is that the mass of the lightest CP -even Higgs boson is bounded from above:

$$m_h \leq M_Z |\cos 2\beta|.$$

This contrasts sharply with the SM, in which the Higgs boson mass is bounded from above only by perturbativity and unitarity considerations. In the large m_A limit, also called the decoupling limit [160], one finds $m_h^2 \simeq (M_Z \cos 2\beta)^2$ and $m_A \simeq m_H \simeq m_{H^\pm}$, up to corrections of $\mathcal{O}(M_Z^2/m_A)$. Below the scale m_A , the Higgs sector of the effective low-energy theory consists only of h , which behaves as the SM Higgs boson.

The phenomenology of the Higgs sector depends on the couplings of the Higgs bosons to gauge bosons, and fermions. The couplings of the two CP -even Higgs bosons to W^\pm and Z bosons are given in terms of the angles α and β by

$$g_{hVV} = g_V m_V \sin(\beta - \alpha) \quad g_{HVV} = g_V m_V \cos(\beta - \alpha),$$

where $g_V \equiv 2m_V/v$. There are no tree-level couplings of A or H^\pm to VV . The couplings of the Z boson to two neutral Higgs bosons, which must have opposite CP -quantum numbers, are given by

$$g_{hAZ} = g_Z \cos(\beta - \alpha)/2 \quad g_{HAZ} = -g_Z \sin(\beta - \alpha)/2.$$

Charged Higgs- W boson couplings to neutral Higgs bosons and four-point couplings of vector bosons and Higgs bosons can be found in Ref. 13.

The tree-level Higgs couplings to fermions obey the following property: the neutral components of one Higgs doublet couple exclusively to down-type fermion pairs while the neutral components of the other doublet couple exclusively to up-type fermion pairs [13,161]. This Higgs-fermion coupling structure defines the Type-II 2HDM [162], and differs from

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

Type-I 2HDM [163] in which one Higgs field couples to all fermions while the other field is decoupled from them. In the MSSM, fermion masses are generated when both neutral Higgs components acquire vacuum expectation values, and the relations between Yukawa couplings and fermion masses are (in third-generation notation)

$$h_b = \sqrt{2} m_b / v_d = \sqrt{2} m_b / (v \cos \beta)$$

$$h_t = \sqrt{2} m_t / v_u = \sqrt{2} m_t / (v \sin \beta).$$

Similarly, one can define the Yukawa coupling of the Higgs boson to τ -leptons (the latter is a down-type fermion).

The couplings of the neutral Higgs bosons to $f\bar{f}$ relative to the SM value, $gm_f/2M_W$, are given by

$$h\bar{b}b: \quad -\sin \alpha / \cos \beta = \sin(\beta - \alpha) - \tan \beta \cos(\beta - \alpha),$$

$$ht\bar{t}: \quad \cos \alpha / \sin \beta = \sin(\beta - \alpha) + \cot \beta \cos(\beta - \alpha),$$

$$H\bar{b}b: \quad \cos \alpha / \cos \beta = \cos(\beta - \alpha) + \tan \beta \sin(\beta - \alpha),$$

$$Ht\bar{t}: \quad \sin \alpha / \sin \beta = \cos(\beta - \alpha) - \cot \beta \sin(\beta - \alpha),$$

$$A\bar{b}b: \quad \gamma_5 \tan \beta, \quad At\bar{t}: \quad \gamma_5 \cot \beta,$$

where the γ_5 indicates a pseudoscalar coupling. In each relation above, the factor listed for $b\bar{b}$ also pertains to $\tau^+\tau^-$. The charged Higgs boson couplings to fermion pairs are given by

$$g_{H^-t\bar{b}} = \frac{g}{\sqrt{2}M_W} [m_t \cot \beta P_R + m_b \tan \beta P_L],$$

$$g_{H^- \tau^+ \nu} = \frac{g}{\sqrt{2}M_W} [m_\tau \tan \beta P_L],$$

with $P_{L,R} = (1 \mp \gamma_5)/2$.

The Higgs couplings to down-type fermions can be significantly enhanced at large $\tan \beta$ in the following two cases: (i) If $m_A \gg M_Z$, then $|\cos(\beta - \alpha)| \ll 1$, $m_H \simeq m_A$, and the $b\bar{b}H$ and $b\bar{b}A$ couplings have equal strength and are significantly enhanced by a factor of $\tan \beta$ relative to the corresponding SM coupling, whereas the VVH coupling is negligibly small. The values of the VVh and $b\bar{b}h$ couplings are equal to the corresponding couplings of the SM Higgs boson. (ii) If $m_A < M_Z$ and $\tan \beta \gg 1$, then $|\cos(\beta - \alpha)| \approx 1$ and $m_h \simeq m_A$. In this case, the $b\bar{b}h$ and $b\bar{b}A$ couplings have equal strength and are significantly enhanced by a factor of $\tan \beta$ relative to the corresponding SM coupling, while the VVh coupling is negligibly small. In addition, the VVH coupling is equal in strength to the corresponding SM VVH coupling and one can refer to H as a SM-like Higgs boson. The value of the $b\bar{b}H$ coupling can differ from the corresponding SM coupling and converges to it only for $m_A \ll M_Z$ for which $\tan \beta \sin(\beta - \alpha) \rightarrow 0$. Note that in both cases (i) and (ii) above, only two of the three neutral Higgs bosons have significantly enhanced couplings to $b\bar{b}$.

III.1. Radiatively-Corrected MSSM Higgs Masses and Couplings

Radiative corrections have a significant impact on the values of Higgs boson masses and couplings in the MSSM. Important

contributions come from loops of third generation SM particles as well as their supersymmetric partners. The dominant effects to the Higgs mass arise from the incomplete cancellation between top and scalar-top (stop) loops and at large $\tan \beta$ also from sbottom and stau loops. The stop, sbottom and stau masses and mixing angles depend on the supersymmetric Higgsino mass parameter μ and on the soft-supersymmetry-breaking parameters [12,157]: M_Q, M_U, M_D, M_L, M_E , and A_t, A_b, A_τ . The first three of these are the left-chiral and the two right-chiral top and bottom scalar quark mass parameters. The next two are the left-chiral stau/sneutrino and the right-chiral stau mass parameters, and the last three are the trilinear parameters that enter in the off-diagonal squark/slepton mixing elements: $X_t \equiv A_t - \mu \cot \beta$ and $X_{b,\tau} \equiv A_{b,\tau} - \mu \tan \beta$. The corrections affecting the Higgs boson masses, production, and decay properties depend on all of these parameters in various ways. At the two-loop level, also the masses of the gluino and the electroweak gaugino enter in the calculations. For simplicity, we shall initially assume that A_t, A_b, A_τ, μ , and the gluino and electroweak gaugino masses are real parameters. The impact of complex phases on MSSM parameters, which will induce CP -violation in the Higgs sector, is addressed below.

Radiative corrections to the Higgs boson masses have been computed using a number of techniques, with a variety of approximations; see Refs. [165–176]. They depend strongly on the top quark mass ($\sim m_t^4$) and the stop mixing parameter X_t , and there is also a logarithmic dependence on the stop masses. One of the most striking effects is the increase of the upper bound of the light CP -even Higgs boson mass, as first noted in Refs. [165,166]. The value of m_h is maximized for large $m_A \gg M_Z$, when all other MSSM parameters are fixed. Moreover, $\tan \beta \gg 1$ also maximizes m_h , when all other parameters are held fixed. Taking m_A large (the decoupling limit) and $\tan \beta \gg 1$, the value of m_h can be further maximized at one-loop level for $X_t \simeq \sqrt{6} M_{\text{SUSY}}$, where $M_{\text{SUSY}} \simeq M_Q \simeq M_U \simeq M_D$ is an assumed common value of the soft SUSY-breaking squark mass parameters. This choice of X_t is called the “maximal-mixing scenario” which will be indicated by m_h -max. Instead, for $X_t = 0$, which is called the “no-mixing scenario,” the value of m_h has its lowest possible value, for fixed m_A and all other MSSM parameters. The value of m_h also depends on the specific value of M_{SUSY} , and, for example, raising M_{SUSY} from 1 TeV to 2 TeV can increase m_h by 2–5 GeV. Variation of the value of m_t by 1 GeV changes the value of m_h by about the same amount. As mentioned above, m_h also depends on μ and more weakly on the electroweak gaugino mass as well as the gluino mass at the two-loop level. For any given scenario defined by a full set of MSSM parameters, we will denote the maximum value of m_h by $m_h^{\text{max}}(\tan \beta)$, for each value of $\tan \beta$. Allowing for the experimental uncertainty on m_t and for the uncertainty inherent in the theoretical analysis, one finds for $M_{\text{SUSY}} \lesssim 2$ TeV, large m_A and $\tan \beta \gg 1$, $m_h^{\text{max}} = 135$ GeV in the m_h -max scenario, and $m_h^{\text{max}} = 122$ GeV in the no-mixing scenario [177,178]. In

See key on page 457

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

practice, parameter values leading to maximal mixing are not obtained in most models of supersymmetry breaking, so typical upper limits on m_h will lie between these two extremes [179]. In the large $\tan\beta$ regime light staus and/or sbottoms with sizable mixing, governed by the μ parameter, yield negative radiative corrections to the mass of the lightest Higgs boson, and can lower it by several GeV [173,180]. Hence, if the Higgs boson were to have a mass of about 125 GeV, a sizable mixing in the stop sector would be required [180,181] ($X_t \geq 1.5M_{\text{SUSY}}$, or even larger if $\tan\beta$ is large). The relatively small mass of the lightest neutral scalar boson is a prediction for both the CP -conserving (CPC) and CP -violating (CPV) [182] MSSM scenarios. This is particularly interesting in the light of the intriguing excesses observed at the Tevatron and the LHC and given that masses above 130 GeV are strongly disfavored by LHC data.

Radiative corrections also modify significantly the values of the Higgs boson couplings to fermion pairs and to vector boson pairs. The tree-level Higgs couplings depend strongly on the value of $\cos(\beta - \alpha)$. In a first approximation, when radiative corrections of the Higgs squared-mass matrix are computed, the diagonalizing angle α is shifted from its tree-level value, and hence one may compute a “radiatively-corrected” value for $\cos(\beta - \alpha)$. This shift provides one important source of the radiative corrections to the Higgs couplings. In particular, depending on the sign of μX_t and the magnitude of X_t/M_{SUSY} , modifications of α can lead to important variations of the SM-like Higgs boson coupling to bottom quarks and tau leptons [175]. Similar corrections to the mixing angle α can come for large $\tan\beta$ from the stau/sbottom sector for sizable $A_{b,\tau}$ [180]. Additional contributions from the one-loop vertex corrections to tree-level Higgs couplings must also be considered [170–189]. These contributions alter significantly the Higgs-fermion Yukawa couplings at large $\tan\beta$, both in the neutral and charged Higgs sector. Moreover, these radiative corrections can modify the basic relationship $g_{h,H,A\bar{b}b}/g_{h,H,A\tau^+\tau^-} \propto m_b/m_\tau$, and change the main features of MSSM Higgs phenomenology.

III.2. Decay Properties and Production Mechanisms of MSSM Higgs Bosons

In the MSSM, neglecting CP -violating effects, one must consider the decay properties of three neutral Higgs bosons and one charged Higgs pair. In the region of parameter space where $m_A \gg m_Z$ and the masses of supersymmetric particles are large, the decoupling limit applies, and the decay rates of h into SM particles are nearly indistinguishable from those of the SM Higgs boson. Hence, the h boson will decay mainly to fermion pairs, since the mass, less than about 135 GeV, is below the W^+W^- threshold. The SM-like branching ratios of h are modified if decays into supersymmetric particles are kinematically allowed [190]. In addition, if light superpartners exist that can couple to photons and/or gluons, then the effective couplings to gg and $\gamma\gamma$ could deviate from the corresponding

SM predictions [180,191,192]. In the decoupling limit, the heavier Higgs states, H , A and H^\pm , are roughly mass degenerate, and their decay branching ratios strongly depend on $\tan\beta$ as discussed below. The AWW and AZZ couplings vanish, and the HWW and HZZ couplings are very small. For values of $m_A \sim \mathcal{O}(M_Z)$, all Higgs boson masses lie below 200 GeV. In this regime, there is a significant area of the parameter space in which none of the neutral Higgs boson decay properties approximates that of the SM Higgs boson. For $\tan\beta \gg 1$, the resulting predictions show marked differences from those for the SM Higgs boson [193]. Significant modifications to the $b\bar{b}$ and/or the $\tau^+\tau^-$ decay rates may occur via radiative effects.

After incorporating the leading radiative corrections to Higgs couplings from both QCD and supersymmetry, the following decay features are relevant in the MSSM. The decay modes $h, H, A \rightarrow b\bar{b}, \tau^+\tau^-$ dominate when $\tan\beta$ is large for all values of the Higgs boson masses. For small $\tan\beta$, these modes are significant for neutral Higgs boson masses below $2m_t$ (although there are other competing modes in this mass range), whereas the $t\bar{t}$ decay mode dominates above its kinematic threshold. In contrast to the SM Higgs boson, the vector boson decay modes of H are strongly suppressed at large m_H due to the suppressed HVV couplings in the decoupling limit. For the charged Higgs boson, $H^+ \rightarrow \tau^+\nu_\tau$ dominates below the $t\bar{b}$ threshold, while $H^+ \rightarrow t\bar{b}$ dominates for large values of m_{H^\pm} . For low values of $\tan\beta$ ($\lesssim 1$) and low values of the charged Higgs boson mass ($\lesssim 120$ GeV), the decay mode $H^+ \rightarrow c\bar{s}$ becomes relevant.

In addition to the decay modes of the neutral Higgs bosons into fermion and gauge boson final states, additional decay channels may be allowed which involve scalars of the extended Higgs sector, *e.g.*, $h \rightarrow AA$. Supersymmetric final states from Higgs boson decays into charginos, neutralinos and third-generation squarks and sleptons can be important if they are kinematically allowed [194]. One interesting possibility is a significant branching ratio for the decay of a neutral Higgs boson to the invisible mode $\tilde{\chi}_1^0\tilde{\chi}_1^0$ (where the lightest neutralino $\tilde{\chi}_1^0$ is the lightest supersymmetric particle) [195], which poses a challenge at hadron colliders.

The production mechanisms for the SM Higgs boson at e^+e^- and hadron colliders can also be relevant for the production of the MSSM neutral Higgs bosons. However, one must take into account the possibility of enhanced or suppressed couplings with respect to those of the Standard Model, since these can significantly modify the production cross sections of neutral Higgs bosons. The supersymmetric-QCD corrections due to the exchange of virtual squarks and gluinos may modify the cross sections depending on the values of these supersymmetric particle masses. At both lepton and hadron colliders there are new mechanisms that produce two neutral Higgs bosons, as well as processes that produce charged Higgs bosons singly or in pairs. In the following we summarize the main processes

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

for MSSM Higgs boson production. For a more detailed discussion and consideration of state-of-the-art calculations, see Refs. [44,75,159].

The main production mechanisms for the neutral MSSM Higgs bosons at e^+e^- colliders are Higgs-strahlung ($e^+e^- \rightarrow Zh, ZH$), vector boson fusion ($e^+e^- \rightarrow \nu\bar{\nu}h, \nu\bar{\nu}H$)—with W^+W^- fusion about an order of magnitude larger than ZZ fusion—and s -channel Z boson exchange ($e^+e^- \rightarrow Ah, AH$) [196]. For the Higgs-strahlung process, it is possible to reconstruct the mass and momentum of the Higgs boson recoiling against the particles from the Z boson decay, and hence sensitive searches for Higgs bosons decaying even to invisible final states can be applied.

The main charged Higgs boson production process at e^+e^- colliders is via s -channel γ or Z boson exchange ($e^+e^- \rightarrow H^+H^-$). Charged Higgs bosons can also be produced in top quark decays via $t \rightarrow b + H^+$ if $m_H^\pm < m_t - m_b$ or via the one-loop process $e^+e^- \rightarrow W^\pm H^\mp$ [197,198], which allows the production of a charged Higgs boson with $m_H^\pm > \sqrt{s}/2$, even when H^+H^- production is kinematically forbidden. Other single charged Higgs production mechanisms include $t\bar{b}H^-/\bar{t}bH^+$ production [51], $\tau^+\nu H^-/\tau^-\bar{\nu}H^+$ production [199], and a variety of processes in which H^\pm is produced in association with a one or two other gauge and/or Higgs bosons [200].

At hadron colliders, the dominant neutral Higgs production mechanism over the majority of the MSSM parameter space is gluon-gluon fusion, mediated by triangle loops containing heavy top and bottom quarks and the corresponding supersymmetric partners [201]. Higgs boson radiation from bottom quarks becomes important for large $\tan\beta$, where at least two of the three neutral Higgs bosons have enhanced couplings to bottom-type fermions [202,203]. A more detailed discussion is presented in Sec. (III.3). The vector boson fusion and Higgs-strahlung production of the CP -even Higgs bosons as well as the associated production of neutral Higgs bosons with top quark pairs have lower production cross sections by least an order of magnitude with respect to the dominant ones, depending on the precise region of MSSM parameter space.

Charged Higgs bosons can be produced in several different modes at hadron colliders. If $m_{H^\pm} < m_t - m_b$, the charged Higgs boson can be produced in decays of the top quark via the decay $t \rightarrow bH^+$, which would compete with the SM process $t \rightarrow bW^+$. Relevant QCD and SUSY-QCD corrections to $\text{BR}(t \rightarrow H^+b)$ have been computed [204–207]. For values of m_{H^\pm} near m_t , width effects are important. In addition, the full $2 \rightarrow 3$ processes $pp/p\bar{p} \rightarrow H^+\bar{t}b + X$ and $pp/p\bar{p} \rightarrow H^-\bar{t}b + X$ must be considered. If $m_{H^\pm} > m_t - m_b$, then charged Higgs boson production occurs mainly through radiation from a third generation quark. Charged Higgs bosons may also be produced singly in association with a top quark via the $2 \rightarrow 3$ partonic processes $gg, q\bar{q} \rightarrow t\bar{b}H^-$ (and the charge conjugate final states). For charged Higgs boson production cross section predictions for the Tevatron and the LHC, see Refs. [12,43,76,208–214]. Charged Higgs bosons can also be

produced via associated production with W^\pm bosons through $b\bar{b}$ annihilation and gg -fusion [215]. They can also be produced in pairs via $q\bar{q}$ annihilation [216]. The inclusive H^+H^- cross section is less than the cross section for single charged Higgs associated production [216–218].

III.3. Searches for Neutral Higgs Bosons in the CP -Conserving (CPC) Scenario

Most of the experimental investigations carried out at LEP, the Tevatron, and the LHC, assume CP -conservation (CPC) in the MSSM Higgs sector. In many cases the search results are interpreted in a number of specific benchmark models where a representative set of the relevant SUSY breaking parameters are specified [177].

III.3.1. Searches for Neutral MSSM Higgs Bosons at LEP

In e^+e^- collisions at LEP energies, the main production mechanisms of the neutral MSSM Higgs bosons are the Higgs-strahlung processes $e^+e^- \rightarrow hZ, HZ$ and the pair production processes $e^+e^- \rightarrow hA, HA$, while the fusion processes play a marginal role. Higgs boson decays to $b\bar{b}$ and $\tau^+\tau^-$ are used in these searches.

The searches and limits from the four LEP experiments are described in Refs. [219–222]. The combined LEP data did not contain any excess of events which would imply the production of a Higgs boson, and combined limits were derived [34]. For $m_A \gg M_Z$ the limit on m_h is nearly that of the SM searches, as $\sin^2(\beta - \alpha) \approx 1$. For high values of $\tan\beta$ and low m_A ($m_A \leq m_h^{\text{max}}$) the $e^+e^- \rightarrow hA$ searches become the most important, and the lightest Higgs h is non SM-like. In this region, the 95% C.L. mass bounds are $m_h > 92.8$ GeV and $m_A > 93.4$ GeV. In the m_h -max. scenario, values of $\tan\beta$ from 0.7 to 2.0 are excluded taking $m_t = 174.3$ GeV, while a much larger $\tan\beta$ region is excluded for other benchmark scenarios such as the no-mixing one.

Neutral Higgs bosons may also be produced by Yukawa processes $e^+e^- \rightarrow f\bar{f}\phi$, where the Higgs particle $\phi \equiv h, H, A$, is radiated off a massive fermion ($f \equiv b$ or τ^\pm). These processes can be dominant at low masses, and whenever the $e^+e^- \rightarrow hZ$ and hA processes are suppressed. The corresponding ratios of the $f\bar{f}h$ and $f\bar{f}A$ couplings to the SM coupling are $\sin\alpha/\cos\beta$ and $\tan\beta$, respectively. The LEP data have been used to search for $b\bar{b}b\bar{b}, b\bar{b}\tau^+\tau^-$, and $\tau^+\tau^-\tau^+\tau^-$ final states [223,224]. Regions of low mass and high enhancement factors are excluded by these searches.

III.3.2. Searches for Neutral MSSM Higgs Bosons at Hadron Colliders

Over a large fraction of the MSSM parameter space, one of the CP -even neutral Higgs bosons (h or H) couples to the vector bosons with SM-like strength and has a mass below 135 GeV. Hence, if the current 95% C.L. exclusion limits for a SM Higgs boson from ATLAS and CMS are interpreted in terms of the SM-like supersymmetric Higgs boson, there is a region of SUSY parameter space beyond that excluded by LEP

See key on page 457

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

that is strongly disfavored. In particular, the minimal mixing scenario with $M_{SUSY} \leq 2$ TeV is disfavored considering the LEP and ATLAS data. At the same time, if the excess of events observed in the Higgs boson searches in the diphoton and ZZ channels are confirmed, this could be interpreted as a SM-like MSSM Higgs boson.

Scenarios with enhanced Higgs boson production cross sections are studied at hadron colliders. The best sensitivity is in the regime with low to moderate m_A and with large $\tan\beta$ which enhances the couplings of the Higgs bosons to down-type fermions. The corresponding limits on the Higgs boson production cross section times the branching ratio of the Higgs boson into down-type fermions can be interpreted in MSSM benchmark scenarios [225]. If $\phi = A, H$ for $m_A > m_h^{\max}$, and $\phi = A, h$ for $m_A < m_h^{\max}$, the most promising channels at the Tevatron are $b\bar{b}\phi, \phi \rightarrow b\bar{b}$ or $\phi \rightarrow \tau^+\tau^-$, with three tagged b -jets or $b\tau\tau$ in the final state, respectively, and the inclusive $p\bar{p} \rightarrow \phi \rightarrow \tau^+\tau^-$ process, with contributions from both $gg \rightarrow \phi$ and $b\bar{b}\phi$ production. Although Higgs boson production via gluon fusion has a higher cross section than via associated production, it cannot be used to study the $\phi \rightarrow b\bar{b}$ decay mode since the signal is overwhelmed by QCD background.

The CDF and DØ collaborations have searched for neutral Higgs bosons produced in association with bottom quarks and which decay into $b\bar{b}$ [226,227], or into $\tau^+\tau^-$ [228,229]. The most recent searches in the $b\bar{b}\phi$ channel with $\phi \rightarrow b\bar{b}$ analyze approximately 2.6 fb^{-1} of data (CDF) and 5.2 fb^{-1} (DØ), seeking events with at least three b -tagged jets. The cross section is defined such that at least one b quark not from ϕ decay is required to have $p_T > 20$ GeV and $|\eta| < 5$. The decay widths of the Higgs bosons are assumed to be much smaller than the experimental resolution. The invariant mass of the two leading jets as well as b -tagging variables are used to discriminate the signal from the backgrounds. The QCD background rates and shapes are inferred from data control samples, in particular, the sample with two b tagged jets and a third, untagged jet. Separate signal hypotheses are tested and limits are placed on $\sigma(p\bar{p} \rightarrow b\bar{b}\phi) \times \text{BR}(\phi \rightarrow b\bar{b})$. CDF sees a local excess of approximately 2.5σ significance in the mass range of 130-160 GeV, but DØ's search is more sensitive and sets stronger limits. The DØ result shown in Fig. 14 displays a ≈ 2 sigma local upward fluctuation in the 110 to 125 GeV mass range.

CDF and DØ have also performed searches for inclusive production of Higgs bosons with subsequent decays to $\tau^+\tau^-$ [230,231,232], although these limits have been superseded by the LHC searches.

In order to interpret the experimental data in terms of MSSM benchmark scenarios, it is necessary to consider carefully the effect of radiative corrections on the production and decay processes. The bounds from the $b\bar{b}\phi, \phi \rightarrow b\bar{b}$ channel depend strongly on the radiative corrections affecting the relation between the bottom quark mass and the bottom Yukawa

Figure 14: The 95% C.L. limits on $\sigma(p\bar{p} \rightarrow b\bar{b}) \times \text{BR}(\phi \rightarrow b\bar{b})$ from CDF and DØ. The observed limits are indicated with solid lines, and the expected limits are indicated with dashed lines. The limits are to be compared with the sum of signal predictions for Higgs bosons with similar masses.

coupling. In the channels with $\tau^+\tau^-$ final states, however, compensations occur between large corrections in the Higgs boson production and decay. The total production rates of bottom quarks and τ pairs mediated by the production of a CP -odd Higgs boson in the large $\tan\beta$ regime are approximately given by

$$\sigma_{b\bar{b}A} \times \text{BR}(A \rightarrow b\bar{b}) \simeq \sigma_{b\bar{b}A}^{\text{SM}} \frac{\tan^2\beta}{(1 + \Delta_b)^2} \frac{9}{(1 + \Delta_b)^2 + 9},$$

and

$$\sigma_{gg \rightarrow A, b\bar{b}A} \times \text{BR}(A \rightarrow \tau^+\tau^-) \simeq \sigma_{gg \rightarrow A, b\bar{b}A}^{\text{SM}} \frac{\tan^2\beta}{(1 + \Delta_b)^2 + 9},$$

where $\sigma_{b\bar{b}A}^{\text{SM}}$ and $\sigma_{gg \rightarrow A, b\bar{b}A}^{\text{SM}}$ denote the values of the corresponding SM Higgs boson cross sections for a SM Higgs boson mass equal to m_A . The function Δ_b includes the dominant effects of SUSY radiative corrections for large $\tan\beta$ [170,175,187,188], and it depends strongly on $\tan\beta$ and on the SUSY mass parameters. The $b\bar{b}A$ channel is more sensitive to the value of Δ_b through the factor $1/(1 + \Delta_b)^2$ than the inclusive $\tau^+\tau^-$ channel, for which this leading dependence on Δ_b cancels out. As a consequence, the limits derived from the inclusive $\tau^+\tau^-$ channel depend less on the precise MSSM scenario chosen than those of the $b\bar{b}A$ channel.

The production and decay rates of the CP -even Higgs bosons with $\tan\beta$ -enhanced couplings to down-type fermions— H (or h) for m_A larger (or smaller) than m_h^{\max} , respectively—are governed by formulas similar to the ones presented above. At high $\tan\beta$, one of the CP -even Higgs bosons and the CP -odd Higgs boson are nearly degenerate in mass, enhancing the signal

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

cross section by roughly a factor of two, without complicating the experimental signature except in a small mass region in which the three neutral MSSM Higgs boson masses are close together and each boson contributes to the total production rate. Detailed discussions of the impact of radiative corrections in these search modes are presented in Refs. [225] and [233].

In Fig. 15, the interpretation is shown for DØ's combination of $\phi \rightarrow b\bar{b}$ and $\phi \rightarrow \tau^+\tau^-$ searches [232] in the $(m_A, \tan\beta)$ plane for the m_h -max benchmark scenario with $\mu = 200$ GeV. The neutral Higgs boson searches consider the contribution of both the CP -odd and the CP -even neutral Higgs bosons with enhanced couplings to bottom quarks. As explained above, considering other benchmark scenarios will not relevantly change the region of SUSY parameter space that can be explored via the inclusive di-tau searches, but different regions of SUSY parameter space will be probed in the case of the $b\bar{b}$ searches.

ATLAS and CMS also search for $\phi \rightarrow \tau^+\tau^-$ in pp collisions at $\sqrt{s} = 7$ TeV. ATLAS seeks tau pairs in 1.06 fb^{-1} of data [234,235], and CMS's search uses 4.6 fb^{-1} of data [138,139]. The searches are performed in categories of the decays of the two tau leptons: $e\tau_{\text{had}}$, $\mu\tau_{\text{had}}$, $e\mu$, and $\mu\mu$, where τ_{had} denotes a tau lepton which decays to one or more hadrons plus a tau neutrino, e denotes $\tau \rightarrow e\nu\nu$, and μ denotes $\tau \rightarrow \mu\nu\nu$. The dominant background comes from $Z \rightarrow \tau^+\tau^-$ decays, although $t\bar{t}$, W +jets and Z +jets events contribute as well. Separating events into categories based on the number of b -tagged jets improves the sensitivity in the MSSM. The $b\bar{b}$ annihilation process and radiation of a Higgs boson from a b quark give rise to events in which the Higgs boson is accompanied by a $b\bar{b}$ pair in the final state, sometimes with only one b within the detector acceptance. Requiring the presence of one or more b jets reduces the background from Z +jets. Data control samples are used to constrain background rates. The rates for jets to be identified as a hadronically decaying tau lepton are measured in dijet samples, and W +jets samples provide a measurement of the rate of events that, with a fake hadronic tau, can pass the signal selection requirements. Lepton fake rates are measured using samples of unisolated lepton candidates and same-sign lepton candidates. Constraints from ATLAS's and CMS's searches for $h \rightarrow \tau^+\tau^-$ are also shown in Fig. 15 in the m_h -max benchmark scenario, with $\mu = 200$ GeV. The neutral Higgs boson searches consider the contributions of both the CP -odd and CP -even neutral Higgs bosons with enhanced couplings to bottom quarks, as they were for the Tevatron results. As explained above, the di-tau inclusive search limits do not significantly change by considering other benchmark scenarios.

In addition to $\phi \rightarrow \tau^+\tau^-$ at the LHC, studies indicate that with about 30 fb^{-1} of data one can search for the non-standard neutral Higgs bosons of the MSSM in the $b\bar{b}\phi, \phi \rightarrow b\bar{b}$ channel with three b 's in the final state [233]. Due to the dependence of this production and decay mode on the SUSY radiative corrections there is complementarity between the $3b$ channel and the inclusive tau pair channel in exploring the supersymmetric parameter space.

Figure 15: The 95% C.L. MSSM exclusion contours m_h -max benchmark scenario obtained by the ATLAS [234], CMS [138], and DØ [232] collaborations. The LHC collaborations contribute searches for $H \rightarrow \tau^+\tau^-$ and $H^\pm \rightarrow \tau\nu_\tau$ while DØ combines $H \rightarrow \tau^+\tau^-$ with $H \rightarrow b\bar{b}$ searches for these results. Also shown is the region excluded by LEP searches [34], assuming a top quark mass of 174.3 GeV.

The LHC has the potential to explore a broad range of SUSY parameter space through the search for non-SM-like Higgs bosons. Nevertheless, Fig. 15 shows a broad region with intermediate $\tan\beta$ and large values of m_A that is not tested by present neutral or charged Higgs boson searches, and which might be difficult to cover completely via these searches, even with much larger data sets. In this region of parameter space it is possible that only the SM-like Higgs boson can be within the LHC's reach. If a SM-like Higgs boson is discovered, it may be challenging to determine only from the Higgs sector whether there is a supersymmetric extension of the SM in nature.

III.4. Searches for Charged MSSM Higgs Bosons

Searches for the charged Higgs bosons predicted by 2HDMs have been conducted at LEP, the Tevatron, and the LHC, and the results of these searches have been interpreted in terms of the MSSM. Due to the correlations among Higgs boson masses in the MSSM, the experimental results do not yet significantly constrain the MSSM parameter space beyond what is already obtained from the searches for neutral Higgs bosons. In the near future, however, the LHC experiments will be sensitive to charged Higgs boson decays up to ≈ 170 GeV for all values of $\tan\beta$ [236].

At LEP, searches were performed for pair-produced charged Higgs bosons. In the MSSM and in more general Type-II 2HDMs, for masses which are accessible at LEP energies,

See key on page 457

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

the decays $H^+ \rightarrow c\bar{s}$ and $\tau^+\nu_\tau$ dominate. The final states $H^+H^- \rightarrow (c\bar{s})(\bar{c}s)$, $(\tau^+\nu_\tau)(\tau^-\bar{\nu}_\tau)$, and $(c\bar{s})(\tau^-\bar{\nu}_\tau) + (\bar{c}s)(\tau^+\nu_\tau)$ were considered, and the search results are usually presented as functions of $\text{BR}(H^+ \rightarrow \tau^+\nu)$. The sensitivity of the LEP searches was limited to $m_{H^\pm} < 90$ GeV, due to the background from $e^+e^- \rightarrow W^+W^-$ [237], and the kinematic limitation on the production cross section. The combined LEP data constrain $m_{H^\pm} > 78.6$ GeV independently of $\text{BR}(H^+ \rightarrow \tau^+\nu_\tau)$ [238].

At the Tevatron, the CDF and DØ collaborations have searched for charged Higgs bosons in top quark decays with subsequent decays of the charged Higgs boson to $\tau\nu$ or to $c\bar{s}$ [239,240,241]. Assuming $\text{BR}(H^+ \rightarrow c\bar{s}) = 100\%$, the limits on $\text{BR}(t \rightarrow H^+b)$ from CDF and DØ are $\approx 20\%$ in the mass range $90 \text{ GeV} < m_{H^+} < 160 \text{ GeV}$. Assuming $\text{BR}(H^+ \rightarrow \tau^+\nu_\tau) = 100\%$, DØ's limits on $\text{BR}(t \rightarrow H^+b)$ are also $\approx 20\%$ in the same mass range. These limits are valid in general 2HDMs, and they have also been interpreted in terms of the MSSM in the references.

The ATLAS collaboration has also searched for charged Higgs bosons produced in the decay of top quarks in $t\bar{t}$ events. ATLAS has searched for the decay $H^+ \rightarrow \tau^+\nu_\tau$ in three final state topologies: 1) lepton+jets: with $t\bar{t} \rightarrow \bar{b}WH^+ \rightarrow \bar{b}\bar{b}(q\bar{q}')(\tau_{\text{lep}}\nu)$, i.e., the W boson decays hadronically and the tau decays into an electron or a muon, with two neutrinos; 2) τ +lepton: with $t\bar{t} \rightarrow \bar{b}WH^+ \rightarrow \bar{b}\bar{b}(l\nu)(\tau_{\text{had}}\nu)$ i.e., the W boson decays leptonically (with $l = e, \mu$) and the tau decays hadronically; 3) τ +jets: $t\bar{t} \rightarrow \bar{b}WH^+ \rightarrow \bar{b}\bar{b}(q\bar{q}')(\tau_{\text{had}}\nu)$, i.e., both the W boson and the τ decay hadronically [242]. Assuming $\text{BR}(H^+ \rightarrow \tau^+\nu_\tau) = 100\%$, ATLAS sets upper limits on $\text{BR}(t \rightarrow H^+b)$ between 5% and 1% for charged Higgs boson masses between 90 GeV to 160 GeV, respectively. These limits are shown in Fig. 16. When interpreted in the context of the m_h^{max} scenario of the MSSM, these bounds exclude $\tan\beta$ values above 20 in this range of charged Higgs boson masses, but also provide sensitivity for $\tan\beta < 4$ due to the increasing predicted decay rate for $t \rightarrow H^+b$ at low $\tan\beta$. The high- $\tan\beta$ interpretation of this result is shown in Fig. 15. ATLAS has also searched for charged Higgs bosons in top quark decays assuming $\text{BR}(H^+ \rightarrow c\bar{s}) = 100\%$ [243], and sets limits of $\approx 20\%$ on $\text{BR}(t \rightarrow H^+b)$ in the $90 \text{ GeV} < m_{H^+} < 160 \text{ GeV}$ mass range.

The CMS collaboration has also searched for the charged Higgs boson in the decay products of top quark pairs: $t\bar{t} \rightarrow H^\pm W^\mp b\bar{b}$ and $t\bar{t} \rightarrow H^+H^-b\bar{b}$ [244]. Three types of final states with large missing transverse energy and jets originating from b -quark hadronization have been analyzed: the fully-hadronic channel with a hadronically decaying tau in association with jets, the di-lepton channel with a hadronically decaying tau in association with an electron or muon and the di-lepton channel with an electron-muon pair. Combining the results of these three analyses and assuming $\text{BR}(H^\pm \rightarrow \tau\nu) = 1$, the upper limits on $\text{BR}(t \rightarrow H^+b)$ are less than 2% to 3% depending on the charged Higgs boson mass in the interval 80 GeV

Figure 16: 95% C.L. limit on $\text{BR}(t \rightarrow H^+b)$ assuming $\text{BR}(H^+ \rightarrow \tau\nu) = 100\%$ from the ATLAS collaboration [242].

$< m_{H^+} < 160$ GeV. The results of this search have been translated into limits in the $(M_A, \tan\beta)$ plane for the m_h -max benchmark scenario and are shown in Fig. 15.

III.5. Effects of CP Violation on the MSSM Higgs Spectrum

In the Standard Model, CP -violation (CPV) is induced by phases in the Yukawa couplings of the quarks to the Higgs field, which results in one non-trivial phase in the CKM mixing matrix. SUSY scenarios with new CPV phases are theoretically appealing, since additional CPV beyond that observed in the K , D , and B meson systems is required to explain the observed cosmic matter-antimatter asymmetry [245,246]. In the MSSM, there are additional sources of CPV from phases in the various mass parameters. In particular, the gaugino mass parameters (M_i , $i = 1, 2, 3$), the Higgsino mass parameter, μ , the bilinear Higgs squared-mass parameter, m_{12}^2 , and the trilinear couplings of the squark and slepton fields to the Higgs fields, A_f , may carry non-trivial phases. The two parameter combinations $\arg[\mu A_f(m_{12}^2)^*]$ and $\arg[\mu M_i(m_{12}^2)^*]$ are invariant under phase redefinitions of the MSSM fields [247,248]. Therefore, if one of these quantities is non-zero, there would be new sources of CP -violation, which affects the MSSM Higgs sector through radiative corrections [182,248–253]. The mixing of the neutral CP -odd and CP -even Higgs boson states is no longer forbidden. Hence, m_A is no longer a physical parameter. However, the charged Higgs boson mass m_{H^\pm} is still physical and can be used as an input for the computation of the neutral Higgs spectrum of the theory.

For large values of m_{H^\pm} , corresponding to the decoupling limit, the properties of the lightest neutral Higgs boson state approach those of the SM Higgs boson. That is, for $m_{H^\pm} \gg M_W$,

Higgs Bosons — H^0 and H^\pm

the lightest neutral Higgs boson is approximately a CP -even state, with CPV couplings that are suppressed by terms of $\mathcal{O}(m_W^2/m_{H^\pm}^2)$. In particular, the upper bound on the lightest neutral Higgs boson mass, takes the same value as in the CP -conserving case [248]. Nevertheless, there still can be significant mixing between the two heavier neutral mass eigenstates. For a detailed study of the Higgs boson mass spectrum and parametric dependence of the associated radiative corrections, see Refs. [249,252].

Major variations to the MSSM Higgs phenomenology occur in the presence of explicit CPV phases. In the CPV case, vector boson pairs couple to all three neutral Higgs boson mass eigenstates, H_i ($i = 1, 2, 3$), with couplings

$$g_{H_i V V} = \cos \beta \mathcal{O}_{1i} + \sin \beta \mathcal{O}_{2i}$$

$$g_{H_i H_j Z} = \mathcal{O}_{3i}(\cos \beta \mathcal{O}_{2j} - \sin \beta \mathcal{O}_{1j}) - \mathcal{O}_{3j}(\cos \beta \mathcal{O}_{2i} - \sin \beta \mathcal{O}_{1i})$$

where the $g_{H_i V V}$ couplings are normalized to the analogous SM coupling and the $g_{H_i H_j Z}$ have been normalized to $g_Z^{\text{SM}}/2$. \mathcal{O}_{ij} is the orthogonal matrix relating the weak eigenstates to the mass eigenstates. It has non-zero off-diagonal entries mixing the CP -even and CP -odd components of the weak eigenstates. The above couplings obey the relations

$$\sum_{i=1}^3 g_{H_i Z Z}^2 = 1 \quad \text{and} \quad g_{H_k Z Z} = \varepsilon_{ijk} g_{H_i H_j Z}$$

where ε_{ijk} is the Levi-Civita symbol.

Another consequence of CPV effects in the scalar sector is that all neutral Higgs bosons can couple to both scalar and pseudoscalar fermion bilinear densities. The couplings of the mass eigenstates H_i to fermions depend on the loop-corrected fermion Yukawa couplings (similarly to the CPC case), on $\tan \beta$ and on the \mathcal{O}_{ji} . The resulting expressions for the scalar and pseudoscalar components of the neutral Higgs boson mass eigenstates to fermions and the charged Higgs boson to fermions are given in Refs. [249,254].

The production processes of neutral MSSM Higgs bosons in the CPV scenario are similar to those in the CPC scenario, except for the fact that in any process, the CP eigenstates h , H , and A can be replaced by any of the three neutral Higgs mass eigenstates H_i . This is the case, since, in the presence of CP violation, the H_i 's do not have well-defined CP quantum numbers. Regarding the decay properties, the lightest mass eigenstate, H_1 , predominantly decays to $b\bar{b}$ if kinematically allowed, with a smaller fraction decaying to $\tau^+\tau^-$, similar to the CPC case. If kinematically allowed, a SM-like neutral Higgs boson, H_2 or H_3 can decay predominantly to $H_1 H_1$ leading to many new interesting signals both at lepton and hadron colliders; otherwise it will decay preferentially to $b\bar{b}$.

III.6. Searches for Neutral Higgs Bosons in CPV Scenarios

At LEP, all three neutral Higgs eigenstates could have been produced by Higgs-strahlung, $e^+e^- \rightarrow H_i Z$, and in pairs, $e^+e^- \rightarrow Z^* \rightarrow H_i H_j$, with $i \neq j$. The production rates depend

on the details of the CPV scenario. Possible cascade decays such as H_2 or $H_3 \rightarrow H_1 H_1$ can lead to interesting experimental signatures in the Higgs-strahlung processes, $e^+e^- \rightarrow H_2 Z$ or $H_3 Z$, however, the searches in the CPV MSSM scenario are experimentally more difficult. The cross sections for the Higgs-strahlung and pair production processes are given in Refs [182,248,249,253].

The Higgs boson searches at LEP were interpreted [34] in a CPV benchmark scenario [182] for which the parameters were chosen so as to maximize the phenomenological differences with respect to the CPC scenario. Using the most conservative theoretical calculations available at each point in the $(m_{H_1}, \tan \beta)$ plane, parts of the region $m_{H_1} < 60$ GeV and $\tan \beta < 40$ were excluded, and values of $\tan \beta$ lower than 3 were excluded for all values of $m_{H_1} < 114$ GeV. The Tevatron CP -conserving results and projections for MSSM Higgs searches, as well as the existing projections for LHC MSSM CP -conserving searches have been reinterpreted in the framework of CP -violating MSSM Higgs in Ref. 255.

III.7. Indirect Constraints on Supersymmetric Higgs Bosons

Indirect bounds from a global fit to precision measurements of electroweak observables can be derived in terms of MSSM parameters [256] in a way similar to what was done in the SM. Given the MSSM and SM predictions for M_W as a function of m_t , and varying the Higgs boson mass and the SUSY spectrum, one finds that the MSSM overlaps with the SM when SUSY masses are large, of $\mathcal{O}(2 \text{ TeV})$, and the light SM-like Higgs boson has a mass in the experimentally preferred mass range: $m_h \hat{=} 114\text{--}129$ GeV. The MSSM Higgs boson mass expectations are compatible with the constraints provided by the measurements of m_t and M_W [257]. A global fit for m_h in the Constrained MSSM, for example, yields $m_h = 119.1_{-2.9}^{+3.4}$ GeV after including the constraints from LHC data, instead of the pre-LHC value of $m_h = 111.5_{-1.2}^{+3.5}$ GeV, improving the consistency of the model predictions with the LEP exclusion [258]⁴. These global fit studies show that a SM-like Higgs with mass 125 GeV or larger would start to build up some tension with $g_\mu - 2$ that may ultimately lead to exclude the CMSSM or other types of constrained SUSY scenarios for which similar results can be obtained.

Improvements in our understanding of B -physics observables put indirect constraints on MSSM scenarios in regions in which Higgs boson searches at the Tevatron and the LHC are sensitive. In particular, $\text{BR}(B_s \rightarrow \mu^+\mu^-)$, $\text{BR}(b \rightarrow s\gamma)$, and $\text{BR}(B_u \rightarrow \tau\nu)$ play an important role within minimal flavor-violating (MFV) models [259], in which flavor effects proportional to the CKM matrix elements are induced, as in the SM. For example, see Refs. [260–263]. The supersymmetric contributions to these observables come both at the tree- and loop-level, and have a different parametric dependence,

⁴ This fit does not include the direct limits on the Higgs boson mass from any collider.

Higgs Bosons — H^0 and H^\pm

but share the property that they become significant for large values of $\tan\beta$, which is also the regime in which searches for non-standard MSSM Higgs bosons at hadron colliders are the most powerful.

In the SM, the relevant contributions to the rare decay $B_s \rightarrow \mu^+\mu^-$ come through the Z -penguin and the W^\pm -box diagrams [264]. In supersymmetry with large $\tan\beta$, there are also significant contributions from Higgs-mediated neutral currents [265–268], which depend on the SUSY spectra, and grow with the sixth power of $\tan\beta$ and decrease with the fourth power of the CP -odd Higgs boson mass m_A . Therefore, the upper limits from the Tevatron and the LHC [269] put strong restrictions on possible flavor-changing neutral currents (FCNC) in the MSSM at large $\tan\beta$ [270].

Further constraints are obtained from the rare decay $b \rightarrow s\gamma$. The SM rate is known up to NNLO corrections [271,272] and is in good agreement with measurements [273]. In the Type-II 2HDM and in the absence of other sources of new physics at the electroweak scale, a bound $m_{H^\pm} > 295$ GeV has been derived [271]. Although this indirect bound appears much stronger than the results from direct charged Higgs searches, it can be invalidated by new physics contributions, such as those which can be present in the MSSM. In the minimal flavor-violating MSSM, there are new contributions from charged Higgs as well as chargino-stop and gluino-sbottom diagrams. The charged Higgs boson's contribution is enhanced for small values of its mass and can be partially canceled by the chargino and gluino contributions or by higher-order $\tan\beta$ -enhanced loop effects.

The branching ratio $B_u \rightarrow \tau\nu$, measured by the Belle [274,275] and BaBar [276,277] collaborations, also constrains the MSSM. The SM expectation is in slight tension with the latest experimental results [278]. In the MSSM, there is an extra tree-level contribution from the charged Higgs which interferes destructively with the SM contribution, and which increases for small values of the charged Higgs boson mass and large values of $\tan\beta$ [279]. Charged Higgs effects on $B \rightarrow D\tau\nu$ decays [280], constrain in an important way the parameter space for small values of the charged Higgs boson mass and large values of $\tan\beta$, and exclude a region that is otherwise allowed by values of $B_u \rightarrow \tau\nu$ [278,281,282]. These two observables are only mildly dependent on the SUSY spectra.

Charged Higgs bosons can play a role in explaining the evidence for CP violation in $D^0 \rightarrow \pi^+\pi^-$, K^+K^- decays recently presented by LHCb [283] and CDF [284]. In a particular minimal flavor violating 2HDM, tree-level charged Higgs insertions can give large contributions to CP violation in D^0 decays while also being consistent with stringent bounds from $D^0 - \bar{D}^0$ mixing, $\text{BR}(b \rightarrow s\gamma)$, and $\text{BR}(B_u \rightarrow \tau\nu)$, as well as direct searches such as $H \rightarrow \tau^+\tau^-$ [285].

Several studies [260–263,286,287] have shown that, in extended regions of parameter space, the combined B -physics measurements impose strong constraints on the MSSM models to which Higgs boson searches at the Tevatron and the LHC

are sensitive. Consequently, the observation of a non-SM Higgs boson at the Tevatron or the LHC would point to a rather narrow, well-defined region of MSSM parameter space [260,288] or to something beyond the minimal flavor violation framework.

Another indirect constraint on the Higgs sector comes from the search for dark matter. If dark matter particles are weakly interacting and massive, then particle physics can provide models which predict the correct relic density of the universe. In particular, the lightest supersymmetric particle, typically the lightest neutralino, is an excellent dark matter particle candidate [289]. Within the MSSM, the measured relic density places constraints in the parameter space, which in turn - for specific SUSY low energy spectra- have implications for Higgs searches at colliders, and also for experiments looking for direct evidence of dark matter particles in elastic scattering with atomic nuclei. Large values of $\tan\beta$ and small m_A are relevant for the $b\bar{b}A/H$ and $A/H \rightarrow \tau^+\tau^-$ searches at the Tevatron and the LHC, and also provide a significant contribution from the CP -even Higgs H exchange to the spin-independent cross sections for direct detection experiments such as CDMS or Xenon, for example. Consequently, a signal at colliders would raise prospects for a signal in indirect detection experiments and vice-versa [286,288,290–292]. However, there are theoretical uncertainties in the calculation of dark matter scattering cross sections, and in the precise value of the local dark matter density and velocity distributions, which may dilute these model-dependent correlations.

IV. Other Model Extensions

There are many ways to extend the minimal Higgs sector of the Standard Model. In the preceding sections we have considered the phenomenology of the MSSM Higgs sector⁵, which at tree level is a constrained Type-II 2HDM (with restrictions on the Higgs boson masses and couplings). One can consider general Type-II 2HDMs [13,44,162], with no correlations between masses and couplings, or Type-I 2HDMs [163]. The different patterns of Higgs-fermion couplings in each case will lead to different phenomenology. It is also possible to consider models with a SM Higgs boson and one or more additional scalar SU(2) doublets that acquire no vacuum expectation value (vev) and hence play no role in the EWSB mechanism. These models are dubbed Inert Higgs Doublet Models [293]. Due to the lack of vev, the inert Higgs bosons cannot decay into a pair of gauge bosons, and imposing a Z_2 symmetry that prevents them from coupling to the fermions it follows that if the lightest inert Higgs boson is neutral it becomes a good dark matter candidate with interesting associated collider signals.

Other extensions of the Higgs sector can include [15,164] multiple copies of SU(2)_L doublets, additional Higgs singlets, triplets or more complicated combinations of Higgs multiplets.

⁵ In the searches for charged Higgs bosons the results are presented for given branching ratio assumptions within a general 2HDM, and then interpreted in the MSSM.

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

It is also possible to enlarge the gauge symmetry beyond $SU(2)_L \times U(1)_Y$ along with the necessary Higgs structure to generate gauge boson and fermion masses. There are two main experimental constraints that govern these extensions: (i) precision measurements which constrain $\rho = m_W^2 / (m_Z^2 \cos^2 \theta_W)$ to be very close to 1 and (ii) flavor changing neutral current (FCNC) effects. In electroweak models based on the SM gauge group, the tree-level value of ρ is determined by the Higgs multiplet structure. By suitable choices for the hypercharges, and in some cases the mass splitting between the charged and neutral Higgs sector or the vacuum expectation values of the Higgs fields, it is possible to obtain a richer combination of singlets, doublets, triplets and higher multiplets compatible with precision measurements [294]. Concerning the constraints coming from FCNC effects, the Glashow-Weinberg theorem [295] states that, in the presence of multiple Higgs doublets the tree-level FCNC's mediated by neutral Higgs bosons will be absent if all fermions of a given electric charge couple to no more than one Higgs doublet. The Higgs doublet models Type-I and Type-II are two different ways of satisfying this theorem. The coupling pattern of these two types can be arranged by imposing either a discrete symmetry or, in the case of Type-II, supersymmetry. The resulting phenomenology of extended Higgs sectors can differ significantly from that of the SM Higgs boson.

In supersymmetry, the most studied extensions of the MSSM have a scalar singlet and its supersymmetric partner [296–298]. These models have an extended Higgs sector with two additional neutral scalar states, one CP -even and one CP -odd, beyond those present in the MSSM. In these models, the tree-level bound on the lightest Higgs boson, considering arguments of perturbativity of the theory up to the GUT scale, is about 100 GeV. The radiative corrections to the masses are similar to those in the MSSM and yield an upper bound of about 145 GeV for the mass of the lightest neutral CP -even scalar, for stop masses in the TeV range [16,299]. The couplings of the Higgs bosons to the gauge bosons and fermions are weakened somewhat from mixing with the singlet and this can alter significantly the Higgs phenomenology with respect to the MSSM case.

Another extension of the MSSM which can raise the value of the lightest Higgs boson mass to a few hundred GeV is based on gauge extensions of the MSSM [17,18]. The addition of asymptotically-free gauge interactions naturally yields extra contributions to the quartic Higgs couplings. These extended gauge sector models can be combined with the presence of extra singlets or replace the singlet with a pair of triplets [19].

It is also possible that the MSSM is the low energy effective field theory of a more fundamental SUSY theory that includes additional particles with masses at or somewhat above the TeV range, and that couple significantly to the MSSM Higgs sector. A model-independent analysis of the spectrum and couplings of the MSSM Higgs fields, based on an effective theory of the MSSM degrees of freedom has been studied [18,20,21,300]. In these scenarios the tree-level mass of the lightest CP -even state

can easily be above the LEP bound of 114 GeV, thus allowing for a relatively light spectrum of superpartners, restricted only by direct searches. The Higgs spectrum and couplings can be significantly modified compared to the MSSM ones, often allowing for interesting new decay modes. It is also possible to moderately enhance the gluon fusion production cross section of the SM-like Higgs with respect to both the Standard Model and the MSSM.

Many non-SUSY solutions to the problem of electroweak symmetry breaking and the hierarchy problem are being developed. For example, Little Higgs models [25–27] propose additional sets of heavy vector-like quarks, gauge bosons, and scalar particles, with masses in the 100 GeV to a few TeV range. The couplings of the new particles are tuned in such a way that the quadratic divergences induced in the SM by the top, gauge-boson and Higgs loops are canceled at the one-loop level. If the Little Higgs mechanism successfully resolves the hierarchy problem, it should be possible to detect some of these new states at the LHC. For reviews of models and phenomenology, and a more complete list of references, see Refs. [301–303].

In Little Higgs models the production and decays of the Higgs boson are modified. For example, when the dominant production mode of the Higgs is through gluon fusion, the contribution of new fermions in the loop diagrams involved in the effective ϕgg vertex can reduce the production rate. The rate is generally suppressed relative to the SM rate due to the symmetries which protect the Higgs boson mass from quadratic divergences at the one-loop level. As a result, the branching ratio of the Higgs boson to photon pairs can be enhanced in these models [304]. By design, Little Higgs models are valid only up to a scale $\Lambda \sim 5$ -10 TeV. The new physics which would enter above Λ remains unspecified, and will impact the Higgs sector. In general, it can modify Higgs couplings to third-generation fermions and gauge bosons, though these modifications are suppressed by $1/\Lambda$ [305].

Distinctive features in the Higgs phenomenology of Little Higgs models may also stem from the fact that loop-level electroweak precision bounds on models with a tree-level custodial symmetry allows for a Higgs boson heavier than the one permitted by precision electroweak fits in the SM. This looser bound follows from a cancellation of the effects on the ρ parameter of a higher mass Higgs boson and the heavy partner of the top quark. The Higgs boson can have a mass as high as 800-1000 GeV in some Little Higgs models and still be consistent with electroweak precision data [306]. Lastly, the scalar content of a Little Higgs structure is model dependent. There could be two, or even more scalar doublets in a little Higgs model, or even different representations of the electroweak gauge group [26].

Models of extra space dimensions present an alternative way of avoiding the hierarchy problem [28]. New states, known as Kaluza-Klein (KK) excitations, can appear at the TeV scale, where gravity-mediated interactions may become relevant. They share the quantum numbers of the graviton and/or SM particles. In a particular realization of these models, based on

See key on page 457

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

warped extra dimensions, a light Higgs-like particle, the radion, may appear in the spectrum [307]. The mass of the radion, as well as its possible mixing with the light Higgs boson, depends strongly on the mechanism that stabilizes the extra dimension, and on the curvature-Higgs mixing.

The radion couples to the trace of the energy-momentum tensor of the SM particles, leading to effective interactions with quarks, leptons, and weak gauge bosons which are similar to the ones of the Higgs boson, although they are suppressed by the ratio of the weak scale to the characteristic mass of the new excitations. An important characteristic of the radion is its enhanced coupling to gluons. Therefore, if it is light and mixes with the Higgs boson, it may modify the standard Higgs phenomenology at lepton and hadron colliders. A search for the radion conducted by OPAL at LEP gave negative results [308]. Radion masses below 58 GeV are excluded for the mass eigenstate which becomes the Higgs boson in the no-mixing limit, for all parameters of the Randall-Sundrum model. Most recently there has been a study of the effects of radion-Higgs mixing in Higgs boson searches at the LHC [309].

In models of warped extra dimensions in which the SM particles propagate in the extra dimensions, the KK excitations of the vector-like fermions may be pair-produced at colliders and decay into combinations of two Higgs bosons and jets, or one Higgs boson, a gauge boson, and jets. KK excitations may also be singly-produced. Some of these interesting possible new signatures for SM-like Higgs bosons in association with top or bottom quarks have been studied [27,29]. Most interesting, in models with warped extra dimensions the Kaluza-Klein excitations of the quarks and leptons which can be exchanged as virtual particles in the loops, can significantly change the Higgs production via gluon fusion, as well as its decay into diphotons. These results may depend on the precise localization of the SM-like Higgs in the extra dimension as well as on the precise particle content of the models. There are many studies in the literature that address these issues and compute the effects on the Higgs phenomenology [27,310].

Models of flat extra dimensions, in which SM particles propagate in the extra dimensions, are named Universal Extra Dimensions (UED) [311]. In such models the KK particles affect the Higgs couplings at the 1-loop level. In the minimal UED model, for tree-level masses of the lowest KK particles of order 1 TeV the $gg \rightarrow h$ production rate is increased by $\approx 20\%$ while the $h \rightarrow \gamma\gamma$ decay width is decreased by a factor of $\lesssim 3\%$ [312].

It is also possible to consider a simple description of models in which electroweak symmetry breaking is triggered by a light composite Higgs, which emerges from a strongly-interacting sector as a pseudo-Goldstone boson, by utilizing an effective low-energy Lagrangian approach [31]. Recent studies of the phenomenology relevant for collider searches can be found in Ref. 313.

The Higgs boson can also be a portal to hidden sectors, in particular, the Higgs boson can decay to the particles of a

low-mass hidden sector; these models are referred to as hidden valley models [314,315]. Since a light Higgs boson is a particle with a narrow width, even modest couplings to new states can give rise to a significant modification of Higgs phenomenology through exotic decays. Simple hidden valley models exist in which the Higgs boson decays to an invisible fundamental particle, which has a long lifetime to decay back to SM particles through small mixings with the SM Higgs boson; Ref. 315 describes an example. The Higgs boson may also decay to a pair of hidden valley “v-quarks,” which subsequently hadronize in the hidden sector, forming “v-mesons.” These mesons often prefer to decay to the heaviest state kinematically available, so that a possible signature is $h \rightarrow 4b$. Some of the v-mesons may be stable, implying a mixed missing energy plus heavy flavor final state. In other cases, the v-mesons may decay to leptons, implying the presence of low mass lepton resonances in high H_T events [316]. Other scenarios have been studied [317] in which Higgs bosons decay predominantly into light hidden sector particles, either directly, or through light SUSY states, and with subsequent cascades that increase the multiplicity of hidden sector particles. In such scenarios, the high multiplicity hidden sector particles, after decaying back into the Standard Model, appear in the detector as clusters of collimated leptons known as lepton jets.

If Higgs bosons are not discovered at the Tevatron or the LHC, other studies might be able to test alternative theories of dynamical electroweak symmetry breaking which do not involve a Higgs particle [318].

V. Searches for Higgs Bosons Beyond the MSSM

In extensions of the MSSM with one or more additional scalar singlets, limits have been set at e^+e^- and hadron colliders. The ALEPH [319] and DELPHI [320] collaborations place constraints on such models. Precise LEP 2 bounds on the Higgs boson masses depend on the couplings of the Higgs bosons to the gauge bosons and such couplings tend to be weakened somewhat from mixing with the singlet(s). At hadron colliders, searches for a light pseudoscalar boson predicted by the NMSSM have been performed by DØ [321], CDF [322], CMS [323], and ATLAS [324]. No significant excesses have been found and limits have been set on these models.

Most of the searches for the processes $e^+e^- \rightarrow hZ$ and hA , which have been discussed in the context of the CPC-MSSM, rely on the assumption that the Higgs bosons have a sizable branching ratio to $b\bar{b}$. However, for specific parameters of the MSSM [325], the general 2HDM case, or composite models [175,177,326], decays to non- $b\bar{b}$ final states may be significantly enhanced. Flavor-independent hadronically-decaying Higgs boson searches have been performed at LEP which do not require the experimental signature of a b -jet [327], and a preliminary combination of LEP data has been performed [34,328]. If Higgs bosons are produced at the SM rate and decay only to jets of hadrons, then the 95% C.L. lower limit on the mass of the Higgs boson is 112.9 GeV, independent of the fractions

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

of gluons and b , c , s , u and d -quarks in Higgs boson decay. In conjunction with b -flavor sensitive searches, large domains of the general Type-II 2HDM parameter space have been excluded [329].

In the Type-I 2HDM, if the CP -odd neutral Higgs boson A is light (which is not excluded in the general 2HDM case, nor in some extensions of the MSSM), the decay $H^\pm \rightarrow W^{\pm*}A$ may be dominant for masses accessible at LEP, a possibility that was investigated by DELPHI [330] and OPAL [331]. CDF's search for this decay chain in top quark decays [322] may also be interpreted in this scenario.

The LEP collaborations searched for Higgs bosons produced in pairs, in association with Z bosons, b quarks, and τ leptons. The decays considered are $\phi_{i,j} \rightarrow b\bar{b}, \tau^+\tau^-$, and $\phi_j \rightarrow \phi_i\phi_i$, when kinematically allowed, yielding four- b , four- b +jets, six- b and four- τ final states as well as mixed modes with b -quarks and tau leptons. No evidence for a Higgs boson was found [34,224], and mass-dependent coupling limits on a variety of processes, which apply to a large class of models were, set. The limits on the cross sections of Yukawa production of Higgs bosons are typically more than 100 times larger than the SM predictions [224]. Limits on pair-produced Higgs bosons extend up to $m_{\phi_i} + m_{\phi_j}$ in the range 140- 200 GeV for full-strength production, assuming $b\bar{b}$ and $\tau^+\tau^-$ decays. Limits on Higgs-strahlung production with subsequent decay of the Higgs into lighter Higgs pairs exclude Higgs masses of the Higgs produced in association with the Z up to 114 GeV, if the lighter Higgs bosons decay to $b\bar{b}$. Weaker limits are set if the lighter Higgs pair decays to four tau leptons, or to a mixture of tau leptons and b quarks [34].

Decays of Higgs bosons into invisible (weakly-interacting and neutral) particles may occur in many models⁶. For example, Higgs bosons might decay into pairs of Goldstone bosons or Majorons [332]. In the process $e^+e^- \rightarrow hZ$, the mass of the invisible Higgs boson can be inferred from the kinematics of the reconstructed Z boson by using the beam energy constraint. Results from the LEP experiments can be found in Refs. [219] and [333]. A preliminary combination of LEP data yields a 95% C.L. lower bound of 114.4 GeV for the mass of a Higgs boson, if it is produced with SM production rate, and if it decays exclusively into invisible final states [334].

OPAL's decay-mode independent search for $e^+e^- \rightarrow S^0Z$ [80] provides sensitivity to arbitrarily-decaying scalar particles, as only the recoiling Z boson decaying into leptons is required to be reconstructed. The energy and momentum constraints provided by the e^+e^- collisions allow the S^0 's four-vector to be reconstructed and limits placed on its production independent of its decay characteristics, allowing sensitivity for very light scalar masses. The limits obtained in this search are less than one-tenth of the SM Higgs-strahlung production rate for

⁶ As discussed above, in the MSSM the Higgs can decay into pairs of lightest, stable neutralinos.

1 keV < m_{S^0} < 19 GeV, and less than the SM Higgs-strahlung rate for m_{S^0} < 81 GeV.

Hidden-valley models predict a rich phenomenology of new particles, some of which can be long-lived and hadronize with SM particles to form exotic particles which decay at measurable distances in collider experiments. CDF and DØ have searched for pair-produced long-lived particles produced resonantly and which decay to $b\bar{b}$ pairs, and set limits on Higgs boson production in hidden-valley models [335,336]. The Higgs boson can also be the portal to high multiplicity hidden sector particles that may produce multiple charged leptons in the final state. A search for additional leptons in events containing a leptonically decaying W or Z boson by CDF [337] is sensitive to such models and others predicting multi-lepton final states; the results are consistent with SM expectations.

Photonic final states from the processes $e^+e^- \rightarrow Z/\gamma^* \rightarrow H\gamma$ and from $H \rightarrow \gamma\gamma$, could be significantly enhanced, over the SM loop induced effects, in models with anomalous couplings [338]. Searches for the processes $e^+e^- \rightarrow (H \rightarrow b\bar{b})\gamma$, $(H \rightarrow \gamma\gamma)q\bar{q}$, and $(H \rightarrow \gamma\gamma)\gamma$ have been used to set limits on such anomalous couplings [339]. These searches also contribute in the combinations of searches for the standard model Higgs boson, although the small predicted signal rates imply that they contribute less than other channels.

Searches with photonic final states are experimentally very appealing and they have been used to constrain fermiophobic Higgs models, in which the Higgs boson has SM-like properties except that its tree-level couplings to fermions are assumed to be absent or very small. Fermiophobic Higgs models are however quite challenging to construct; they are generally strongly fine-tuned and imply new strong dynamics at low energy scales. A Type-I fermiophobic 2HDM could predict an enhanced $h_f \rightarrow \gamma\gamma$ branching ratio, where h_f denotes a fermiophobic Higgs boson. The LEP searches are described in Ref. 340. In a preliminary combination of LEP data [341], a fermiophobic Higgs boson with mass less than 108.2 GeV (95% C.L.) has been excluded. Fermiophobic models would also predict enhanced branching ratios for the decays $h_f \rightarrow W^*W$ and Z^*Z , a possibility that has been addressed by L3 [342] and ALEPH [343]. At hadron colliders, the process $gg \rightarrow h_f$ has a negligible rate in a fermiophobic Higgs model, but the Wh_f , Zh_f , and VBF production cross sections remain close to their SM predictions and the Higgs boson branching ratios to $\gamma\gamma$, W^+W^- , and ZZ are enhanced. A search for the SM Higgs boson at a hadron collider can not therefore be re-interpreted as a search in a fermiophobic model, even if a limit is set on the total production cross section times a specific decay branching ratio, due to the different kinematic distributions from the different production modes affecting the signal acceptance. CDF and DØ have re-optimized their $h_f \rightarrow \gamma\gamma$ searches for the fermiophobic model, and with results based on 9.7 fb⁻¹ of DØ data [344,345] and 10.0 fb⁻¹ of CDF data [346,347], combined with $h_f \rightarrow W^+W^-$ and $h_f \rightarrow ZZ$ searches extend the exclusion in the fermiophobic Higgs model to 119 GeV [110,348]. Other

production of fermiophobic Higgs bosons, leading to a 3-photons final state, has also been searched for by $D\bar{O}$ [349].

ATLAS and CMS search for a fermiophobic Higgs boson in $h_f \rightarrow \gamma\gamma$ searches optimized for the fermiophobic signature [350,351], and CMS combines these with searches for $h_f \rightarrow W^+W^-$ and $h_f \rightarrow ZZ$ assuming fermiophobic production and decay [10]. CMS excludes a fermiophobic Higgs boson in the range $110 \text{ GeV} < m_H < 188 \text{ GeV}$ at the 95% C.L.

Higgs bosons with double electric charge are predicted, for example, by models with additional triplet scalar fields or left-right symmetric models [352]. It has been emphasized that the see-saw mechanism could lead to doubly-charged Higgs bosons with masses which are accessible to current and future colliders [353]. Searches were performed at LEP for the pair-production process $e^+e^- \rightarrow H^{++}H^{--}$ with four prompt leptons in the final state [354–356]. Lower mass bounds between 95 GeV and 100 GeV were obtained for left-right symmetric models (the exact limits depend on the lepton flavors). Doubly-charged Higgs bosons were also searched for in single production [357]. Furthermore, such particles would modify the Bhabha scattering cross section and forward-backward asymmetry via t -channel exchange. The absence of a significant deviation from the SM prediction puts constraints on the Yukawa coupling of $H^{\pm\pm}$ to electrons for Higgs boson masses which reach into the TeV range [356,357].

Searches have also been carried out at the Tevatron for the pair production process $p\bar{p} \rightarrow H^{++}H^{--}$. The $D\bar{O}$ search is performed in the $\mu^+\mu^+\mu^-\mu^-$ final state [358], while CDF also considers $e^+e^+e^-e^-$ and $e^+\mu^+e^-\mu^-$, and final states with τ leptons [359]. A search by CDF for a long-lived $H^{\pm\pm}$ boson, which would decay outside the detector, is described in [360].

CMS has searched for doubly-charged Higgs bosons which are either pair produced, $pp \rightarrow H^{++}H^{--}$ or produced in association with a singly-charged Higgs boson via s -channel W^\pm exchange, $pp \rightarrow H^{++}H^-$, assuming decays of the form $\ell^+\ell'^-$, where ℓ, ℓ' are combinations of $e, \mu,$ and τ leptons [361]. No significant excess is seen, and limits on the mass of the doubly-charged Higgs boson vary from 165 GeV to 457 GeV, depending on the production and decay mode. ATLAS has searched for doubly charged Higgs bosons in the dimuon decay [362], setting a limit on the mass of 355 GeV assuming a decay branching ratio to dimuons of 100% and coupling to left-handed fermions, and a limit on the mass of 251 GeV assuming coupling to right-handed fermions.

VI. Outlook

The Tevatron has completed its run and is finalizing its Higgs boson search results with up to 10 fb^{-1} of data analyzed. The combination of the preliminary results from CDF and $D\bar{O}$'s searches for the SM Higgs boson shows an excess of data events with respect to the background estimation in the mass range $115 \text{ GeV} < m_H < 135 \text{ GeV}$, dominated by the $H \rightarrow b\bar{b}$ channels. The global significance for such an excess anywhere in the full mass range is 2.2 standard deviations.

In 2011, the LHC delivered approximately 5 fb^{-1} of pp collision data at $\sqrt{s} = 7 \text{ TeV}$. A variety of searches targeting the SM Higgs boson in the mass range $100 \text{ GeV} < m_H < 600 \text{ GeV}$ have been performed, excluding all masses except the range between 114 GeV and 129 GeV. Most of the region below 123 GeV is also excluded by the ATLAS experiment but not by other experiments. Within the allowed mass range, both ATLAS and CMS observe independent excesses of events consistent with a SM-like Higgs boson with a mass of $\approx 125 \text{ GeV}$, with global significances of 1.3σ and 2.1σ , respectively. Both experiments observe excesses of data over the corresponding background predictions in searches for Higgs bosons decaying into diphotons and Z bosons pairs. More data, at $\sqrt{s} = 8 \text{ TeV}$, being collected in 2012, are required to understand this excess. The LHC will either exclude the SM Higgs boson or confirm the existence of a SM-like Higgs particle. In the latter case, accurate measurements of the properties of the Higgs particle as well as searches for new particles will be of most relevance.

Searches at the LHC for additional Higgs bosons: charged Higgs bosons, doubly charged Higgs bosons, the neutral Higgs bosons of the MSSM, and other exotic Higgs particles, have yielded results consistent with background expectations and strong limits have been placed in significant regions of parameter space. An upgrade of the center of mass energy to 13–14 TeV is planned for the near future. This upgrade will allow the LHC to explore a wide variety of extended Higgs sectors and search for new particles expected in models beyond the SM. This upgrade will also allow for increased precision of measurements of the properties of a SM-like Higgs boson, if one exists.

A high-energy e^+e^- linear collider may be built in the future, allowing ultimate high-precision measurements of the properties of Higgs boson(s) and other particles beyond those of the SM. At a $\mu^+\mu^-$ collider, mass measurements with a precision of a few MeV would be possible, and energy scans may distinguish between signals of Higgs particles nearly degenerate in mass, as predicted in many extended Higgs models.

In the theoretical landscape, numerous models are available with novel approaches to the problem of electroweak symmetry breaking. In the next decade, the LHC's exploration of the multi-TeV energy scale will solidify our understanding of the mechanism of mass generation of the known elementary particles.

VII. Addendum

Updated July 12, 2012.

On July 4, 2012, the ATLAS and CMS collaborations simultaneously announced observation of a new particle produced in pp collision data at high energies [363–366]. The data samples used correspond to between 4.6 and 5.1 fb^{-1} of collision data collected at $\sqrt{s} = 7 \text{ TeV}$ in 2011, and between 5.3 and 5.9 fb^{-1} of collisions collected at $\sqrt{s} = 8 \text{ TeV}$ in 2012. The observed decay modes indicate that the new particle is a boson. The evidence is strong that the new particle decays to $\gamma\gamma$ and ZZ with rates consistent with those predicted for the Standard

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

Model (SM) Higgs boson. There are indications that the new particle might also decay to W^+W^- , and decays to $b\bar{b}$ and $\tau^+\tau^-$ are being sought as well.

The ATLAS collaboration has updated its SM Higgs boson searches in the $H \rightarrow \gamma\gamma$ and $H \rightarrow ZZ \rightarrow \ell^+\ell^-\ell'^+\ell'^-$ [367] modes with new data collected at $\sqrt{s} = 8$ TeV and improved analysis techniques applied to both the 7 TeV and 8 TeV data. ATLAS has also finalized its $\sqrt{s} = 7$ TeV analyses in the $H \rightarrow ZZ \rightarrow \ell^+\ell^-\nu\bar{\nu}$, $H \rightarrow ZZ \rightarrow \ell^+\ell^-q\bar{q}$, $H \rightarrow W^+W^- \rightarrow \ell^+\nu_\ell\ell'^-\bar{\nu}_{\ell'}$, $H \rightarrow W^+W^- \rightarrow \ell^+\nu_\ell q\bar{q}'$, $H \rightarrow \tau^+\tau^-$, and $WH, ZH \rightarrow Wb\bar{b}, Zb\bar{b}$ channels [368], and includes them in its SM Higgs boson combined results [369,364]. ATLAS's $H \rightarrow \gamma\gamma$ search has been improved with respect to the previous version by separating events with two jets and two photons from other events, which improves the sensitivity for the vector boson fusion (VBF) process, and by improved photon identification and isolation algorithms. ATLAS's $H \rightarrow ZZ \rightarrow \ell^+\ell^-\ell'^+\ell'^-$ search has been improved with respect to the previous results by re-optimizing the kinematic cuts, improving electron reconstruction and identification efficiency at low p_T , and improved robustness to pileup events.

The CMS collaboration has updated its SM Higgs boson searches in the $H \rightarrow \gamma\gamma$, $H \rightarrow ZZ \rightarrow \ell^+\ell^-\ell'^+\ell'^-$, $H \rightarrow ZZ \rightarrow \ell^+\ell^-\nu\bar{\nu}$, $H \rightarrow W^+W^- \rightarrow \ell^+\nu_\ell\ell'^-\bar{\nu}_{\ell'}$, $H \rightarrow b\bar{b}$, and $H \rightarrow \tau^+\tau^-$ channels, all of which include 8 TeV data collected in 2012 [370]. The $t\bar{t}H \rightarrow t\bar{t}b\bar{b}$ [370] search is new and based on 2011 data. The $H \rightarrow W^+W^- \rightarrow \ell^+\nu_\ell q\bar{q}'$ [370] search is included for the first time in the combination.

CMS's $H \rightarrow \gamma\gamma$ search has been improved with respect to its earlier version by dividing the diphoton plus two jet category into two, depending on the dijet invariant mass and the jet p_T , and also by removing jets from pileup collisions. The $H \rightarrow ZZ \rightarrow \ell^+\ell^-\ell'^+\ell'^-$ search has been improved with respect to its previous version, benefiting from improved lepton identification and isolation algorithms, as well as final state radiation recovery. The discriminant variables used now to separate the expected signal from the backgrounds are two-dimensional, plotting the invariant mass of the four leptons versus a matrix-element-based likelihood discriminant. CMS's $H \rightarrow W^+W^-$ search combines the results from the multivariate analysis (MVA) for the 7 TeV data with the results of a cut-based analysis on the 8 TeV data sample, which is described in Ref. 372. CMS's $VH \rightarrow Vb\bar{b}$ (with $V = W$ or Z) search encompasses five channels: $WH \rightarrow e\nu b\bar{b}$, $WH \rightarrow \mu\nu b\bar{b}$, $ZH \rightarrow e^+e^-b\bar{b}$, $ZH \rightarrow \mu^+\mu^-b\bar{b}$, and $ZH \rightarrow \nu\bar{\nu}b\bar{b}$. CMS's $H \rightarrow \tau^+\tau^-$ search divides the candidate events by tau lepton decay type and subdivides the samples based on number of jets (0,1) or on VBF type. The 0 and 1 jet categories are also further subdivided according to low or high p_T of the τ .

Each experiment, ATLAS and CMS, separately combine their data to obtain independent results of their searches, computing the significance of the observation, measuring the production rates times the decay branching fractions for each

Figure 17: Local p -values for the ATLAS SM Higgs boson search (left), and the CMS SM Higgs boson search (right), separately for each decay mode. The solid lines show the observed p -values and the dashed lines show the median expected p -values, assuming a SM Higgs boson is present, computed at each value of m_H separately.

channel analyzed, and updating the mass and rate exclusions [364,366]. The separate results provide independent confirmations of the observation. The significance is quantified by a p -value, which is the probability to observe an upward fluctuation of the background which gives a result at least as signal-like as that observed in the data. A p -value of 2.87×10^{-7} corresponds to a five standard deviation excess over the background prediction. The p -values are shown for the analysis channels separately for ATLAS and CMS in Fig. 17. ATLAS observes an excess with a local significance of 5.0σ at a mass $m_H = 126.5$ GeV, with an expected significance of 4.6σ if a SM Higgs boson were present at such mass value. CMS observes

See key on page 457

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

an excess with a local significance of 4.9σ at a mass 125.5 GeV, with an expected significance of 5.9σ , and measures the mass of the new boson as $m_H = 125.3 \pm 0.6$ GeV. Fig. 18 shows the best-fit cross sections times the relevant decay branching fractions for the new particle, normalized to the SM predictions for Higgs boson production and decay, assuming it has a mass of 126.5 GeV (ATLAS), and 125 GeV (CMS). ATLAS's combined signal strength fit, assuming SM ratios for the production and decay modes, is $\mu = \sigma/\sigma_{\text{SMH}} = 1.2 \pm 0.3$, and CMS's combined fit is $\mu = 0.80 \pm 0.22$. Within the current experimental uncertainties, the measurements are consistent with SM predictions. Both ATLAS and CMS separately exclude SM Higgs bosons with masses outside a narrow range near the local excesses.

The Tevatron collaborations updated their Higgs boson search results on July 2, 2012 [373]. The D0 collaboration has updated its $VH \rightarrow Vb\bar{b}$ search results by improving the acceptance of the lepton selection, dividing the events into more categories based on the number and quality of b tags, and improving the MVA treatment [374]. Additional data and analysis improvements also improve the sensitivity of D0's $H \rightarrow W^+W^-$ searches by 5-10% with respect to the previous result [375]. The CDF Higgs boson searches were updated with the full Run II data set and improved b -tagging for the Winter 2012 conferences [376]. CDF and D0 combine their results together, and, with the full suite of SM Higgs boson search analyses, see a broad excess in the range $115 \text{ GeV} < m_H < 135 \text{ GeV}$, with a global signal significance of 2.5σ , and a maximum local significance of 3.0σ . Fig. 19 shows the measured cross sections times the relevant decay branching ratios normalized to those expected for a SM Higgs boson at mass $m_H = 125$ GeV for the combined CDF and D0 searches for $H \rightarrow W^+W^-$, $H \rightarrow \gamma\gamma$, and $VH \rightarrow Vb\bar{b}$ searches. The combined result, assuming SM ratios for the production and decay modes, is $\mu = 1.4 \pm 0.6$. In the dominant decay channel, $VH \rightarrow Vb\bar{b}$, the global significance is 2.9σ , with a maximum local significance of 3.2σ . Assuming the existence of a new particle, this provides the first strong indication for its decay into a fermion pair at a rate consistent with the SM prediction for a Higgs boson of such a mass.

In summary, a new particle has been observed at the LHC. Within the experimental uncertainties, it has characteristics consistent with those expected from the Higgs boson predicted by the Standard Model, with a mass near 125 GeV. Tevatron data also are consistent with the production and decay of a SM-like Higgs boson at this mass. However, the present experimental uncertainties still allow for a wide variety of new physics alternatives.

The LHC will continue to run until early 2013, and it is expected to deliver at least 15 fb^{-1} more data to both ATLAS and CMS, at $\sqrt{s} = 8 \text{ TeV}$. After this run, a shutdown will occur to improve the accelerator components to allow data taking at higher energies. The much larger dataset to be collected will provide the opportunity to make increasingly precise measurements of the properties of the new particle, and

Figure 18: Best-fit production cross sections times branching ratios to $H \rightarrow \gamma\gamma$, $H \rightarrow ZZ$, $H \rightarrow W^+W^-$, $H \rightarrow b\bar{b}$, and $H \rightarrow \tau^+\tau^-$, normalized to the SM predictions for Higgs boson production and decay, assuming it has a mass of 126.5 GeV (ATLAS, left), and 125 GeV (CMS, right). The combined result, assuming SM ratios for the production and decay modes, is shown as a separate point on the ATLAS graph at $\mu = \sigma/\sigma_{\text{SMH}} = 1.2 \pm 0.3$ and is shown with the shaded band on the CMS graph at $\mu = 0.80 \pm 0.22$.

test whether it is the SM Higgs boson or point the way to physics beyond the SM.

STANDARD MODEL H^0 (Higgs Boson) MASS LIMITS

These limits apply to the Higgs boson of the three-generation Standard Model with the minimal Higgs sector. For a review and a bibliography, see the above review on “Higgs Bosons: Theory and Searches,” where the latest unpublished results are also described.

Note: the addendum to the Higgs boson review describes the latest news reported in July 2012 on the discovery of a boson whose properties are consistent with the Standard Model Higgs boson.

 H^0 Direct Search Limits

All data that have been superseded by newer results are marked as “not used” or have been removed from this compilation, and are documented in previous editions of this Review of Particle Physics.

¹AAD 12E combine data from AAD 11V, AAD 11AB, AAD 12, AAD 12D, AAD 12F, AAD 12G. The 99% CL exclusion range is 133–230 and 260–437 GeV. An excess of events over background with a local significance of 3.5 σ is observed at about $m_{H^0} = 126$ GeV.

²CHATRCHYAN 12B combine CHATRCHYAN 12E, CHATRCHYAN 12F, CHATRCHYAN 12G, CHATRCHYAN 12H, CHATRCHYAN 12I, CHATRCHYAN 12C, CHATRCHYAN 12D, as well as a search in the decay mode $H^0 \rightarrow \tau\tau$. The 99% CL exclusion range is 129–525 GeV. An excess of events over background with a local significance of 3.1 σ is observed at about $m_{H^0} = 124$ GeV.

³AALTONEN 10F combine searches for H^0 decaying to $W^+ W^-$ in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV with 4.8 fb⁻¹ (CDF) and 5.4 fb⁻¹ (D0).

⁴Search for $e^+ e^- \rightarrow H^0 Z$ at $E_{cm} \leq 209$ GeV in the final states $H^0 \rightarrow b\bar{b}$ with $Z \rightarrow \ell\bar{\ell}, \nu\bar{\nu}, q\bar{q}, \tau^+ \tau^-$ and $H^0 \rightarrow \tau^+ \tau^-$ with $Z \rightarrow q\bar{q}$.

⁵Combination of the results of all LEP experiments.

⁶A 3 σ excess of candidate events compatible with m_{H^0} near 114 GeV is observed in the combined channels $q\bar{q}q\bar{q}, q\bar{q}\ell\bar{\ell}, q\bar{q}\tau^+\tau^-$.

⁷AAD 12 search for H^0 production with $H \rightarrow ZZ \rightarrow \ell^+ \ell^- q\bar{q}$ in 1.04 fb⁻¹ of pp collisions at $E_{cm} = 7$ TeV. A limit on cross section times branching ratio which is (1.7–13) times larger than the expected Standard Model cross section is given for $m_{H^0} = 200$ –600 GeV at 95% CL. The best limit is at $m_{H^0} = 360$ GeV.

⁸AAD 12b search for H^0 production with $H \rightarrow ZZ^{(*)} \rightarrow 4\ell$ in 4.8 fb⁻¹ of pp collisions at $E_{cm} = 7$ TeV in the mass range $m_{H^0} = 110$ –600 GeV. An excess of events over background with a local significance of 2.1 σ is observed at 125 GeV.

⁹AAD 12f search for H^0 production with $H \rightarrow WW^{(*)} \rightarrow \ell^+ \nu \ell^- \bar{\nu}$ in 2.05 fb⁻¹ of pp collisions at $E_{cm} = 7$ TeV in the mass range $m_{H^0} = 110$ –300 GeV.

¹⁰AAD 12g search for H^0 production with $H \rightarrow \gamma\gamma$ in 4.9 fb⁻¹ of pp collisions at $E_{cm} = 7$ TeV in the mass range $m_{H^0} = 110$ –150 GeV. An excess of events over background with a local significance of 2.8 σ is observed at 126.5 GeV.

¹¹AALTONEN 12 search for $H^0 \rightarrow \gamma\gamma$ in 7.0 fb⁻¹ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. A limit on cross section times branching ratio which is (8.5–29) times larger than the expected Standard Model cross section is given for $m_{H^0} = 100$ –150 GeV at 95% CL.

¹²CHATRCHYAN 12c search for H^0 production with $H \rightarrow ZZ \rightarrow \ell^+ \ell^- \tau^+ \tau^-$ in 4.7 fb⁻¹ of pp collisions at $E_{cm} = 7$ TeV. A limit on cross section times branching ratio which is (4–12) times larger than the expected Standard Model cross section is given for $m_{H^0} = 190$ –600 GeV at 95% CL. The best limit is at $m_{H^0} = 200$ GeV.

¹³CHATRCHYAN 12d search for H^0 production with $H \rightarrow ZZ^{(*)} \rightarrow \ell^+ \ell^- q\bar{q}$ in 4.6 fb⁻¹ of pp collisions at $E_{cm} = 7$ TeV. A limit on cross section times branching ratio which corresponds to (1–22) times the expected Standard Model cross section is given for $m_{H^0} = 130$ –164 GeV, 200–600 GeV at 95% CL. The best limit is at $m_{H^0} = 230$ GeV. In the Standard Model with an additional generation of heavy quarks and leptons which receive their masses via the Higgs mechanism, m_{H^0} values in the ranges $m_{H^0} = 154$ –161 GeV and 200–470 GeV are excluded at 95% CL.

¹⁴CHATRCHYAN 12e search for H^0 production with $H \rightarrow WW^{(*)} \rightarrow \ell^+ \nu \ell^- \bar{\nu}$ in 4.6 fb⁻¹ of pp collisions at $E_{cm} = 7$ TeV in the mass range $m_{H^0} = 110$ –600 GeV.

¹⁵CHATRCHYAN 12f search for associated $H^0 W$ and $H^0 Z$ production followed by $W \rightarrow \ell\nu, Z \rightarrow \ell^+ \ell^-, \nu\bar{\nu},$ and $H^0 \rightarrow b\bar{b}$, in 4.7 fb⁻¹ of pp collisions at $E_{cm} = 7$ TeV. A limit on cross section times branching ratio which is (3.1–9.0) times larger than the expected Standard Model cross section is given for $m_{H^0} = 110$ –135 GeV at 95% CL. The best limit is at $m_{H^0} = 110$ GeV.

¹⁶CHATRCHYAN 12g search for H^0 production with $H \rightarrow \gamma\gamma$ in 4.8 fb⁻¹ of pp collisions at $E_{cm} = 7$ TeV in the mass range $m_{H^0} = 110$ –150 GeV. An excess of events over background with a local significance of 3.1 σ is observed at 124 GeV.

See key on page 457

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

- 17 CHATRCHYAN 12H search for H^0 production with $H \rightarrow ZZ^*(*) \rightarrow 4\ell$ in 4.7 fb $^{-1}$ of pp collisions at $E_{cm} = 7$ TeV in the mass range $m_{H^0} = 110$ –600 GeV. Excesses of events over background are observed around 119, 126 and 320 GeV. The region $m_{H^0} = 114.4$ –134 GeV remains consistent with the expectation for the production of a SM-like Higgs boson.
- 18 CHATRCHYAN 2012I search for H^0 production with $H \rightarrow ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$ in 4.6 fb $^{-1}$ of pp collisions at $E_{cm} = 7$ TeV in the mass range $m_{H^0} = 250$ –600 GeV.
- 19 AAD 11AB search for H^0 production with $H \rightarrow W^+ W^- \rightarrow \ell \nu q \bar{q}$ in 1.04 fb $^{-1}$ of pp collisions at $E_{cm} = 7$ TeV. A limit on cross section times branching ratio which is (2.7–20) times larger than the expected Standard Model cross section is given for $m_{H^0} = 240$ –600 GeV at 95% CL. The best limit is at $m_{H^0} = 400$ GeV.
- 20 AAD 11T search for H^0 production with $H \rightarrow ZZ^*(*) \rightarrow 4\ell$ in 2.1 fb $^{-1}$ of pp collisions at $E_{cm} = 7$ TeV. A limit on cross section times branching ratio which corresponds to (0.8–12) times the expected Standard Model cross section is given for $m_{H^0} = 120$ –600 GeV at 95% CL. Superseded by AAD 12b.
- 21 AAD 11U search for H^0 production with $H^0 \rightarrow \gamma\gamma$ in 1.08 fb $^{-1}$ of pp collisions at $E_{cm} = 7$ TeV. A limit on cross section times branching ratio which is (2.0–5.8) times larger than the expected Standard Model cross section is given for $m_{H^0} = 110$ –150 GeV at 95% CL. Superseded by AAD 12c.
- 22 AAD 11V search for H^0 production with $H \rightarrow ZZ \rightarrow \ell^+ \ell^- \nu \bar{\nu}$ in 1.04 fb $^{-1}$ of pp collisions at $E_{cm} = 7$ TeV. A limit on cross section times branching ratio which corresponds to (0.6–6) times the expected Standard Model cross section is given for $m_{H^0} = 200$ –600 GeV at 95% CL.
- 23 AAD 11W search for Higgs boson production in the decay channels $\gamma\gamma$, $ZZ^*(*) \rightarrow 4\ell$, $ZZ \rightarrow \ell\ell\nu\nu$, $ZZ \rightarrow \ell\ell q\bar{q}$, $WW^*(*) \rightarrow \ell\ell\nu\nu$, $WW^*(*) \rightarrow \ell\nu q\bar{q}$ in 35–40 pb $^{-1}$ of pp collisions at $E_{cm} = 7$ TeV. A limit on cross section times branching ratio which is (2–40) times larger than the expected Standard Model cross section is given for $m_{H^0} = 110$ –600 GeV at 95% CL. In the Standard Model with an additional generation of heavy quarks and leptons which receive their masses via the Higgs mechanism, m_{H^0} values between 140 and 185 GeV are excluded at 95% CL. The results for the Standard Model Higgs are superseded by AAD 12e.
- 24 AALTONEN 11AA search in 4.0 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV for associated $H^0 W$ and $H^0 Z$ production followed by $W/Z \rightarrow q\bar{q}$, and for $p\bar{p} \rightarrow H^0 q\bar{q} X$ (vector boson fusion), both with $H^0 \rightarrow b\bar{b}$. A limit on cross section times branching ratio which is (9–100) times larger than the expected Standard Model cross section is given for $m_{H^0} = 100$ –150 GeV at 95% CL. The best limit is at $m_{H^0} = 115$ GeV.
- 25 ABAZOV 11AB search for associated $H^0 W$ and $H^0 Z$ production followed by $H^0 \rightarrow WW^*(*)$ in like-sign dilepton final states using 5.3 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. A limit on cross section times branching ratio which is (6.4–18) times larger than the expected Standard Model cross section is given for $m_{H^0} = 115$ –200 GeV at 95% CL. The best limit is for $m_{H^0} = 135$ and 165 GeV.
- 26 ABAZOV 11c search for H^0 production in 5.4 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow WW^*(*) \rightarrow \ell\nu q\bar{q}$ (and processes with similar final states). A limit on cross section times branching ratio which is (3.9–37) times larger than the expected Standard Model cross section is given for $m_{H^0} = 115$ –200 GeV at 95% CL. The best limit is at $m_{H^0} = 160$ GeV.
- 27 ABAZOV 11j search for associated $H^0 W$ production in 5.3 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the final state $H^0 \rightarrow b\bar{b}$, $W \rightarrow \ell\nu$. A limit on cross section times branching ratio which is (2.7–30) times larger than the expected Standard Model cross section is given for $m_{H^0} = 100$ –150 GeV at 95% CL. The limit at $m_{H^0} = 115$ GeV is 4.5 times larger than the expected Standard Model cross section.
- 28 ABAZOV 11y search for $H^0 \rightarrow \gamma\gamma$ in 8.2 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. A limit on cross section times branching ratio which is (10–25) times larger than the expected Standard Model cross section is given for $m_{H^0} = 100$ –150 GeV at 95% CL.
- 29 CHATRCHYAN 11J search for H^0 production with $H \rightarrow W^+ W^- \rightarrow \ell\ell\nu\nu$ in 36 pb $^{-1}$ of pp collisions at $E_{cm} = 7$ TeV. See their Fig. 6 for a limit on cross section times branching ratio for $m_{H^0} = 120$ –600 GeV at 95% CL. In the Standard Model with an additional generation of heavy quarks and leptons which receive their masses via the Higgs mechanism, m_{H^0} values between 144 and 207 GeV are excluded at 95% CL.
- 30 AALTONEN 10AD search for associated $H^0 Z$ production in 4.1 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $Z \rightarrow \ell^+ \ell^-$. A limit $\sigma \cdot B(H^0 \rightarrow b\bar{b}) < (4.5\text{--}43) \sigma \cdot B_{SM}$ (95% CL) is given for $m_{H^0} = 100$ –150 GeV. The limit for $m_{H^0} = 115$ GeV is 5.9 times larger than the expected Standard Model cross section.
- 31 AALTONEN 10G search for H^0 production in 4.8 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow WW^*(*)$. A limit on $\sigma(H^0)$ which is (1.3–39) times larger than the expected Standard Model cross section is given for $m_{H^0} = 110$ –200 GeV at 95% CL. The best limit is obtained for $m_{H^0} = 165$ GeV.
- 32 AALTONEN 10J search for associated $H^0 W$ and $H^0 Z$ production in 2.1 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the final state with (b) jets and missing p_T . A limit $\sigma < (5.8\text{--}50) \sigma_{SM}$ (95% CL) is given for $m_{H^0} = 110$ –150 GeV. The limit for $m_{H^0} = 115$ GeV is 6.9 times larger than the expected Standard Model cross section.
- 33 AALTONEN 10M combine searches for H^0 decaying to $W^+ W^-$ in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV with 4.8 fb $^{-1}$ (CDF) and 5.4 fb $^{-1}$ (DØ) and derive limits $\sigma(p\bar{p} \rightarrow H^0) \cdot B(H^0 \rightarrow W^+ W^-) < (1.75\text{--}0.38)$ pb for $m_H = 120$ –165 GeV, where H^0 is produced in gg fusion. In the Standard Model with an additional generation of heavy quarks, m_{H^0} between 131 and 204 GeV is excluded at 95% CL.
- 34 ABAZOV 10B search for H^0 production in 5.4 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow WW^*(*)$. A limit on $\sigma(H^0)$ which is (1.6–21) times larger than the expected Standard Model cross section is given for $m_{H^0} = 115$ –200 GeV at 95% CL. The best limit is obtained for $m_{H^0} = 165$ GeV.
- 35 ABAZOV 10C search for associated $H^0 Z$ and $H^0 W$ production in 5.2 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the final states $H^0 \rightarrow b\bar{b}$, $Z \rightarrow \nu\bar{\nu}$, and $W \rightarrow (\ell)\nu$, where ℓ is not identified. A limit $\sigma \cdot B(H^0 \rightarrow b\bar{b}) < (3.4\text{--}38) \sigma \cdot B_{SM}$ (95% CL) is given for $m_{H^0} = 100$ –150 GeV. The limit for $m_{H^0} = 115$ GeV is 3.7 times larger than the expected Standard Model cross section.
- 36 ABAZOV 10T search for associated $H^0 Z$ production in 4.2 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $Z \rightarrow \ell^+ \ell^-$. A limit $\sigma \cdot B(H^0 \rightarrow b\bar{b}) < (3.0\text{--}49) \sigma \cdot B_{SM}$ (95% CL) is given for $m_{H^0} = 100$ –150 GeV. The limit for $m_{H^0} = 115$ GeV is 5.9 times larger than the expected Standard Model cross section.
- 37 AALTONEN 09A search for H^0 production in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow WW^*(*) \rightarrow \ell^+ \ell^- \nu \bar{\nu}$. A limit on $\sigma(H^0) \cdot B(H^0 \rightarrow WW^*(*))$ between 0.7 and 2.5 pb (95% CL) is given for $m_{H^0} = 110$ –200 GeV, which is 1.7–4.5 times larger than the expected Standard Model cross section. The best limit is obtained for $m_{H^0} = 160$ GeV.
- 38 AALTONEN 09AG search for associated $H^0 W$ production in 1.9 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $W \rightarrow \ell\nu$. A limit on $\sigma(H^0 W) \cdot B(H^0 \rightarrow b\bar{b})$ (95% CL) is given for $m_{H^0} = 110$ –150 GeV, which is 7.5–101.9 times larger than the expected Standard Model cross section. The limit for $m_{H^0} = 115$ GeV is 9.0 times larger than the expected Standard Model cross section. Superseded by AALTONEN 09AI.
- 39 AALTONEN 09AI search for associated $H^0 W$ production in 2.7 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $W \rightarrow \ell\nu$. A limit on $\sigma(H^0 W) \cdot B(H^0 \rightarrow b\bar{b})$ (95% CL) is given for $m_{H^0} = 100$ –150 GeV, which is 3.3–75.5 times larger than the expected Standard Model cross section. The limit for $m_{H^0} = 115$ GeV is 5.6 times larger than the expected Standard Model cross section.
- 40 AALTONEN 09AO search for associated $H^0 Z$ production in 2.7 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $Z \rightarrow \ell^+ \ell^-$. A limit on $\sigma(H^0 Z) \cdot B(H^0 \rightarrow b\bar{b})$ (95% CL) is given for $m_{H^0} = 100$ –150 GeV, which is 7.0–71.3 times larger than the expected Standard Model cross section. The limit for $m_{H^0} = 115$ GeV is 8.2 times larger than the expected Standard Model cross section. Superseded by AALTONEN 10AD.
- 41 AALTONEN 09AS search for associated $H^0 W$ and $H^0 Z$ production in 2.0 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $W/Z \rightarrow q\bar{q}$. A limit (95% CL) is given for $m_{H^0} = 100$ –150 GeV, which is 29.4–263 times larger than the expected Standard Model cross section. The limit for $m_{H^0} = 120$ GeV is 37.5 times larger than the expected Standard Model cross section. Superseded by AALTONEN 11AA.
- 42 ABAZOV 09c search for associated $H^0 W$ production in 1 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $W \rightarrow \ell\nu$. A limit $\sigma(H^0 W) \cdot B(H^0 \rightarrow b\bar{b}) < (2.1\text{--}0.95)$ pb (95% CL) is given for $m_{H^0} = 100$ –150 GeV, which is 9.1–84 times larger than the expected Standard Model cross section. Superseded by ABAZOV 11I.
- 43 ABAZOV 09g search for $H^0 \rightarrow \gamma\gamma$ in 2.7 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the mass range $m_{H^0} = 100$ –150 GeV. A limit (95% CL) is given for $m_{H^0} = 115$ –130 GeV, which is about 20 times larger than the expected Standard Model cross section. Superseded by ABAZOV 11Y.
- 44 ABAZOV 09u search for $H^0 \rightarrow \tau^+ \tau^-$ with $\tau \rightarrow$ hadrons in 1 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. The production mechanisms include associated $W/Z+H^0$ production, weak boson fusion, and gluon fusion. A limit (95% CL) is given for $m_{H^0} = 105$ –145 GeV, which is 20–82 times larger than the expected Standard Model cross section. The limit for $m_{H^0} = 115$ GeV is 29 times larger than the expected Standard Model cross section.
- 45 AALTONEN 08x search for associated $H^0 Z$ and $H^0 W$ production in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $Z \rightarrow \nu\bar{\nu}$ and $W \rightarrow (\ell)\nu$, where ℓ is not detected. A limit $\sigma \cdot B(H^0 \rightarrow b\bar{b}) < (4.7\text{--}3.3)$ pb (95% CL) is given for $m_{H^0} = 110$ –140 GeV, which is 18–66 times larger than the expected Standard Model cross section. Superseded by AALTONEN 10J.
- 46 ABAZOV 08a search for associated $H^0 Z$ and $H^0 W$ production in 0.9 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $Z \rightarrow \nu\bar{\nu}$ and $W \rightarrow (\ell)\nu$, where ℓ is not detected. A limit $\sigma \cdot B(H^0 \rightarrow b\bar{b}) < (2.6\text{--}2.3)$ pb (95% CL) is given for $m_{H^0} = 105$ –135 GeV, which is 8.7–34 times larger than the expected Standard Model cross section. Superseded by ABAZOV 10c.
- 47 ABAZOV 08y search for associated $H^0 W$ production in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the decay mode $H^0 \rightarrow b\bar{b}$, $W \rightarrow \ell\nu$. A limit $\sigma(H^0 W) \cdot B(H^0 \rightarrow b\bar{b}) < (1.9\text{--}1.6)$ pb (95% CL) is given for $m_{H^0} = 105$ –145 GeV, which is 10–93 times larger than the expected Standard Model cross section. These results are combined with ABAZOV 06, ABAZOV 06a, ABAZOV 06b, and ABAZOV 07x to give cross section limits for $m_{H^0} = 100$ –200 GeV which are 6–24 times larger than the Standard Model expectation.
- 48 ABAZOV 07x search for associated $H^0 Z$ production in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the final state $Z \rightarrow e^+ e^-$ or $\mu^+ \mu^-$; $H^0 \rightarrow b\bar{b}$. A limit $\sigma(ZH^0) \cdot B(H^0 \rightarrow b\bar{b}) < (4.4\text{--}3.1)$ pb (95% CL) is given for $m_{H^0} = 105$ –145 GeV, which is more than 40 times larger than the expected Standard Model cross section. Superseded by ABAZOV 10T.
- 49 ABAZOV 06 search for Higgs boson production in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV with the decay chain $H^0 \rightarrow WW^* \rightarrow \ell^\pm \ell^\mp \nu \bar{\nu}$. A limit $\sigma(H^0) \cdot B(H^0 \rightarrow WW^*) < (5.6\text{--}3.2)$ pb (95% CL) is given for $m_{H^0} = 120$ –200 GeV, which far exceeds the expected Standard Model cross section.
- 50 ABAZOV 06a search for associated $H^0 W$ production in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV with the decay $H^0 \rightarrow WW^*$, in the final states $\ell^\pm \ell^\mp \nu \bar{\nu} X$ where $\ell = e, \mu$. A limit $\sigma(H^0 W) \cdot B(H^0 \rightarrow WW^*) < (3.2\text{--}2.8)$ pb (95% CL) is given for $m_{H^0} = 115$ –175 GeV, which far exceeds the expected Standard Model cross section.

 H^0 Indirect Mass Limits from Electroweak Analysis

For limits obtained before the direct measurement of the top quark mass, see the 1996 (Physical Review **D54** 1 (1996)) Edition of this Review. Other studies based on data available prior to 1996 can be found in the 1998 Edition (The European Physical Journal **C3** 1 (1998)) of this Review. For indirect limits obtained from other considerations of theoretical nature, see the Note on “Searches for Higgs Bosons.”

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

- ⁵¹ ERLER 10a makes Standard Model fits to Z and neutral current parameters, m_t , m_W measurements available in 2009 (using also preliminary data). The quoted result is obtained from a fit that does not include the limits from the direct Higgs searches. With direct search data from LEP2 and Tevatron added to the fit, the 90% CL (99% CL) interval is 115–148 (114–197) GeV.
- ⁵² FLACHER 09 make Standard Model fits to Z and neutral current parameters, m_t , m_W , and Γ_W measurements available in 2008 (using also preliminary data). The 2σ (3σ) interval is 39–155 (26–209) GeV. The quoted results are obtained from a fit that does not include the limit from the direct Higgs searches.
- ⁵³ LEP-SLC 06 make Standard Model fits to Z parameters from LEP/SLC and m_t , m_W , and Γ_W measurements available in 2005 with $\Delta\alpha_{\text{had}}^{(5)}(m_Z) = 0.02758 \pm 0.00035$. The 95% CL limit is 285 GeV.

MASS LIMITS FOR NEUTRAL HIGGS BOSONS IN SUPERSYMMETRIC MODELS

The minimal supersymmetric model has two complex doublets of Higgs bosons. The resulting physical states are two scalars [H_1^0 and H_2^0], where we define $m_{H_1^0} < m_{H_2^0}$, a pseudoscalar (A^0), and a charged Higgs pair (H^\pm). H_1^0 and H_2^0 are also called h and H in the literature. There are two free parameters in the theory which can be chosen to be m_{A^0} and $\tan\beta = v_2/v_1$, the ratio of vacuum expectation values of the two Higgs doublets. Tree-level Higgs masses are constrained by the model to be $m_{H_1^0} \leq m_Z$, $m_{H_2^0} \geq m_Z$, $m_{A^0} \geq m_{H_1^0}$, and $m_{H^\pm} \geq m_W$. However, as described in the review on “Searches for Higgs Bosons” in this Volume these relations are violated by radiative corrections.

Unless otherwise noted, the experiments in e^+e^- collisions search for the processes $e^+e^- \rightarrow H_1^0 Z^0$ in the channels used for the Standard Model Higgs searches and $e^+e^- \rightarrow H_1^0 A^0$ in the final states $b\bar{b}b\bar{b}$ and $b\bar{b}\tau^+\tau^-$. In $p\bar{p}$ collisions the experiments search for a variety of processes, as explicitly specified for each entry. Limits on the A^0 mass arise from these direct searches, as well as from the relations valid in the minimal supersymmetric model between m_{A^0} and $m_{H_1^0}$. As discussed in the review on “Searches for Higgs Bosons” in this Volume, these relations depend, via potentially large radiative corrections, on the mass of the t quark and on the supersymmetric parameters, in particular those of the stop sector. The limits are weaker for larger t and \tilde{t} masses. To include the radiative corrections to the Higgs masses, unless otherwise stated, the listed papers use theoretical predictions incorporating two-loop corrections and examine the two scenarios of no scalar top mixing and the m_h^{max} benchmark scenario (which gives rise to the most conservative upper bound on the mass of H_1^0 for given values of m_{A^0} and $\tan\beta$), see CARENA 99b and CARENA 03.

Limits in the low-mass region of H_1^0 , as well as other by now obsolete limits from different techniques, have been removed from this compilation, and can be found in earlier editions of this Review. Unless otherwise stated, the following results assume no invisible H_1^0 or A^0 decays.

- ⁵⁴ ABDALLAH 08B give limits in eight CP -conserving benchmark scenarios and some CP -violating scenarios. See paper for excluded regions for each scenario. Supersedes ABDALLAH 04.
- ⁵⁵ SCHAEEL 06B make a combined analysis of the LEP data. The quoted limit is for the m_h^{max} scenario with $m_t = 174.3$ GeV. In the CP -violating CPX scenario no lower bound on $m_{H_1^0}$ can be set at 95% CL. See paper for excluded regions in various scenarios. See Figs. 2–6 and Tabs. 14–21 for limits on $\sigma(ZH^0) \cdot B(H^0 \rightarrow b\bar{b}, \tau^+\tau^-)$ and $\sigma(H_1^0 H_2^0) \cdot B(H_1^0 H_2^0 \rightarrow b\bar{b}, \tau^+\tau^-)$.
- ⁵⁶ Search for $e^+e^- \rightarrow H_1^0 A^0$ in the final states $b\bar{b}b\bar{b}$ and $b\bar{b}\tau^+\tau^-$, and $e^+e^- \rightarrow H_1^0 Z$. Universal scalar mass of 1 TeV, SU(2) gaugino mass of 200 GeV, and $\mu = -200$ GeV are assumed, and two-loop radiative corrections incorporated. The limits hold for $m_t = 175$ GeV, and for the m_h^{max} scenario.
- ⁵⁷ ABBIENDI 04M exclude $0.7 < \tan\beta < 1.9$, assuming $m_t = 174.3$ GeV. Limits for other MSSM benchmark scenarios, as well as for CP violating cases, are also given.
- ⁵⁸ ACHARD 02H also search for the final state $H_1^0 Z \rightarrow 2A^0 q\bar{q}$, $A^0 \rightarrow q\bar{q}$. In addition, the MSSM parameter set in the “large- μ ” and “no-mixing” scenarios are examined.
- ⁵⁹ ABAZOV 12 search for production of a Higgs boson followed by the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$ in 5.4 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. See their Fig. 2 for the limit on cross section times branching ratio and Fig. 3 for the excluded region in the MSSM parameter space.
- ⁶⁰ AAD 11R search for production of a Higgs boson followed by the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$ in 36 pb $^{-1}$ of $p\bar{p}$ collisions at $E_{\text{cm}} = 7$ TeV. See their Fig. 3 for the limit on cross section times branching ratio and for the excluded region in the MSSM parameter space.
- ⁶¹ ABAZOV 11K search for associated production of a Higgs boson and a b quark, followed by the decay $H_{1,2}^0/A^0 \rightarrow b\bar{b}$, in 5.2 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. See their Fig. 5/Table 2 for the limit on cross section times branching ratio and Fig. 6 for the excluded region in the MSSM parameter space for $\mu = -200$ GeV.
- ⁶² ABAZOV 11W search for associated production of a Higgs boson and a b quark, followed by the decay $H_{1,2}^0/A^0 \rightarrow \tau\tau$, in 7.3 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. See their Fig. 2 for the limit on cross section times branching ratio and for the excluded region in the MSSM parameter space.
- ⁶³ CHATRCHYAN 11H search for production of a Higgs boson followed by the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$ in 36 pb $^{-1}$ of $p\bar{p}$ collisions at $E_{\text{cm}} = 7$ TeV. See their Fig. 2 for the limit on cross section times branching ratio and Fig. 3 for the excluded region in the MSSM parameter space.
- ⁶⁴ ABAZOV 10D search for associated production of a Higgs boson and a b quark in 2.7 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV, with the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$. See their Fig. 1 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-)$ (for different Higgs masses) and for the excluded region in the MSSM parameter space for $\mu = -200$ GeV. Superseded by ABAZOV 11W.
- ⁶⁵ AALTONEN 09AR search for Higgs bosons decaying to $\tau^+\tau^-$ in two doublet models in 1.8 fb $^{-1}$ of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. See their Fig. 2 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-)$ for different Higgs masses, and see their Fig. 3 for the excluded region in the MSSM parameter space.
- ⁶⁶ ABAZOV 09F search for associated production of a Higgs boson and a b quark in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV with the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$. See their Fig. 2 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-)$ (for different Higgs masses) and for the excluded region in the MSSM parameter space for $\mu = \pm 200$ GeV. Superseded by ABAZOV 10D.
- ⁶⁷ ABAZOV 08AJ search for associated production of a Higgs boson and a b quark in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV with the decay $H_{1,2}^0/A^0 \rightarrow b\bar{b}$. See their Tab. 3 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow b\bar{b})$ for different Higgs masses, and see their Fig. 3 for the excluded region in the MSSM parameter space for $\mu = \pm 200$ GeV. Superseded by ABAZOV 11K.
- ⁶⁸ ABAZOV 08W search for Higgs boson production in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV with the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$. See their Fig. 3 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-)$ for different Higgs masses, and see their Fig. 4 for the excluded region in the MSSM parameter space. Superseded by ABAZOV 12.
- ⁶⁹ This limit applies also in the no-mixing scenario. Furthermore, ABDALLAH 04 excludes the range $0.54 < \tan\beta < 2.36$. The limit improves in the region $\tan\beta < 6$ (see Fig. 28). Limits for $\mu = 1$ TeV are given in Fig. 30.
- ⁷⁰ ABBIENDI 03G search for $e^+e^- \rightarrow H_1^0 Z$ followed by $H_1^0 \rightarrow A^0 A^0$, $A^0 \rightarrow c\bar{c}$, $g\bar{g}$, or $\tau^+\tau^-$. In the no-mixing scenario, the region $m_{H_1^0} = 45\text{--}85$ GeV and $m_{A^0} = 2\text{--}9.5$ GeV is excluded at 95% CL.
- ⁷¹ HEISTER 02 excludes the range $0.7 < \tan\beta < 2.3$. A wider range is excluded with different stop mixing assumptions. Updates BARATE 01c.

- ⁷² ABDALLAH 08B give limits in eight CP -conserving benchmark scenarios and some CP -violating scenarios. See paper for excluded regions for each scenario. Supersedes ABDALLAH 04.
- ⁷³ SCHAEEL 06B make a combined analysis of the LEP data. The quoted limit is for the m_h^{max} scenario with $m_t = 174.3$ GeV. In the CP -violating CPX scenario no lower bound on $m_{H_1^0}$ can be set at 95% CL. See paper for excluded regions in various scenarios. See Figs. 2–6 and Tabs. 14–21 for limits on $\sigma(ZH^0) \cdot B(H^0 \rightarrow b\bar{b}, \tau^+\tau^-)$ and $\sigma(H_1^0 H_2^0) \cdot B(H_1^0, H_2^0 \rightarrow b\bar{b}, \tau^+\tau^-)$.
- ⁷⁴ Search for $e^+e^- \rightarrow H_1^0 A^0$ in the final states $b\bar{b}b\bar{b}$ and $b\bar{b}\tau^+\tau^-$, and $e^+e^- \rightarrow H_1^0 Z$. Universal scalar mass of 1 TeV, SU(2) gaugino mass of 200 GeV, and $\mu = -200$ GeV are assumed, and two-loop radiative corrections incorporated. The limits hold for $m_t = 175$ GeV, and for the m_h^{max} scenario.
- ⁷⁵ ABBIENDI 04M exclude $0.7 < \tan\beta < 1.9$, assuming $m_t = 174.3$ GeV. Limits for other MSSM benchmark scenarios, as well as for CP violating cases, are also given.
- ⁷⁶ ACHARD 02H also search for the final state $H_1^0 Z \rightarrow 2A^0 q\bar{q}, A^0 \rightarrow q\bar{q}$. In addition, the MSSM parameter set in the “large- μ ” and “no-mixing” scenarios are examined.
- ⁷⁷ HEISTER 02 excludes the range $0.7 < \tan\beta < 2.3$. A wider range is excluded with different stop mixing assumptions. Updates BARATE 01c.
- ⁷⁸ ABAZOV 12 search for production of a Higgs boson followed by the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$ in 5.4 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. See their Fig. 2 for the limit on cross section times branching ratio and Fig. 3 for the excluded region in the MSSM parameter space.
- ⁷⁹ AAD 11R search for production of a Higgs boson followed by the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$ in 36 pb^{-1} of pp collisions at $E_{\text{cm}} = 7$ TeV. See their Fig. 3 for the limit on cross section times branching ratio and for the excluded region in the MSSM parameter space.
- ⁸⁰ ABAZOV 11k search for associated production of a Higgs boson and a b quark, followed by the decay $H_{1,2}^0/A^0 \rightarrow b\bar{b}$, in 5.2 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. See their Fig. 5/ Table 2 for the limit on cross section times branching ratio and Fig. 6 for the excluded region in the MSSM parameter space for $\mu = -200$ GeV.
- ⁸¹ ABAZOV 11w search for associated production of a Higgs boson and a b quark, followed by the decay $H_{1,2}^0/A^0 \rightarrow \tau\tau$, in 7.3 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. See their Fig. 2 for the limit on cross section times branching ratio and for the excluded region in the MSSM parameter space.
- ⁸² CHATRCHYAN 11H search for production of a Higgs boson followed by the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$ in 36 pb^{-1} of pp collisions at $E_{\text{cm}} = 7$ TeV. See their Fig. 2 for the limit on cross section times branching ratio and Fig. 3 for the excluded region in the MSSM parameter space.
- ⁸³ ABAZOV 10D search for associated production of a Higgs boson and a b quark in 2.7 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV, with the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$. See their Fig. 1 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-)$ (for different Higgs masses) and for the excluded region in the MSSM parameter space for $\mu = -200$ GeV. Superseded by ABAZOV 11w.
- ⁸⁴ AALTONEN 09AR search for Higgs bosons decaying to $\tau^+\tau^-$ in two doublet models in 1.8 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. See their Fig. 2 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-)$ for different Higgs masses, and see their Fig. 3 for the excluded region in the MSSM parameter space.
- ⁸⁵ ABAZOV 09F search for associated production of a Higgs boson and a b quark in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV with the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$. See their Fig. 2 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-)$ (for different Higgs masses) and for the excluded region in the MSSM parameter space for $\mu = \pm 200$ GeV. Superseded by ABAZOV 10D.
- ⁸⁶ ABAZOV 08AJ search for associated production of a Higgs boson and a b quark in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV with the decay $H_{1,2}^0/A^0 \rightarrow b\bar{b}$. See their Tab. 3 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow b\bar{b})$ for different Higgs masses, and see their Fig. 3 for the excluded region in the MSSM parameter space for $\mu = \pm 200$ GeV. Superseded by ABAZOV 11k.
- ⁸⁷ ABAZOV 08W search for Higgs boson production in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV with the decay $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$. See their Fig. 3 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-)$ for different Higgs masses, and see their Fig. 4 for the excluded region in the MSSM parameter space. Superseded by ABAZOV 12.

- ⁸⁸ ACOSTA 05Q search for $H_{1,2}^0/A^0$ production in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.8$ TeV with $H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-$. At $m_{A^0} = 100$ GeV, the obtained cross section upper limit is above theoretical expectation.
- ⁸⁹ This limit applies also in the no-mixing scenario. Furthermore, ABDALLAH 04 excludes the range $0.54 < \tan\beta < 2.36$. The limit improves in the region $\tan\beta < 6$ (see Fig. 28). Limits for $\mu = 1$ TeV are given in Fig. 30.
- ⁹⁰ ABBIENDI 03G search for $e^+e^- \rightarrow H_1^0 Z$ followed by $H_1^0 \rightarrow A^0 A^0, A^0 \rightarrow c\bar{c}, gg,$ or $\tau^+\tau^-$. In the no-mixing scenario, the region $m_{H_1^0} = 45\text{--}85$ GeV and $m_{A^0} = 2\text{--}9.5$ GeV is excluded at 95% CL.
- ⁹¹ AKEROYD 02 examine the possibility of a light A^0 with $\tan\beta < 1$. Electroweak measurements are found to be inconsistent with such a scenario.

H^0 (Higgs Boson) MASS LIMITS in Extended Higgs Models

This Section covers models which do not fit into either the Standard Model or its simplest minimal Supersymmetric extension (MSSM), leading to anomalous production rates, or nonstandard final states and branching ratios. In particular, this Section covers limits which may apply to generic two-Higgs-doublet models (2HDM), or to special regions of the MSSM parameter space where decays to invisible particles or to photon pairs are dominant (see the Note on ‘Searches for Higgs Bosons’ at the beginning of this Chapter). See the footnotes or the comment lines for details on the nature of the models to which the limits apply.

- 92 AALTONEN 12 search for $H^0 \rightarrow \gamma\gamma$ in 7.0 fb⁻¹ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the mass range $m_{H^0} = 100\text{--}150$ GeV. The limit assumes that all fermion Yukawa couplings vanish.
- 93 AALTONEN 11P search in 2.7 fb⁻¹ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV for the decay chain $t \rightarrow bH^+, H^+ \rightarrow W^+A^0, A^0 \rightarrow \tau^+\tau^-$ with m_{A^0} between 4 and 9 GeV. See their Fig. 4 for limits on $B(t \rightarrow bH^+)$ for $90 < m_{H^+} < 160$ GeV.
- 94 ABAZOV 11Y search for $H^0 \rightarrow \gamma\gamma$ in 8.2 fb⁻¹ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the mass range $m_{H^0} = 100\text{--}150$ GeV. The limit assumes that all fermion Yukawa couplings vanish.
- 95 The limit applies at $m_{A^0} = 214.3$ MeV, motivated by PARK 05.
- 96 DEL-AMO-SANCHEZ 11J search for the process $\Upsilon(2S) \rightarrow \Upsilon(1S)\pi^+\pi^- \rightarrow A^0\gamma\pi^+\pi^-$ with A^0 decaying to invisible final states. They give limits on $B(\Upsilon(1S) \rightarrow A^0\gamma)\cdot B(A^0 \rightarrow \text{invisible})$ in the range $(1.9\text{--}4.5) \times 10^{-6}$ (90% CL) for $0 \leq m_{A^0} \leq 8.0$ GeV, and $(2.7\text{--}37) \times 10^{-6}$ for $8.0 \leq m_{A^0} \leq 9.2$ GeV.
- 97 LEES 11H search for the process $\Upsilon(2S, 3S) \rightarrow A^0\gamma$ with A^0 decaying hadronically and give limits on $B(\Upsilon(2S, 3S) \rightarrow A^0\gamma)\cdot B(A^0 \rightarrow \text{hadrons})$ in the range $1 \times 10^{-6}\text{--}8 \times 10^{-5}$ (90% CL) for $0.3 < m_{A^0} < 7$ GeV. The decay rates for $\Upsilon(2S)$ and $\Upsilon(3S)$ are assumed to be equal up to the phase space factor.
- 98 ABBIENDI 10 search for $e^+e^- \rightarrow H^0Z$ with H^0 decaying invisibly. The limit assumes SM production cross section and $B(H^0 \rightarrow \text{invisible}) = 1$.
- 99 ABBIENDI 10 search for $e^+e^- \rightarrow ZH^0$ with the decay chain $H^0 \rightarrow \tilde{\chi}_1^0\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 + (\gamma \text{ or } Z^*)$, when $\tilde{\chi}_1^0$ and $\tilde{\chi}_2^0$ are nearly degenerate. For a mass difference of 2 (4) GeV, a lower limit on m_{H^0} of 108.4 (107.0) GeV (95% CL) is obtained for SM ZH^0 cross section and $B(H^0 \rightarrow \tilde{\chi}_1^0\tilde{\chi}_2^0) = 1$.
- 100 ANDREAS 10 analyze various rare decays and find $m_{A^0} > 210$ MeV or that its couplings to fermions are 4 orders of magnitude below those of the standard Higgs.
- 101 The limit applies at $m_{A^0} = 214.3$ MeV, motivated by PARK 05. HYUN 10 summarize mass-dependent limits in their Table I.
- 102 SCHAEEL 10 search for the process $e^+e^- \rightarrow H^0Z$ followed by the decay chain $H^0 \rightarrow A^0A^0 \rightarrow \tau^+\tau^-\tau^+\tau^-$ with $Z \rightarrow \ell^+\ell^-, \nu\bar{\nu}$ at $E_{cm} = 183\text{--}209$ GeV. For a H^0ZZ coupling equal to the SM value, $B(H^0 \rightarrow A^0A^0) = B(A^0 \rightarrow \tau^+\tau^-) = 1$, and $m_{A^0} = 4\text{--}10$ GeV, m_{H^0} up to 107 GeV is excluded at 95% CL.
- 103 AALTONEN 09AB search for $H^0 \rightarrow \gamma\gamma$ in 3.0 fb⁻¹ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the mass range $m_{H^0} = 70\text{--}150$ GeV. Associated H^0W, H^0Z production and WW, ZZ fusion are considered. The limit assumes that all fermion Yukawa couplings vanish.
- 104 AALTONEN 09AR search for Higgs bosons decaying to $\tau^+\tau^-$ in two doublet models in 1.8 fb⁻¹ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. See their Fig. 2 for the limit on $\sigma \cdot B(H_{1,2}^0/A^0 \rightarrow \tau^+\tau^-)$ for different Higgs masses, and see their Fig. 3 for the excluded region in the MSSM parameter space.
- 105 ABAZOV 09Z search for $H^0 \rightarrow \gamma\gamma$ in 2.7 fb⁻¹ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the mass range $m_{H^0} = 100\text{--}150$ GeV. The limit assumes that all fermion Yukawa couplings vanish. Superseded by ABAZOV 11Y.
- 106 ABAZOV 09V search for H^0 production followed by the decay chain $H^0 \rightarrow A^0A^0 \rightarrow \mu^+\mu^-\mu^+\mu^-$ or $\mu^+\mu^-\tau^+\tau^-$ in 4.2 fb⁻¹ of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. See their Fig. 3 for limits on $\sigma(H^0)\cdot B(H^0 \rightarrow A^0A^0)$ for $m_{A^0} = 3.6\text{--}19$ GeV.
- 107 AUBERT 09P search for the process $\Upsilon(3S) \rightarrow A^0\gamma$ with $A^0 \rightarrow \tau^+\tau^-$ for $4.03 < m_{A^0} < 9.52$ and $9.61 < m_{A^0} < 10.10$ GeV, and give limits on $B(\Upsilon(3S) \rightarrow A^0\gamma)\cdot B(A^0 \rightarrow \tau^+\tau^-)$ in the range $(1.5\text{--}16) \times 10^{-5}$ (90% CL).
- 108 AUBERT 09Z search for the process $\Upsilon(2S) \rightarrow A^0\gamma$ with $A^0 \rightarrow \mu^+\mu^-$ for $0.212 < m_{A^0} < 9.3$ GeV and give limits on $B(\Upsilon(2S) \rightarrow A^0\gamma)\cdot B(A^0 \rightarrow \mu^+\mu^-)$ in the range $(0.3\text{--}8) \times 10^{-6}$ (90% CL).
- 109 AUBERT 09Z search for the process $\Upsilon(3S) \rightarrow A^0\gamma$ with $A^0 \rightarrow \mu^+\mu^-$ for $0.212 < m_{A^0} < 9.3$ GeV and give limits on $B(\Upsilon(3S) \rightarrow A^0\gamma)\cdot B(A^0 \rightarrow \mu^+\mu^-)$ in the range $(0.3\text{--}5) \times 10^{-6}$ (90% CL).
- 110 The limit applies at $m_{A^0} = 214.3$ MeV, motivated by PARK 05. TUNG 09 show mass-dependent limits in their Fig. 5.
- 111 ABAZOV 08U search for $H^0 \rightarrow \gamma\gamma$ in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV in the mass range $m_{H^0} = 70\text{--}150$ GeV. Associated H^0W, H^0Z production and WW, ZZ fusion are considered. See their Tab. 1 for the limit on $\sigma \cdot B(H^0 \rightarrow \gamma\gamma)$, and see their Fig. 3 for the excluded region in the $m_{H^0} - B(H^0 \rightarrow \gamma\gamma)$ plane.
- 112 LOVE 08 search for the process $\Upsilon(1S) \rightarrow A^0\gamma$ with $A^0 \rightarrow \mu^+\mu^-$ (for $m_{A^0} < 2m_\tau$) and $A^0 \rightarrow \tau^+\tau^-$. Limits on $B(\Upsilon(1S) \rightarrow A^0\gamma) \cdot B(A^0 \rightarrow \ell^+\ell^-)$ in the range $10^{-6}\text{--}10^{-4}$ (90% CL) are given.
- 113 ABBIENDI 07 search for $e^+e^- \rightarrow H^0Z$ with $Z \rightarrow q\bar{q}$ and H^0 decaying to invisible final states. The H^0 width is varied between 1 GeV and 3 TeV. A limit $\sigma \cdot B(H^0 \rightarrow \text{invisible}) < (0.07\text{--}0.57)$ pb (95% CL) is obtained at $E_{cm} = 206$ GeV for $m_{H^0} = 60\text{--}114$ GeV.
- 114 BESSON 07 give a limit $B(\Upsilon(1S) \rightarrow \eta_b\gamma) \cdot B(\eta_b \rightarrow \tau^+\tau^-) < 0.27\%$ (95% CL), which constrains a possible A^0 exchange contribution to the η_b decay.
- 115 SCHAEEL 07 search for Higgs bosons in association with a fermion pair and decaying to WW^* . The limit is from this search and HEISTER 02L for a H^0 with SM production cross section and $B(H^0 \rightarrow f\bar{f}) = 0$ for all fermions f .
- 116 ABBIENDI 05A search for $e^+e^- \rightarrow H_1^0A^0$ in general Type-II two-doublet models, with decays $H_1^0, A^0 \rightarrow q\bar{q}, gg, \tau^+\tau^-$, and $H_1^0 \rightarrow A^0A^0$.
- 117 ABDALLAH 05D search for $e^+e^- \rightarrow H^0Z$ and H^0A^0 with H^0, A^0 decaying to two jets of any flavor including gg . The limit is for SM H^0Z production cross section with $B(H^0 \rightarrow jj) = 1$.
- 118 Search for $e^+e^- \rightarrow H^0Z$ with H^0 decaying invisibly. The limit assumes SM production cross section and $B(H^0 \rightarrow \text{invisible}) = 1$.
- 119 PARK 05 found three candidate events for $\Sigma^+ \rightarrow p\mu^+\mu^-$ in the HyperCP experiment. Due to a narrow spread in dimuon mass, they hypothesize the events as a possible signal of a new boson. It can be interpreted as a neutral particle with $m_{A^0} = 214.3 \pm 0.5$ MeV and the branching fraction $B(\Sigma^+ \rightarrow pA^0) \times B(A^0 \rightarrow \mu^+\mu^-) = (3.1_{-1.9}^{+2.4} \pm 1.5) \times 10^{-8}$.
- 120 ABBIENDI 04K search for $e^+e^- \rightarrow H^0Z$ with H^0 decaying to two jets of any flavor including gg . The limit is for SM production cross section with $B(H^0 \rightarrow jj) = 1$.
- 121 ABDALLAH 04 consider the full combined LEP and LEP2 datasets to set limits on the Higgs coupling to W or Z bosons, assuming SM decays of the Higgs. Results in Fig. 26.
- 122 Search for associated production of a $\gamma\gamma$ resonance with a Z boson, followed by $Z \rightarrow q\bar{q}, \ell^+\ell^-$, or $\nu\bar{\nu}$, at $E_{cm} \leq 209$ GeV. The limit is for a H^0 with SM production cross section and $B(H^0 \rightarrow f\bar{f}) = 0$ for all fermions f .
- 123 Updates ABREU 01F.
- 124 ABDALLAH 04o search for $Z \rightarrow b\bar{b}H^0, b\bar{b}A^0, \tau^+\tau^-H^0$ and $\tau^+\tau^-A^0$ in the final states $4b, b\bar{b}\tau^+\tau^-,$ and 4τ . See paper for limits on Yukawa couplings.
- 125 ABDALLAH 04o search for $e^+e^- \rightarrow H^0Z$ and H^0A^0 , with H^0, A^0 decaying to $b\bar{b}, \tau^+\tau^-$, or $H^0 \rightarrow A^0A^0$ at $E_{cm} = 189\text{--}208$ GeV. See paper for limits on couplings.
- 126 ACHARD 04B search for $e^+e^- \rightarrow H^0Z$ with H^0 decaying to $b\bar{b}, c\bar{c}$, or gg . The limit is for SM production cross section with $B(H^0 \rightarrow jj) = 1$.
- 127 ACHARD 04F search for H^0 with anomalous coupling to gauge boson pairs in the processes $e^+e^- \rightarrow H^0\gamma, e^+e^-H^0, H^0Z$ with decays $H^0 \rightarrow f\bar{f}, \gamma\gamma, Z\gamma$, and W^*W at $E_{cm} = 189\text{--}209$ GeV. See paper for limits.
- 128 ABBIENDI 03F search for $H^0 \rightarrow \text{anything in } e^+e^- \rightarrow H^0Z$, using the recoil mass spectrum of $Z \rightarrow e^+e^-$ or $\mu^+\mu^-$. In addition, it searched for $Z \rightarrow \nu\bar{\nu}$ and $H^0 \rightarrow e^+e^-$ or photons. Scenarios with large width or continuum H^0 mass distribution are considered. See their Figs. 11–14 for the results.
- 129 ABBIENDI 03G search for $e^+e^- \rightarrow H_1^0Z$ followed by $H_1^0 \rightarrow A^0A^0, A^0 \rightarrow c\bar{c}, gg$, or $\tau^+\tau^-$ in the region $m_{H_1^0} = 45\text{--}86$ GeV and $m_{A^0} = 2\text{--}11$ GeV. See their Fig. 7 for the limits.
- 130 ACHARD 03c search for $e^+e^- \rightarrow ZH^0$ followed by $H^0 \rightarrow WW^*$ or ZZ^* at $E_{cm} = 200\text{--}209$ GeV and combine with the ACHARD 02c result. The limit is for a H^0 with SM production cross section and $B(H^0 \rightarrow f\bar{f}) = 0$ for all f . For $B(H^0 \rightarrow WW^*) + B(H^0 \rightarrow ZZ^*) = 1, m_{H^0} > 108.1$ GeV is obtained. See fig. 6 for the limits under different BR assumptions.
- 131 ABBIENDI 02D search for $Z \rightarrow b\bar{b}H^0$ and $b\bar{b}A^0$ with $H_1^0/A^0 \rightarrow \tau^+\tau^-$, in the range $4 < m_H < 12$ GeV. See their Fig. 8 for limits on the Yukawa coupling.
- 132 For $B(H^0 \rightarrow \gamma\gamma) = 1, m_{H^0} > 117$ GeV is obtained.
- 133 ACHARD 02c search for associated production of a $\gamma\gamma$ resonance with a Z boson, followed by $Z \rightarrow q\bar{q}, \ell^+\ell^-$, or $\nu\bar{\nu}$, at $E_{cm} \leq 209$ GeV. The limit is for a H^0 with SM production cross section and $B(H^0 \rightarrow f\bar{f}) = 0$ for all fermions f . For $B(H^0 \rightarrow \gamma\gamma) = 1, m_{H^0} > 114$ GeV is obtained.
- 134 For $B(H^0 \rightarrow \gamma\gamma) = 1, m_{H^0} > 113.1$ GeV is obtained.
- 135 HEISTER 02M search for $e^+e^- \rightarrow H^0Z$, assuming that H^0 decays to $q\bar{q}, gg$, or $\tau^+\tau^-$ only. The limit assumes SM production cross section.
- 136 ABBIENDI 01E search for neutral Higgs bosons in general Type-II two-doublet models, at $E_{cm} \leq 189$ GeV. In addition to usual final states, the decays $H_1^0, A^0 \rightarrow q\bar{q}, gg$ are searched for. See their Figs. 15, 16 for excluded regions.
- 137 AFFOLDER 01H search for associated production of a $\gamma\gamma$ resonance and a W or Z (tagged by two jets, an isolated lepton, or missing E_T). The limit assumes Standard Model values for the production cross section and for the couplings of the H^0 to W and Z bosons. See their Fig. 11 for limits with $B(H^0 \rightarrow \gamma\gamma) < 1$.
- 138 ACCIARRI 00M search for $e^+e^- \rightarrow ZH^0$ with H^0 decaying invisibly at $E_{cm} = 183\text{--}189$ GeV. The limit assumes SM production cross section and $B(H^0 \rightarrow \text{invisible}) = 1$. See their Fig. 6 for limits for smaller branching ratios.
- 139 ACCIARRI 00R search for $e^+e^- \rightarrow H^0\gamma$ with $H^0 \rightarrow b\bar{b}, Z\gamma$, or $\gamma\gamma$. See their Fig. 3 for limits on $\sigma \cdot B$. Explicit limits within an effective interaction framework are also given, for which the Standard Model Higgs search results are used in addition.
- 140 ACCIARRI 00R search for the two-photon type processes $e^+e^- \rightarrow e^+e^-H^0$ with $H^0 \rightarrow b\bar{b}$ or $\gamma\gamma$. See their Fig. 4 for limits on $\Gamma(H^0 \rightarrow \gamma\gamma)\cdot B(H^0 \rightarrow \gamma\gamma \text{ or } b\bar{b})$ for $m_{H^0} = 70\text{--}170$ GeV.
- 141 ACCIARRI 00s search for associated production of a $\gamma\gamma$ resonance with a $q\bar{q}, \nu\bar{\nu}$, or $\ell^+\ell^-$ pair in e^+e^- collisions at $E_{cm} = 189$ GeV. The limit is for a H^0 with SM production cross section and $B(H^0 \rightarrow f\bar{f}) = 0$ for all fermions f . For $B(H^0 \rightarrow \gamma\gamma) = 1, m_{H^0} > 98$ GeV is obtained. See their Fig. 5 for limits on $B(H \rightarrow \gamma\gamma)\cdot\sigma(e^+e^- \rightarrow Hf\bar{f})/\sigma(e^+e^- \rightarrow Hf\bar{f})$ (SM).
- 142 BARATE 00L search for associated production of a $\gamma\gamma$ resonance with a $q\bar{q}, \nu\bar{\nu}$, or $\ell^+\ell^-$ pair in e^+e^- collisions at $E_{cm} = 88\text{--}202$ GeV. The limit is for a H^0 with SM production cross section and $B(H^0 \rightarrow f\bar{f}) = 0$ for all fermions f . For $B(H^0 \rightarrow \gamma\gamma) = 1, m_{H^0} > 109$ GeV is obtained. See their Fig. 3 for limits on $B(H \rightarrow \gamma\gamma)\cdot\sigma(e^+e^- \rightarrow Hf\bar{f})/\sigma(e^+e^- \rightarrow Hf\bar{f})$ (SM).

See key on page 457

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm

- 143 ABBIENDI 99E search for $e^+e^- \rightarrow H^0 A^0$ and $H^0 Z$ at $E_{\text{cm}} = 183$ GeV. The limit is with $m_H = m_A$ in general two Higgs-doublet models. See their Fig. 18 for the exclusion limit in the $m_H - m_A$ plane. Updates the results of ACKERSTAFF 98S.
- 144 ABBIENDI 99B search for associated production of a $\gamma\gamma$ resonance with a $q\bar{q}, \nu\bar{\nu}$, or $\ell^+\ell^-$ pair in e^+e^- collisions at 189 GeV. The limit is for a H^0 with SM production cross section and $B(H^0 \rightarrow f\bar{f})=0$, for all fermions f . See their Fig. 4 for limits on $\sigma(e^+e^- \rightarrow H^0 Z^0) \times B(H^0 \rightarrow \gamma\gamma) \times B(X^0 \rightarrow f\bar{f})$ for various masses. Updates the results of ACKERSTAFF 98Y.
- 145 ABBOTT 99B search for associated production of a $\gamma\gamma$ resonance and a dijet pair. The limit assumes Standard Model values for the production cross section and for the couplings of the H^0 to W and Z bosons. Limits in the range of $\sigma(H^0 + Z/W) \cdot B(H^0 \rightarrow \gamma\gamma) = 0.80-0.34$ pb are obtained in the mass range $m_{H^0} = 65-150$ GeV.
- 146 ABREU 99P search for $e^+e^- \rightarrow H^0 \gamma$ with $H^0 \rightarrow b\bar{b}$ or $\gamma\gamma$, and $e^+e^- \rightarrow H^0 q\bar{q}$ with $H^0 \rightarrow \gamma\gamma$. See their Fig. 4 for limits on $\sigma \times B$. Explicit limits within an effective interaction framework are also given.
- 147 GONZALEZ-GARCIA 98B use $D\bar{0}$ limit for $\gamma\gamma$ events with missing E_T in $p\bar{p}$ collisions (ABBOTT 98) to constrain possible ZH or WH production followed by unconventional $H \rightarrow \gamma\gamma$ decay which is induced by higher-dimensional operators. See their Figs. 1 and 2 for limits on the anomalous couplings.
- 148 KRAWCZYK 97 analyse the muon anomalous magnetic moment in a two-doublet Higgs model (with type II Yukawa couplings) assuming no $H^0 Z$ coupling and obtain $m_{H^0} \gtrsim 5$ GeV or $m_{A^0} \gtrsim 5$ GeV for $\tan\beta > 50$. Other Higgs bosons are assumed to be much heavier.
- 149 ALEXANDER 96H give $B(Z \rightarrow H^0 \gamma) \times B(H^0 \rightarrow q\bar{q}) < 1.4 \times 10^{-5}$ (95%CL) and $B(Z \rightarrow H^0 \gamma) \times B(H^0 \rightarrow b\bar{b}) < 0.7-2 \times 10^{-5}$ (95%CL) in the range $20 < m_{H^0} < 80$ GeV.
- 150 See Fig. 4 of ABREU 95H for the excluded region in the $m_{H^0} - m_{A^0}$ plane for general two-doublet models. For $\tan\beta > 1$, the region $m_{H^0} + m_{A^0} \lesssim 87$ GeV, $m_{H^0} < 47$ GeV is excluded at 95% CL.
- 151 PICH 92 analyse H^0 with $m_{H^0} < 2m_\mu$ in general two-doublet models. Excluded regions in the space of mass-mixing angles from LEP, beam dump, and π^\pm, η rare decays are shown in Figs. 3, 4. The considered mass region is not totally excluded.

H^\pm (Charged Higgs) MASS LIMITS

Unless otherwise stated, the limits below assume $B(H^+ \rightarrow \tau^+ \nu) + B(H^+ \rightarrow c\bar{s}) = 1$, and hold for all values of $B(H^+ \rightarrow \tau^+ \nu_\tau)$, and assume H^+ weak isospin of $T_3 = +1/2$. In the following, $\tan\beta$ is the ratio of the two vacuum expectation values in two-doublet models (2HDM).

The limits are also applicable to point-like technipions. For a discussion of techniparticles, see the Review of Dynamical Electroweak Symmetry Breaking in this Review.

For limits obtained in hadronic collisions before the observation of the top quark, and based on the top mass values inconsistent with the current measurements, see the 1996 (Physical Review **D54** 1 (1996)) Edition of this Review.

Searches in e^+e^- collisions at and above the Z pole have conclusively ruled out the existence of a charged Higgs in the region $m_{H^\pm} \lesssim 45$ GeV, and are now superseded by the most recent searches in higher energy e^+e^- collisions at LEP. Results by now obsolete are therefore not included in this compilation, and can be found in the previous Edition (The European Physical Journal **C15** 1 (2000)) of this Review.

In the following, and unless otherwise stated, results from the LEP experiments (ALEPH, DELPHI, L3, and OPAL) are assumed to derive from the study of the $e^+e^- \rightarrow H^+ H^-$ process. Limits from $b \rightarrow s\gamma$ decays are usually stronger in generic 2HDM models than in Supersymmetric models.

- 152 AALTONEN 11P search in 2.7 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV for the decay chain $t \rightarrow bH^+, H^+ \rightarrow W^+ A^0, A^0 \rightarrow \tau^+ \tau^-$ with m_{A^0} between 4 and 9 GeV. See their Fig. 4 for limits on $B(t \rightarrow bH^+)$ for $90 < m_{H^+} < 160$ GeV.
- 153 DESCHAMPS 10 make Type II two Higgs doublet model fits to weak leptonic and semileptonic decays, $b \rightarrow s\gamma, B, B_s$ mixings, and $Z \rightarrow b\bar{b}$. The limit holds irrespective of $\tan\beta$.
- 154 AALTONEN 09AJ search for $t \rightarrow bH^+, H^+ \rightarrow c\bar{s}$ in $t\bar{t}$ events in 2.2 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. Upper limits on $B(t \rightarrow bH^+)$ between 0.08 and 0.32 (95% CL) are given for $m_{H^+} = 60-150$ GeV and $B(H^+ \rightarrow c\bar{s}) = 1$.
- 155 ABAZOV 09AC search for $t \rightarrow bH^+, H^+ \rightarrow \tau^+ \nu$ in $t\bar{t}$ events in 0.9 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. Upper limits on $B(t \rightarrow bH^+)$ between 0.19 and 0.25 (95% CL) are given for $m_{H^+} = 80-155$ GeV and $B(H^+ \rightarrow \tau^+ \nu) = 1$. See their Fig. 4 for an excluded region in a MSSM scenario.
- 156 ABAZOV 09AG measure $t\bar{t}$ cross sections in final states with $\ell + \text{jets}$ ($\ell = e, \mu$), $\ell\ell$, and $\tau\ell$ in 1 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV, which constrains possible $t \rightarrow bH^+$ branching fractions. Upper limits (95% CL) on $B(t \rightarrow bH^+)$ between 0.15 and 0.40 (0.48 and 0.57) are given for $B(H^+ \rightarrow \tau^+ \nu) = 1$ ($B(H^+ \rightarrow c\bar{s}) = 1$) for $m_{H^+} = 80-155$ GeV.
- 157 ABAZOV 09AI search for $t \rightarrow bH^+$ in $t\bar{t}$ events in 1 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. Final states with $\ell + \text{jets}$ ($\ell = e, \mu$), $\ell\ell$, and $\tau\ell$ are examined. Upper limits on $B(t \rightarrow bH^+)$ (95% CL) between 0.15 and 0.19 (0.19 and 0.22) are given for $B(H^+ \rightarrow \tau^+ \nu) = 1$ ($B(H^+ \rightarrow c\bar{s}) = 1$) for $m_{H^+} = 80-155$ GeV. For $B(H^+ \rightarrow \tau^+ \nu) = 1$ also a simultaneous extraction of $B(t \rightarrow bH^+)$ and the $t\bar{t}$ cross section is performed, yielding a limit on $B(t \rightarrow bH^+)$ between 0.12 and 0.26 for $m_{H^+} = 80-155$ GeV. See their Figs. 5-8 for excluded regions in several MSSM scenarios.
- 158 ABAZOV 09P search for H^+ production by $q\bar{q}$ annihilation followed by $H^+ \rightarrow t\bar{b}$ decay in 0.9 fb^{-1} of $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. Cross section limits in several two-doublet models are given for $m_{H^+} = 180-300$ GeV. A region with $20 \lesssim \tan\beta \lesssim 70$ is excluded (95% CL) for $180 \text{ GeV} \lesssim m_{H^+} \lesssim 184 \text{ GeV}$ in type-I models.
- 159 FLACHER 09 make Type II two Higgs doublet model fits to weak leptonic and semileptonic decays, $b \rightarrow s\gamma$, and $Z \rightarrow b\bar{b}$. The limit holds irrespective of $\tan\beta$.
- 160 ABULENCIA 06E search for associated $H^0 W$ production in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.96$ TeV. A fit is made for $t\bar{t}$ production processes in dilepton, lepton + jets, and lepton + τ final states, with the decays $t \rightarrow W^+ b$ and $t \rightarrow H^+ b$ followed by $H^+ \rightarrow \tau^+ \nu, c\bar{s}, t^* \bar{b}$, or $W^+ H^0$. Within the MSSM the search is sensitive to the region $\tan\beta < 1$ or > 30 in the mass range $m_{H^+} = 80-160$ GeV. See Fig. 2 for the excluded region in a certain MSSM scenario.
- 161 ABDALLAH 04I search for $e^+e^- \rightarrow H^+ H^-$ with H^\pm decaying to $\tau\nu, c\bar{s}$, or $W^* A^0$ in Type-I two-Higgs-doublet models.
- 162 ABBIENDI 03 give a limit $m_{H^+} > 1.28 \tan\beta$ GeV (95%CL) in Type II two-doublet models.
- 163 ABAZOV 02B search for a charged Higgs boson in top decays with $H^+ \rightarrow \tau^+ \nu$ at $E_{\text{cm}} = 1.8$ TeV. For $m_{H^+} = 75$ GeV, the region $\tan\beta > 32.0$ is excluded at 95%CL. The excluded mass region extends to over 140 GeV for $\tan\beta$ values above 100.
- 164 BORZUMATI 02 point out that the decay modes such as $b\bar{b} W, A^0 W$, and supersymmetric ones can have substantial branching fractions in the mass range explored at LEP II and Tevatron.
- 165 ABBIENDI 01Q give a limit $\tan\beta/m_{H^+} < 0.53 \text{ GeV}^{-1}$ (95%CL) in Type II two-doublet models.
- 166 BARATE 01E give a limit $\tan\beta/m_{H^+} < 0.40 \text{ GeV}^{-1}$ (90% CL) in Type II two-doublet models. An independent measurement of $B \rightarrow \tau\nu_\tau X$ gives $\tan\beta/m_{H^+} < 0.49 \text{ GeV}^{-1}$ (90% CL).
- 167 GAMBINO 01 use the world average data in the summer of 2001 $B(b \rightarrow s\gamma) = (3.23 \pm 0.42) \times 10^{-4}$. The limit applies for Type-II two-doublet models.
- 168 AFFOLDER 00I search for a charged Higgs boson in top decays with $H^+ \rightarrow \tau^+ \nu$ in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.8$ TeV. The excluded mass region extends to over 120 GeV for $\tan\beta$ values above 100 and $B(t\nu) = 1$. If $B(t \rightarrow bH^+) \gtrsim 0.6$, m_{H^+} up to 160 GeV is excluded. Updates ABE 97L.
- 169 ABBOTT 99E search for a charged Higgs boson in top decays in $p\bar{p}$ collisions at $E_{\text{cm}} = 1.8$ TeV, by comparing the observed $t\bar{t}$ cross section (extracted from the data assuming the dominant decay $t \rightarrow bW^+$) with theoretical expectation. The search is sensitive to regions of the domains $\tan\beta \lesssim 1, 50 < m_{H^+} (\text{GeV}) \lesssim 120$ and $\tan\beta \gtrsim 40, 50 < m_{H^+} (\text{GeV}) \lesssim 160$. See Fig. 3 for the details of the excluded region.
- 170 ACKERSTAFF 99D measure the Michel parameters ρ, ξ, η , and $\xi\delta$ in leptonic τ decays from $Z \rightarrow \tau\tau$. Assuming $e-\mu$ universality, the limit $m_{H^+} > 0.97 \tan\beta$ GeV (95%CL) is obtained for two-doublet models in which only one doublet couples to leptons.
- 171 ACCIARRI 97F give a limit $m_{H^+} > 2.6 \tan\beta$ GeV (90% CL) from their limit on the exclusive $B \rightarrow \tau\nu_\tau$ branching ratio.
- 172 AMMAR 97B measure the Michel parameter ρ from $\tau \rightarrow e\nu\nu$ decays and assumes e/μ universality to extract the Michel η parameter from $\tau \rightarrow \mu\nu\nu$ decays. The measurement is translated to a lower limit on m_{H^+} in a two-doublet model $m_{H^+} > 0.97 \tan\beta$ GeV (90% CL).
- 173 COARASA 97 reanalyzed the constraint on the $(m_{H^\pm}, \tan\beta)$ plane derived from the inclusive $B \rightarrow \tau\nu_\tau X$ branching ratio in GROSSMAN 95B and BUSKULIC 95. They show that the constraint is quite sensitive to supersymmetric one-loop effects.
- 174 GUCHAIT 97 studies the constraints on m_{H^+} set by Tevatron data on $\ell\tau$ final states in $t\bar{t} \rightarrow (Wb)(Hb), W \rightarrow \ell\nu, H \rightarrow \tau\nu_\tau$. See Fig. 2 for the excluded region.
- 175 MANGANO 97 reconsiders the limit in ACCIARRI 97F including the effect of the potentially large $B_c \rightarrow \tau\nu_\tau$ background to $B_u \rightarrow \tau\nu_\tau$ decays. Stronger limits are obtained.
- 176 STAHL 97 fit τ lifetime, leptonic branching ratios, and the Michel parameters and derive limit $m_{H^+} > 1.5 \tan\beta$ GeV (90% CL) for a two-doublet model. See also STAHL 94.
- 177 ALAM 95 measure the inclusive $b \rightarrow s\gamma$ branching ratio at $T(4S)$ and give $B(b \rightarrow s\gamma) < 4.2 \times 10^{-4}$ (95% CL), which translates to the limit $m_{H^+} > [244 + 63/(\tan\beta)]^{1.3}$ GeV in the Type II two-doublet model. Light supersymmetric particles can invalidate this bound.
- 178 BUSKULIC 95 give a limit $m_{H^+} > 1.9 \tan\beta$ GeV (90% CL) for Type-II models from $b \rightarrow \tau\nu_\tau X$ branching ratio, as proposed in GROSSMAN 94.

Gauge & Higgs Boson Particle Listings

Higgs Bosons — H^0 and H^\pm MASS LIMITS for $H^{\pm\pm}$ (doubly-charged Higgs boson)

This section covers searches for a doubly-charged Higgs boson with couplings to lepton pairs. Its weak isospin T_3 is thus restricted to two possibilities depending on lepton chiralities: $T_3(H^{\pm\pm}) = \pm 1$, with the coupling $g_{\ell\ell}$ to $\ell_L^-\ell_L^-$ and $\ell_R^+\ell_R^+$ ("left-handed") and $T_3(H^{\pm\pm}) = 0$, with the coupling to $\ell_R^-\ell_R^-$ and $\ell_L^+\ell_L^+$ ("right-handed"). These Higgs bosons appear in some left-right symmetric models based on the gauge group $SU(2)_L \times SU(2)_R \times U(1)$. These two cases are listed separately in the following. Unless noted, one of the lepton flavor combinations is assumed to be dominant in the decay.

LIMITS for $H^{\pm\pm}$ with $T_3 = \pm 1$

- 179 ABAZOV 12A search for $H^{++}H^{--}$ production in 7.0 fb^{-1} of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV.
- 180 AALTONEN 11AF search for $H^{++}H^{--}$ production in 6.1 fb^{-1} of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV.
- 181 AALTONEN 08AA search for $H^{++}H^{--}$ production in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. The limit assumes 100% branching ratio to the specified final state.
- 182 ABAZOV 08V search for $H^{++}H^{--}$ production in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. The limit is for $B(H \rightarrow \mu\mu) = 1$. The limit is updated in ABAZOV 12A.
- 183 ABDALLAH 03 search for $H^{++}H^{--}$ pair production either followed by $H^{++} \rightarrow \tau^+\tau^+$, or decaying outside the detector.
- 184 ABBIENDI 02c searches for pair production of $H^{++}H^{--}$, with $H^{\pm\pm} \rightarrow \ell^\pm\ell^\pm$ ($\ell, \ell' = e, \mu, \tau$). The limit holds for $\ell = \ell' = \tau$, and becomes stronger for other combinations of leptonic final states. To ensure the decay within the detector, the limit only applies for $g(H\ell\ell) \gtrsim 10^{-7}$.
- 185 AKTAS 06A search for single $H^{\pm\pm}$ production in ep collisions at HERA. Assuming that H^{++} only couples to $e^+\mu^+$ with $g_{e\mu} = 0.3$ (electromagnetic strength), a limit $m_{H^{++}} > 141$ GeV (95% CL) is derived. For the case where H^{++} couples to $e\tau$ only the limit is 112 GeV.
- 186 ACOSTA 05L search for $H^{++}H^{--}$ pair production in $p\bar{p}$ collisions. The limit is valid for $g_{\ell\ell} < 10^{-8}$ so that the Higgs decays outside the detector.
- 187 ABAZOV 04E search for $H^{++}H^{--}$ pair production in $H^{\pm\pm} \rightarrow \mu^\pm\mu^\pm$. The limit is valid for $g_{\mu\mu} \gtrsim 10^{-7}$.
- 188 ACOSTA 04G search for $H^{++}H^{--}$ pair production in $p\bar{p}$ collisions with muon and electron final states. The limit holds for $\mu\mu$. For ee and $e\mu$ modes, the limits are 133 and 115 GeV, respectively. The limits are valid for $g_{\ell\ell} \gtrsim 10^{-5}$. Superseded by AALTONEN 11AF.
- 189 ABBIENDI 03Q searches for single $H^{\pm\pm}$ via direct production in $e^+e^- \rightarrow e^\mp e^\mp H^{\pm\pm}$, and via t -channel exchange in $e^+e^- \rightarrow e^+e^-$. In the direct case, and assuming $B(H^{\pm\pm} \rightarrow \ell^\pm\ell^\pm) = 1$, a 95% CL limit on $h_{ee} < 0.071$ is set for $m_{H^{\pm\pm}} < 160$ GeV (see Fig. 6). In the second case, indirect limits on h_{ee} are set for $m_{H^{\pm\pm}} < 2$ TeV (see Fig. 8).
- 190 GORDEEV 97 search for muonium-antimuonium conversion and find $G_{M\bar{M}}/G_F < 0.14$ (90% CL), where $G_{M\bar{M}}$ is the lepton-flavor violating effective four-fermion coupling. This limit may be converted to $m_{H^{++}} > 210$ GeV if the Yukawa couplings of H^{++} to ee and $\mu\mu$ are as large as the weak gauge coupling. For similar limits on muonium-antimuonium conversion, see the muon Particle Listings.
- 191 ASAKA 95 point out that H^{++} decays dominantly to four fermions in a large region of parameter space where the limit of ACTON 92M from the search of dilepton modes does not apply.
- 192 ACTON 92M limit assumes $H^{\pm\pm} \rightarrow \ell^\pm\ell^\pm$ or $H^{\pm\pm}$ does not decay in the detector. Thus the region $g_{\ell\ell} \approx 10^{-7}$ is not excluded.
- 193 ACTON 92M from $\Delta\Gamma_Z < 40$ MeV.
- 194 SWARTZ 90 assume $H^{\pm\pm} \rightarrow \ell^\pm\ell^\pm$ (any flavor). The limits are valid for the Higgs-lepton coupling $g(H\ell\ell) \gtrsim 7.4 \times 10^{-7} [m_H/\text{GeV}]^{1/2}$. The limits improve somewhat for ee and $\mu\mu$ decay modes.

- 195 ABAZOV 12A search for $H^{++}H^{--}$ production in 7.0 fb^{-1} of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV.
- 196 AALTONEN 11AF search for $H^{++}H^{--}$ production in 6.1 fb^{-1} of $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV.
- 197 ABAZOV 08V search for $H^{++}H^{--}$ production in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. The limit is for $B(H \rightarrow \mu\mu) = 1$. The limit is updated in ABAZOV 12A.
- 198 ABDALLAH 03 search for $H^{++}H^{--}$ pair production either followed by $H^{++} \rightarrow \tau^+\tau^+$, or decaying outside the detector.
- 199 ACHARD 03F search for $e^+e^- \rightarrow H^{++}H^{--}$ with $H^{\pm\pm} \rightarrow \ell^\pm\ell^\pm$. The limit holds for $\ell = \ell' = \tau$, and slightly different limits apply for other flavor combinations. The limit is valid for $g_{\ell\ell} \gtrsim 10^{-7}$.
- 200 ABBIENDI 02c searches for pair production of $H^{++}H^{--}$, with $H^{\pm\pm} \rightarrow \ell^\pm\ell^\pm$ ($\ell, \ell' = e, \mu, \tau$). The limit holds for $\ell = \ell' = \tau$, and becomes stronger for other combinations of leptonic final states. To ensure the decay within the detector, the limit only applies for $g(H\ell\ell) \gtrsim 10^{-7}$.
- 201 AKTAS 06A search for single $H^{\pm\pm}$ production in ep collisions at HERA. Assuming that H^{++} only couples to $e^+\mu^+$ with $g_{e\mu} = 0.3$ (electromagnetic strength), a limit $m_{H^{++}} > 141$ GeV (95% CL) is derived. For the case where H^{++} couples to $e\tau$ only the limit is 112 GeV.
- 202 ACOSTA 05L search for $H^{++}H^{--}$ pair production in $p\bar{p}$ collisions. The limit is valid for $g_{\ell\ell} < 10^{-8}$ so that the Higgs decays outside the detector.
- 203 ABAZOV 04E search for $H^{++}H^{--}$ pair production in $H^{\pm\pm} \rightarrow \mu^\pm\mu^\pm$. The limit is valid for $g_{\mu\mu} \gtrsim 10^{-7}$.
- 204 ACOSTA 04G search for $H^{++}H^{--}$ pair production in $p\bar{p}$ collisions with muon and electron final states. The limit holds for $\mu\mu$. Superseded by AALTONEN 11AF.
- 205 ABBIENDI 03Q searches for single $H^{\pm\pm}$ via direct production in $e^+e^- \rightarrow e^\mp e^\mp H^{\pm\pm}$, and via t -channel exchange in $e^+e^- \rightarrow e^+e^-$. In the direct case, and assuming $B(H^{\pm\pm} \rightarrow \ell^\pm\ell^\pm) = 1$, a 95% CL limit on $h_{ee} < 0.071$ is set for $m_{H^{\pm\pm}} < 160$ GeV (see Fig. 6). In the second case, indirect limits on h_{ee} are set for $m_{H^{\pm\pm}} < 2$ TeV (see Fig. 8).
- 206 GORDEEV 97 search for muonium-antimuonium conversion and find $G_{M\bar{M}}/G_F < 0.14$ (90% CL), where $G_{M\bar{M}}$ is the lepton-flavor violating effective four-fermion coupling. This limit may be converted to $m_{H^{++}} > 210$ GeV if the Yukawa couplings of H^{++} to ee and $\mu\mu$ are as large as the weak gauge coupling. For similar limits on muonium-antimuonium conversion, see the muon Particle Listings.
- 207 ACTON 92M limit assumes $H^{\pm\pm} \rightarrow \ell^\pm\ell^\pm$ or $H^{\pm\pm}$ does not decay in the detector. Thus the region $g_{\ell\ell} \approx 10^{-7}$ is not excluded.
- 208 ACTON 92M from $\Delta\Gamma_Z < 40$ MeV.
- 209 SWARTZ 90 assume $H^{\pm\pm} \rightarrow \ell^\pm\ell^\pm$ (any flavor). The limits are valid for the Higgs-lepton coupling $g(H\ell\ell) \gtrsim 7.4 \times 10^{-7} [m_H/\text{GeV}]^{1/2}$. The limits improve somewhat for ee and $\mu\mu$ decay modes.

W' -BOSON SEARCHES

Revised May 2012 by G. Brooijmans (Columbia University), M.-C. Chen (UC Irvine) and B.A. Dobrescu (Fermilab).

The W' boson is a hypothetical massive particle of electric charge ± 1 and spin 1, which is predicted in various extensions of the Standard Model.

W' couplings to quarks and leptons. The Lagrangian terms describing couplings of a W'^{\pm} boson to fermions are given by

$$\frac{W'^{\pm}}{\sqrt{2}} \left[\bar{u}_i (C_{qij}^R P_R + C_{qij}^L P_L) \gamma^\mu d_j + \bar{\nu}_i (C_{l ij}^R P_R + C_{l ij}^L P_L) \gamma^\mu e_j \right]. \quad (1)$$

Here u, d, ν and e are the Standard Model fermions in the mass eigenstate basis, $i, j = 1, 2, 3$ label the fermion generation,

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

and $P_{R,L} = (1 \pm \gamma_5)/2$. The coefficients C_{qij}^L , C_{qij}^R , C_{lij}^L , C_{lij}^R are complex dimensionless parameters. If $C_{lij}^R \neq 0$, then the i th generation includes a right-handed neutrino. Using this notation, the Standard Model W couplings are $C_q^L = gV_{\text{CKM}}$, $C_l^L = g$ and $C_q^R = C_l^R = 0$.

Unitarity considerations imply that the W' is a gauge boson associated with a spontaneously-broken gauge symmetry. This is true even when it is a composite particle (*e.g.*, techni- ρ^\pm in technicolor theories [1]) if its mass is much smaller than the compositeness scale, or a Kaluza-Klein mode in theories where the W boson propagates in extra dimensions [2]. The simplest extension of the electroweak gauge group that includes a W' boson is $SU(2)_1 \times SU(2)_2 \times U(1)$, but larger groups are encountered in some theories. A generic property of these gauge theories is that they also include a Z' boson; whether the W' boson can be discovered first depends on theoretical details.

The renormalizable photon- W' coupling is fixed by electromagnetic gauge invariance. By contrast, the $W'WZ$ and $W'W'Z$ couplings as well as the W' boson couplings to Z' or Higgs bosons are model-dependent.

A tree-level mass mixing may be induced between the electrically-charged gauge bosons. Upon diagonalization of their mass matrix, the $W - Z$ mass ratio and the couplings of the observed W boson are shifted from the Standard Model values. Given that these are well measured, the $W - W'$ mixing angle must be smaller than about 10^{-2} . Similarly, a $Z - Z'$ mixing is induced in generic theories, leading to even tighter constraints. There are, however, theories in which these mixings are negligible (*e.g.*, due to a new parity [3]), even when the W' and Z' masses are below the electroweak scale.

A popular model [4] is based on the “left-right symmetric” gauge group, $SU(2)_L \times SU(2)_R \times U(1)_{B-L}$, with the Standard Model fermions that couple to the W boson transforming as doublets under $SU(2)_L$, and the other ones transforming as doublets under $SU(2)_R$. In this model the W' boson couples primarily to the right-handed fermions, and its coupling to left-handed fermions arises solely due to $W - W'$ mixing. As a result, C_q^L is proportional to the CKM matrix, and its elements are much smaller than the diagonal elements of C_q^R .

There are many other models based on the $SU(2)_1 \times SU(2)_2 \times U(1)$ gauge symmetry. In the “alternate left-right” model [5], all the couplings shown in Eq. (1) vanish, but there are some new fermions such that the W' boson couples to pairs involving a Standard Model fermion and a new fermion. In the “unified Standard Model” [6], the left-handed quarks are doublets under one $SU(2)$, and the left-handed leptons are doublets under a different $SU(2)$, leading to a mostly leptophobic W' boson: $C_{lij}^L \ll C_{qij}^L$ and $C_{qij}^R = C_{lij}^R = 0$. Fermions of different generations may also transform as doublets under different $SU(2)$ gauge groups [7]. In particular, the couplings to third generation quarks may be enhanced [8].

The W' couplings to Standard Model fermions may be highly suppressed if the quarks and leptons are singlets under one $SU(2)$ [9], or if there are some vectorlike fermions that

mix with the Standard Model ones [10]. Gauge groups that embed the electroweak symmetry, such as $SU(3)_W \times U(1)$ or $SU(4)_W \times U(1)$, also include one or more W' bosons [11].

Collider searches. At LEP-II, W' bosons could have been produced in pairs via their photon and Z couplings. The production cross section depends only on the W' mass, and is large enough to rule out $M_{W'} \leq \sqrt{s}/2 \approx 105$ GeV for most patterns of decay modes.

At hadron colliders, W' bosons can be detected through resonant pair production of fermions or electroweak bosons. Assuming that the W' width is much smaller than its mass, the contribution of the s -channel W' boson exchange to the total rate for $pp \rightarrow f\bar{f}'X$, where f and f' are fermions whose electric charges differ by ± 1 , and X is any final state, may be approximated by the branching fraction $B(W' \rightarrow f\bar{f}')$ times the production cross section

$$\sigma(pp \rightarrow W'X) \simeq \frac{\pi}{48s} \sum_{i,j} \left[(C_{qij}^L)^2 + (C_{qij}^R)^2 \right] w_{ij}(M_{W'}^2/s, M_{W'}). \quad (2)$$

The functions w_{ij} include the information about proton structure, and are given to leading order in α_s by

$$w_{ij}(z, \mu) = \int_z^1 \frac{dx}{x} \left[u_i(x, \mu) \bar{d}_j\left(\frac{z}{x}, \mu\right) + \bar{u}_i(x, \mu) d_j\left(\frac{z}{x}, \mu\right) \right], \quad (3)$$

where $u_i(x, \mu)$ and $d_i(x, \mu)$ are the parton distributions inside the proton at the factorization scale μ for the up- and down-type quark of the i th generation, respectively. QCD corrections to W' production are sizable (they also include quark-gluon initial states), but preserve the above factorization of couplings at next-to-leading order [12].

The most commonly studied W' signal consists of a high-energy electron or muon and large missing transverse energy, with the transverse mass distribution forming a Jacobian peak with its endpoint at $M_{W'}$ (see Fig. 1 of Ref. 13). Given that the branching fractions for $W' \rightarrow e\nu$ and $W' \rightarrow \mu\nu$ could be very different, these channels should be analyzed separately. Searches in these channels often assume that the left-handed couplings vanish (no interference between W and W'), and that the right-handed neutrino of the first generation is light compared to $M_{W'}$ and escapes the detector. However, if a W' boson were discovered and the final state fermions have left-handed helicity, then the effects of $W - W'$ interference could be observed [14], providing useful information about the W' couplings.

In the $e\nu$ channel, the 95% CL limit set by the ATLAS Collaboration [13] with 1 fb^{-1} of data on the cross section (at $\sqrt{s} = 7$ TeV) times branching fraction is shown in Fig. 1. The CMS limit based on 5 fb^{-1} of data in this channel [15], for $M_{W'}$ in the $0.5 - 3$ TeV range, varies between 70 and 2.6 fb . For $M_{W'}$ in the $500 - 600$ GeV range, the strongest limits on W' couplings are set by CDF [16] with 5.3 fb^{-1} (for a comparison, see Fig. 3 of Ref. 13). The limits are much weaker for $M_{W'}$ in the $200 - 500$ GeV range because these were obtained using only

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

Figure 1: 95% CL limit on $\sigma(pp \rightarrow W'X) \times B(W' \rightarrow e\nu)$ from ATLAS [13]. The theoretical prediction (dash-dotted line) is for $C_q^R = gV_{CKM}$, $C_l^R = g$, $C_q^L = C_l^L = 0$.

Figure 2: 95% CL upper limits on W' couplings using the $t\bar{b}$ and $\bar{t}b$ final states, assuming that the diagonal couplings are generation independent. Left panel: D0 [21] limit on C_{q11}^R/g as contours in the $C_{q11}^R/g - M_{W'}$ plane. Right panel: CDF [22] limit on g_W/g_W .

of Tevatron data [17], while the 105 – 200 GeV range has been even less explored (see the UA1 and UA2 references in Ref. 18).

In the $\mu\nu$ channel, the most stringent limit in the 0.5 – 3 TeV range, set by CMS [15] with 5 fb^{-1} , varies between 39 and 2.7 fb. The ATLAS $\mu\nu$ limit [13] is higher by about 50% compared to that shown in Fig. 1. For $M_{W'}$ in the 200 – 500 GeV range there are only weak limits on the W' couplings from the Tevatron Run I [19]. There are no direct limits on $W' \rightarrow \mu\nu$ for $M_{W'}$ in the 105 – 200 GeV range.

Dedicated searches for the $W' \rightarrow \tau\nu$ decay have not yet been performed, but limits can be derived from some searches in the $\ell + \cancel{E}_T$ channel as well as from charged-Higgs searches such as $pp \rightarrow t\bar{b}\tau\nu X$.

The W' decay into a lepton and a right-handed neutrino, ν_R , may also be followed by the ν_R decay through a virtual W' boson into a lepton and two quark jets. The ATLAS search [20] with 2.1 fb^{-1} sets cross-section limits in the $\ell^+\ell^-jj$ channel decreasing from 20 fb to 3 fb for $M_{W'}$ in the 1 – 2.7 TeV range.

The $t\bar{b}$ channel is particularly important because a W' boson that couples only to right-handed fermions cannot decay to leptons when the right-handed neutrinos are heavier than $M_{W'}$ (additional motivations are provided by a W' boson with enhanced couplings to the third generation [8], and by a leptophobic W' boson). The usual signal consists of a leptonically decaying W boson and two b -jets. The upper limits on the W' couplings to left- and right-handed quarks normalized to the Standard Model W boson couplings, set by D0 with 2.3 fb^{-1} [21] and by CDF with 1.9 fb^{-1} [22], respectively, are shown in Fig. 2. LHC searches in this channel have set cross section limits for $M_{W'}$ in the 0.5 – 2.1 TeV range [23].

For $M_{W'} \gg m_t$, one could also use hadronic W boson decays to search for $W' \rightarrow t\bar{b}$ with a boosted top quark. If W' couplings to left-handed quarks are large, then interference effects modify the Standard Model s -channel single-top production [24].

Searches for dijet resonances may be used to set limits on $W' \rightarrow q\bar{q}'$ [18]. In the 105 – 200 GeV mass range the limits are rather weak, as they have been set so far only by the UA2 Collaboration; even in the 200 – 700 GeV range only small data sets from the Tevatron and the LHC have been used so far.

In some theories [3], the W' couplings to Standard Model fermions are suppressed by discrete symmetries. W' production then occurs in pairs, through a photon or Z boson. The decay modes are model-dependent and often involve other new particles. The ensuing collider signals arise from cascade decays and typically include missing transverse energy.

A fermiophobic W' boson which couples to WZ may be produced at hadron colliders in association with a Z boson, or via WZ fusion. This would give rise to $(WZ)Z$ and $(WZ)jj$ final states, where the parentheses represent a resonance [25]. The study of these processes is important for understanding the origin of electroweak symmetry-breaking. The D0 [26] and CDF [27] Collaborations have set limits on $\sigma(pp \rightarrow W'X) \times B(W' \rightarrow WZ)$ for $M_{W'}$ in the 180 – 1000 GeV range, while searches [28] at the 7 TeV LHC have set cross-section limits for $M_{W'}$ in the 200 – 1500 GeV range.

Low-energy constraints. The properties of W' bosons are also constrained by measurements of processes at energies much below $M_{W'}$. The bounds on $W - W'$ mixing [18] are mostly due to the change in the properties of the W boson compared to the Standard Model. Limits on the deviation in the ZWW coupling provide a leading constraint for fermiophobic W' bosons [10].

Constraints arising from low-energy effects of W' exchange are strongly model-dependent. If the W' couplings to quarks are not suppressed, then box diagrams involving a W and a W' boson contribute to neutral meson-mixing. In the case of W' couplings to right-handed quarks as in the left-right symmetric model, the limit from $K_L - K_S$ mixing is severe: $M_{W'} > 2.5 \text{ TeV}$ [29]. However, if no correlation between C_{qij}^R and C_{lij}^R is assumed, then the limit on $M_{W'}$ may be significantly relaxed [30].

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

W' exchange also contributes at tree level to various low-energy processes. In particular, it would impact the measurement of the Fermi constant G_F in muon decay, which in turn would change the predictions of many other electroweak processes. A recent test of parity violation in polarized muon decay [31] has set limits of about 600 GeV on $M_{W'}$, assuming W' couplings to right-handed leptons as in left-right symmetric models. There are also W' contributions to the neutron electric dipole moment, β decays, and other processes [18].

If right-handed neutrinos have Majorana masses, then there are tree-level contributions to neutrinoless double-beta decay, and a limit on $M_{W'}$ versus the ν_R mass may be derived [32]. For ν_R masses below a few GeV, the W' boson contributes to leptonic and semileptonic B meson decays, so that limits may be placed on various combinations of W' parameters [30]. For ν_R masses below ~ 30 MeV, most stringent constraints on $M_{W'}$ are due to the limits on ν_R emission from supernova.

MASS LIMITS for W' (Heavy Charged Vector Boson Other Than W) in Hadron Collider Experiments

Couplings of W' to quarks and leptons are taken to be identical with those of W . The following limits are obtained from $p\bar{p} \rightarrow W'X$ with W' decaying to the mode indicated in the comments. New decay channels (*e.g.*, $W' \rightarrow WZ$) are assumed to be suppressed. The most recent preliminary results can be found in the " W' -boson searches" review above.

¹ The quoted limit is obtained assuming $W'WZ$ coupling strength is the same as the ordinary WWZ coupling strength in the Standard Model.

² ABAZOV 11L limit is for W' with SM-like coupling which interferes with the SM W boson. For W' with right-handed coupling, the bound becomes >885 GeV (>890 GeV) if W' decays to both leptons and quarks (only to quarks). If both left- and right-handed couplings present, the limit becomes >916 GeV.

³ The quoted limit assumes $g_{W'WZ}/g_{WWZ} = (M_W/M_{W'})^2$. See their Fig. 4 for limits in mass-coupling plane.

⁴ The quoted limit assumes $g_{W'WZ}/g_{WWZ} = (M_W/M_{W'})^2$. See their Fig. 3 for limits in mass-coupling plane.

- 12 ABE 00 assume that the neutrino from W' decay is stable and has a mass significantly less than $m_{W'}$.
- 13 ABE 97g search for new particle decaying to dijets.
- 14 For bounds on W_R with nonzero right-handed mass, see Fig. 5 from ABACHI 96c.
- 15 ABACHI 95E assume that the decay $W' \rightarrow WZ$ is suppressed and that the neutrino from W' decay is stable and has a mass significantly less than $m_{W'}$.
- 16 ABE 95M assume that the decay $W' \rightarrow WZ$ is suppressed and the (right-handed) neutrino is light, noninteracting, and stable. If $m_\nu=60$ GeV, for example, the effect on the mass limit is negligible.
- 17 RIZZO 93 analyses CDF limit on possible two-jet resonances. The limit is sensitive to the inclusion of the assumed K factor.

W_R (Right-Handed W Boson) MASS LIMITS

Assuming a light right-handed neutrino, except for BEALL 82, LANGACKER 89b, and COLANGELO 91. $g_R = g_L$ assumed. [Limits in the section MASS LIMITS for W' below are also valid for W_R if $m_{\nu R} \ll m_{W_R}$.] Some limits assume manifest left-right symmetry, i.e., the equality of left- and right Cabibbo-Kobayashi-Maskawa matrices. For a comprehensive review, see LANGACKER 89b. Limits on the W_L - W_R mixing angle ζ are found in the next section. Values in brackets are from cosmological and astrophysical considerations and assume a light right-handed neutrino.

- 18 CZAKON 99 perform a simultaneous fit to charged and neutral sectors.
- 19 WAUTERS 10 limit is from a measurement of the asymmetry parameter of polarized ^{60}Co β decays. The listed limit assumes no mixing.
- 20 MELCONIAN 07 measure the neutrino angular asymmetry in β^+ -decays of polarized ^{37}K , stored in a magneto-optical trap. Result is consistent with SM prediction and does not constrain the W_L - W_R mixing angle appreciably.
- 21 SCHUMANN 07 limit is from measurements of the asymmetry $\langle \bar{p}_\nu \cdot \sigma_n \rangle$ in the β decay of polarized neutrons. Zero mixing is assumed.
- 22 CYBURT 05 limit follows by requiring that three light ν_R 's decouple when $T_{dec} > 140$ MeV. For different T_{dec} , the bound becomes $M_{W_R} > 3.3 \text{ TeV} (T_{dec} / 140 \text{ MeV})^{3/4}$.
- 23 THOMAS 01 limit is from measurement of β^+ polarization in decay of polarized ^{12}N . The listed limit assumes no mixing.
- 24 ACKERSTAFF 99D limit is from τ decay parameters. Limit increase to 145 GeV for zero mixing.

- 25 BARENBOIM 98 assumes minimal left-right model with Higgs of $SU(2)_R$ in $SU(2)_L$ doublet. For Higgs in $SU(2)_L$ triplet, $m_{W_R} > 1100$ GeV. Bound calculated from effect of corresponding Z_{LR} on electroweak data through Z - Z_{LR} mixing.
- 26 The quoted limit is from μ decay parameters. BARENBOIM 97 also evaluate limit from K_L - K_S mass difference.
- 27 STAHL 97 limit is from fit to τ -decay parameters.
- 28 ALLET 96 measured polarization-asymmetry correlation in ^{12}N β^+ decay. The listed limit assumes zero L - R mixing.
- 29 KUZNETSOV 95 limit is from measurements of the asymmetry $\langle \bar{p}_\nu \cdot \sigma_n \rangle$ in the β decay of polarized neutrons. Zero mixing assumed. See also KUZNETSOV 94b.
- 30 KUZNETSOV 94b limit is from measurements of the asymmetry $\langle \bar{p}_\nu \cdot \sigma_n \rangle$ in the β decay of polarized neutrons. Zero mixing assumed.
- 31 BHATTACHARYYA 93 uses Z - Z' mixing limit from LEP '90 data, assuming a specific Higgs sector of $SU(2)_L \times SU(2)_R \times U(1)$ gauge model. The limit is for $m_t=200$ GeV and slightly improves for smaller m_t .
- 32 SEVERIJNS 93 measured polarization-asymmetry correlation in ^{107}In β^+ decay. The listed limit assumes zero L - R mixing. Value quoted here is from SEVERIJNS 94 erratum.
- 33 IMAZATO 92 measure positron asymmetry in $K^+ \rightarrow \mu^+ \nu_\mu$ decay and obtain $\xi_{P,\mu} > 0.990$ (90% CL). If W_R couples to $u\bar{s}$ with full weak strength ($V_{us}^R=1$), the result corresponds to $m_{W_R} > 653$ GeV. See their Fig. 4 for m_{W_R} limits for general $|V_{us}^R|^2=1-|V_{ud}^R|^2$.
- 34 POLAK 92b limit is from fit to muon decay parameters and is essentially determined by JODIDIO 86 data assuming $\zeta=0$. Supersedes POLAK 91.
- 35 AQUINO 91 limits obtained from neutron lifetime and asymmetries together with unitarity of the CKM matrix. Manifest left-right symmetry assumed. Stronger of the two limits also includes muon decay results.
- 36 COLANGELO 91 limit uses hadronic matrix elements evaluated by QCD sum rule and is less restrictive than BEALL 82 limit which uses vacuum saturation approximation. Manifest left-right symmetry assumed.
- 37 POLAK 91 limit is from fit to muon decay parameters and is essentially determined by JODIDIO 86 data assuming $\zeta=0$. Superseded by POLAK 92b.
- 38 BARBIERI 89b limit holds for $m_{\nu R} \leq 10$ MeV.
- 39 LANGACKER 89b limit is for any ν_R mass (either Dirac or Majorana) and for a general class of right-handed quark mixing matrices.
- 40 BALKE 88 limit is for $m_{\nu e R} = 0$ and $m_{\nu \mu R} \leq 50$ MeV. Limits come from precise measurements of the muon decay asymmetry as a function of the positron energy.
- 41 JODIDIO 86 is the same TRIUMF experiment as STOKER 85 (and CARR 83); however, it uses a different technique. The results given here are combined results of the two techniques. The technique here involves precise measurement of the end-point e^+ spectrum in the decay of the highly polarized μ^+ .
- 42 STOKER 85 is same TRIUMF experiment as CARR 83. Here they measure the decay e^+ spectrum asymmetry above 46 MeV/c using a muon-spin-rotation technique. Assumed a light right-handed neutrino. Quoted limits are from combining with CARR 83.
- 43 BERGSMA 83 set limit $m_{W_2}/m_{W_1} > 1.9$ at CL = 90%.
- 44 CARR 83 is TRIUMF experiment with a highly polarized μ^+ beam. Looked for deviation from $V-A$ at the high momentum end of the decay e^+ energy spectrum. Limit from previous world-average muon polarization parameter is $m_{W_R} > 240$ GeV. Assumes a light right-handed neutrino.
- 45 BEALL 82 limit is obtained assuming that W_R contribution to K_L^0 - K_S^0 mass difference is smaller than the standard one, neglecting the top quark contributions. Manifest left-right symmetry assumed.

Limit on W_L - W_R Mixing Angle ζ

Lighter mass eigenstate $W_1 = W_L \cos \zeta - W_R \sin \zeta$. Light ν_R assumed unless noted. Values in brackets are from cosmological and astrophysical considerations.

49 MISHRA 92 limit is from the absence of extra large- x , large- y $\bar{\nu}_\mu N \rightarrow \bar{\nu}_\mu X$ events at Tevatron, assuming left-handed ν and right-handed $\bar{\nu}$ in the neutrino beam. The result gives $\zeta^2(1-2m_W^2/m_{W_2}^2) < 0.0015$. The limit is independent of ν_R mass.				
50 AQUINO 91 limits obtained from neutron lifetime and asymmetries together with unitarity of the CKM matrix. Manifest left-right asymmetry is assumed.				
51 BARBIERI 89b limit holds for $m_{\nu R} \leq 10$ MeV.				
52 First JODIDIO 86 result assumes $m_{W_R} = \infty$, second is for unconstrained m_{W_R} .				

Z' -BOSON SEARCHES

Revised May 2012 by G. Brooijmans (Columbia University), M.-C. Chen (UC Irvine), and B.A. Dobrescu (Fermilab).

The Z' boson is a hypothetical massive, electrically-neutral and color-singlet particle of spin 1. This particle is predicted

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

in many extensions of the Standard Model, and has been the object of extensive phenomenological studies [1].

Z' boson couplings to quarks and leptons. The couplings of a Z' boson to the first-generation fermions are given by

$$Z'_\mu (g_u^L \bar{u}_L \gamma^\mu u_L + g_d^L \bar{d}_L \gamma^\mu d_L + g_u^R \bar{u}_R \gamma^\mu u_R + g_d^R \bar{d}_R \gamma^\mu d_R + g_\nu^L \bar{\nu}_L \gamma^\mu \nu_L + g_e^L \bar{e}_L \gamma^\mu e_L + g_e^R \bar{e}_R \gamma^\mu e_R) , \quad (1)$$

where u, d, ν and e are the quark and lepton fields in the mass eigenstate basis, and the coefficients $g_u^L, g_d^L, g_u^R, g_d^R, g_\nu^L, g_e^L, g_e^R$ are real dimensionless parameters. If the Z' couplings to quarks and leptons are generation-independent, then these seven parameters describe the couplings of the Z' boson to all Standard Model fermions. More generally, however, the Z' couplings to fermions are generation-dependent, in which case Eq. (1) may be written with generation indices $i, j = 1, 2, 3$ labeling the quark and lepton fields, and with the seven coefficients promoted to 3×3 Hermitian matrices (e.g., $g_{eij}^L \bar{e}_L^i \gamma^\mu e_L^j$, where e_L^2 is the left-handed muon, etc.).

These parameters describing the Z' boson interactions with quarks and leptons are subject to some theoretical constraints. Quantum field theories that include a heavy spin-1 particle are well behaved at high energies only if that particle is a gauge boson associated with a spontaneously broken gauge symmetry. Quantum effects preserve the gauge symmetry only if the couplings of the gauge boson to fermions satisfy anomaly cancellation conditions. Furthermore, the fermion charges under the new gauge symmetry are constrained by the requirement that the quarks and leptons get masses from gauge-invariant interactions with Higgs doublets or whatever else breaks the electroweak symmetry.

The relation between the couplings displayed in Eq. (1) and the gauge charges z_{fi}^L and z_{fi}^R of the fermions $f = u, d, \nu, e$ involves the unitary 3×3 matrices V_f^L and V_f^R that transform the gauge eigenstate fermions f_L^i and f_R^i , respectively, into the mass eigenstates. In addition, the Z' couplings are modified if the new gauge boson in the gauge eigenstate basis (\tilde{Z}'_μ) has a kinetic mixing $(-\chi/2)B^{\mu\nu}\tilde{Z}'_{\mu\nu}$ with the hypercharge gauge boson B^μ (due to a dimension-4 or 6 operator, depending on whether the new gauge symmetry is Abelian or not), or a mass mixing $\delta M^2 \tilde{Z}'^\mu \tilde{Z}'_\mu$ with the linear combination (\tilde{Z}_μ) of neutral bosons which has same couplings as the Standard Model Z^0 [2]. Both the kinetic and mass mixings shift the mass and couplings of the Z boson, such that the electroweak measurements impose upper limits on χ and $\delta M^2/(M_{Z'}^2 - M_Z^2)$ of the order of 10^{-3} [3]. Keeping only linear terms in these two small quantities, the couplings of the mass-eigenstate Z' boson are given by

$$g_{fij}^L = g_z V_{fii'}^L z_{f'i'}^L (V_f^L)_{i'j}^\dagger + \frac{e}{c_W} \left(\frac{s_W \chi M_{Z'}^2 + \delta M^2}{2s_W (M_{Z'}^2 - M_Z^2)} \sigma_f^3 - \epsilon Q_f \right) ,$$

$$g_{fij}^R = g_z V_{fii'}^R z_{f'i'}^R (V_f^R)_{i'j}^\dagger - \frac{e}{c_W} \epsilon Q_f , \quad (2)$$

where g_z is the new gauge coupling, Q_f is the electric charge of f , e is the electromagnetic gauge coupling, s_W and c_W are the

Table 1: Examples of generation-independent $U(1)'$ charges for quarks and leptons. The parameter x is an arbitrary rational number. Anomaly cancellation requires certain new fermions [4].

fermion	$U(1)_{B-xL}$	$U(1)_{10+x5}$	$U(1)_{d-xu}$	$U(1)_{q+xu}$
(u_L, d_L)	1/3	1/3	0	1/3
u_R	1/3	-1/3	-x/3	x/3
d_R	1/3	-x/3	1/3	(2-x)/3
(ν_L, e_L)	-x	x/3	(-1+x)/3	-1
e_R	-x	-1/3	x/3	-(2+x)/3

sine and cosine of the weak mixing angle, $\sigma_f^3 = +1$ for $f = u, \nu$ and $\sigma_f^3 = -1$ for $f = d, e$, and

$$\epsilon = \frac{\chi (M_{Z'}^2 - c_W^2 M_Z^2) + s_W \delta M^2}{M_{Z'}^2 - M_Z^2} . \quad (3)$$

$U(1)$ gauge groups. A simple origin of a Z' boson is a new $U(1)'$ gauge symmetry. In that case, the matricial equalities $z_u^L = z_d^L$ and $z_\nu^L = z_e^L$ are required by the $SU(2)_W$ gauge symmetry. Given that the $U(1)'$ interaction is not asymptotically free, the theory may be well-behaved at high energies (for example, by embedding $U(1)'$ in a non-Abelian gauge group) only if the Z' couplings are commensurate numbers, i.e. any ratio of couplings is a rational number. Satisfying the anomaly cancellation conditions (which include an equation cubic in charges) with rational numbers is highly nontrivial, and in general new fermions charged under $U(1)'$ are necessary.

Consider first the case where the couplings are generation-independent (the V_f matrices then disappear from Eq. (2)), so that there are five commensurate couplings: $g_q^L, g_u^R, g_d^R, g_l^L, g_e^R$. Four sets of charges are displayed in Table 1, each of them spanned by one free parameter, x [4]. The first set, labelled $B-xL$, has charges proportional to the baryon number minus x times the lepton number. These charges allow all Standard Model Yukawa couplings to a Higgs doublet which is neutral under $U(1)_{B-xL}$, so that there is no tree-level $\tilde{Z}-\tilde{Z}'$ mixing. For $x=1$ one recovers the $U(1)_{B-L}$ group, which is non-anomalous in the presence of one ‘‘right-handed neutrino’’ (a chiral fermion that is a singlet under the Standard Model gauge group) per generation. For $x \neq 1$, it is necessary to include some fermions that are vector-like (i.e. their mass terms are gauge invariant) with respect to the electroweak gauge group and chiral with respect to $U(1)_{B-xL}$. In the particular cases $x=0$ or $x \gg 1$ the Z' is leptophobic or quark-phobic, respectively.

The second set, $U(1)_{10+x5}$, has charges that commute with the representations of the $SU(5)$ grand unified group. Here x is related to the mixing angle between the two $U(1)$ bosons encountered in the $E_6 \rightarrow SU(5) \times U(1) \times U(1)$ symmetry breaking patterns of grand unified theories [1,6]. This set leads to $\tilde{Z}-\tilde{Z}'$ mass mixing at tree level, such that for a Z' mass close to the electroweak scale, the measurements at

See key on page 457

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

the Z -pole require some fine tuning between the charges and VEVs of the two Higgs doublets. Vector-like fermions charged under the electroweak gauge group and also carrying color are required (except for $x = -3$) to make this set anomaly free. The particular cases $x = -3, 1, -1/2$ are usually labelled $U(1)_\chi$, $U(1)_\psi$, and $U(1)_\eta$, respectively. Under the third set, $U(1)_{d-xu}$, the weak-doublet quarks are neutral, and the ratio of u_R and d_R charges is $-x$. For $x = 1$ this is the “right-handed” group $U(1)_R$. For $x = 0$, the charges are those of the E_6 -inspired $U(1)_I$ group, which requires new quarks and leptons. Other generation-independent sets of $U(1)'$ charges are given in [5].

Table 2: Lepton-flavor dependent charges under various $U(1)$ gauge groups. No new fermions other than right-handed neutrinos are required.

fermion	$B - xL_e - yL_\mu$	2+1 leptocratic
q_{1L}, q_{2L}, q_{3L}	1/3	1/3
u_R, c_R, t_R	1/3	$x/3$
d_R, s_R, b_R	1/3	$(2 - x)/3$
(ν_L^e, e_L)	$-x$	$-1 - 2y$
(ν_L^μ, μ_L)	$-y$	$-1 + y$
(ν_L^τ, τ_L)	$x + y - 3$	$-1 + y$
e_R	$-x$	$-(2 + x)/3 - 2y$
μ_R	$-y$	$-(2 + x)/3 + y$
τ_R	$x + y - 3$	$-(2 + x)/3 + y$

In the absence of new fermions charged under the Standard Model group, the most general generation-independent charge assignment is $U(1)_{q+xu}$, which is a linear combination of hypercharge and $B - L$. Many other anomaly-free solutions exist if generation-dependent charges are allowed. Table 2 shows such solutions that depend on two free parameters, x and y , with generation dependence only in the lepton sector, which includes one right-handed neutrino per generation. The charged-lepton masses may be generated by Yukawa couplings to a single Higgs doublet. These are forced to be flavor diagonal by the generation-dependent $U(1)'$ charges, so that there are no tree-level flavor-changing neutral current (FCNC) processes involving electrically-charged leptons. For the “leptocratic” set, neutrino masses are induced by operators of high dimensionality that may explain their smallness [7].

If the $SU(2)_W$ -doublet quarks have generation-dependent $U(1)'$ charges, then the mass eigenstate quarks have flavor off-diagonal couplings to the Z' boson (see Eq. (1), and note that $V_u^L (V_d^L)^\dagger$ is the CKM matrix). These are severely constrained by measurements of FCNC processes, which in this case are mediated at tree-level by Z' boson exchange [8]. The constraints are relaxed if the first and second generation charges are the same, although they are increasingly tightened by the measurements of B meson properties. If only the $SU(2)_W$ -singlet quarks have generation-dependent $U(1)'$ charges, there is more

freedom in adjusting the flavor off-diagonal couplings because the $V_{u,d}^R$ matrices are not observable in the Standard Model.

The anomaly cancellation conditions for $U(1)'$ could be relaxed only if at scales above $\sim 4\pi M_{Z'}/g_z$ there is an axion which has certain dimension-5 couplings to the gauge bosons. However, such a scenario violates unitarity unless the quantum field theory description breaks down at a scale near $M_{Z'}$ [9].

Other models. Z' bosons may also arise from larger gauge groups. These may be orthogonal to the electroweak group, as in $SU(2)_W \times U(1)_Y \times SU(2)'$, or may embed the electroweak group, as in $SU(3)_W \times U(1)$ [10]. If the larger group is spontaneously broken down to $SU(2)_W \times U(1)_Y \times U(1)'$ at a scale $v_\star \gg M_{Z'}/g_z$, then the above discussion applies up to corrections of order $M_{Z'}^2/(g_z v_\star)^2$. For $v_\star \sim M_{Z'}/g_z$, additional gauge bosons have masses comparable to $M_{Z'}$, including at least a W' boson [10]. If the larger gauge group breaks together with the electroweak symmetry directly to the electromagnetic $U(1)_{em}$, then the left-handed fermion charges are no longer correlated ($z_u^L \neq z_d^L, z_\nu^L \neq z_e^L$) and a $Z'W^+W^-$ coupling is induced.

If the electroweak gauge bosons propagate in extra dimensions, then their Kaluza-Klein excitations include a series of Z' boson pairs. Each of these pairs can be associated with a different $SU(2) \times U(1)$ gauge group in four dimensions. The properties of the Kaluza-Klein particles depend strongly on the extra-dimensional theory [11]. For example, in universal extra dimensions there is a parity that forces all couplings of Eq. (1) to vanish in the case of the lightest Kaluza-Klein bosons, while allowing couplings to pairs of fermions involving a Standard Model one and a heavy vector-like fermion. There are also 4-dimensional gauge theories (*e.g.*, little Higgs with T parity) with Z' bosons exhibiting similar properties. By contrast, in a warped extra dimension, the couplings of Eq. (1) may be sizable even when Standard Model fields propagate along the extra dimension.

Z' bosons may also be composite particles. For example, in technicolor theories [12], the techni- ρ is a spin-1 boson that may be interpreted as arising from a spontaneously broken gauge symmetry [13].

Resonances versus cascade decays. In the presence of the couplings shown in Eq. (1), the Z' boson may be produced in the s -channel at colliders, and would decay to pairs of fermions. The decay width into a pair of electrons is given by

$$\Gamma(Z' \rightarrow e^+e^-) \simeq \left[(g_e^L)^2 + (g_e^R)^2 \right] \frac{M_{Z'}}{24\pi}, \quad (4)$$

where small corrections from electroweak loops are not included. The decay width into $q\bar{q}$ is similar, except for an additional color factor of 3, QCD radiative corrections, and fermion mass corrections. Thus, one may compute the Z' branching fractions in terms of the couplings of Eq. (1). However, other decay channels, such as WW or a pair of new particles, could have large widths and need to be added to the total decay width.

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

As mentioned above, there are theories in which the Z' couplings are controlled by a discrete symmetry which does not allow its decay into a pair of Standard Model particles. Typically, such theories involve several new particles, which may be produced only in pairs and undergo cascade decays through Z' bosons, leading to signals involving some missing (transverse) energy. Given that the cascade decays depend on the properties of new particles other than Z' , this case is not discussed further here.

LEP-II limits. The Z' contribution to the cross sections for $e^+e^- \rightarrow f\bar{f}$ proceeds through an s -channel Z' exchange (when $f = e$, there are also t - and u -channel exchanges). For $M_{Z'} < \sqrt{s}$, the Z' appears as an $f\bar{f}$ resonance in the radiative return process where photon emission tunes the effective center-of-mass energy to $M_{Z'}$. The agreement between the LEP-II measurements and the Standard Model predictions implies that either the Z' couplings are smaller than or of order 10^{-2} , or else $M_{Z'}$ is above 209 GeV, the maximum energy of LEP-II. In the latter case, the Z' effects may be approximated up to corrections of order $s/M_{Z'}^2$, by the contact interactions

$$\frac{g_z^2}{M_{Z'}^2 - s} [\bar{e}\gamma_\mu (z_e^L P_L + z_e^R P_R) e] [\bar{f}\gamma^\mu (z_f^L P_L + z_f^R P_R) f] \quad , \quad (5)$$

where $P_{L,R}$ are chirality projection operators, and the relation between Z' couplings and charges (see Eq. (2) in the limit where the mass and kinetic mixings are neglected) was used assuming generation-independent charges. The four LEP collaborations have set limits on the coefficients of such operators for all possible chiral structures and for various combinations of fermions [14]. Thus, one may derive bounds on $(M_{Z'}/g_z)|z_e^L z_f^L|^{-1/2}$ and the analogous combinations of LR , RL and RR charges, which are typically on the order of a few TeV. LEP-II limits were derived in Ref. [4] on the four sets of charges shown in Table 1.

Somewhat stronger bounds could be set on $M_{Z'}/g_z$ for specific sets of Z' couplings if the effects of several operators from Eq. (5) are combined. Dedicated analyses by the LEP collaborations have set limits on Z' bosons for particular values of the gauge coupling (see section 3.5.2 of [14]).

Searches at hadron colliders. Z' bosons with couplings to quarks (see Eq. (1)) may be produced at hadron colliders in the s channel, and would show up as resonances in the invariant mass distribution of the decay products. The cross section for producing a Z' boson at the LHC which then decays to some $f\bar{f}$ final state takes the form

$$\sigma(pp \rightarrow Z'X \rightarrow f\bar{f}X) \simeq \frac{\pi}{48s} \sum_q c_q^f w_q(s, M_{Z'}^2) \quad (6)$$

for flavor-diagonal couplings to quarks. Here we have neglected the interference with the Standard Model contribution to $f\bar{f}$ production, which is a good approximation for a narrow Z' resonance. The coefficients

$$c_q^f = \left[(g_q^L)^2 + (g_q^R)^2 \right] B(Z' \rightarrow f\bar{f}) \quad (7)$$

contain all the dependence on the Z' couplings, while the functions w_q include all the information about parton distributions and QCD corrections [4,5]. This factorization holds exactly to NLO, and the deviations from it induced at NNLO are very small. Note that the w_u and w_d functions are substantially larger than the w_q functions for the other quarks. Eq. (6) also applies to the Tevatron, except for changing the pp initial state to $p\bar{p}$, which implies that the $w_q(s, M_{Z'}^2)$ functions are replaced by some other functions $\bar{w}_q((1.96 \text{ TeV})^2, M_{Z'}^2)$.

It is common to present results of Z' searches as limits on the cross section versus $M_{Z'}$ (e.g., see Fig. 1). An alternative is to plot exclusion curves for fixed $M_{Z'}$ values in the $c_u^f - c_d^f$ planes, allowing a simple derivation of the mass limit within any Z' model. LHC limits in the $c_u^\ell - c_d^\ell$ plane ($\ell = e$ or μ) for different $M_{Z'}$ are shown in Fig. 2 (for Tevatron limits, see [15]).

Figure 1: Upper limit on $\sigma(pp \rightarrow Z'X \rightarrow \ell^+\ell^-X)$ with $\ell = e$ or μ as a function of $M_{Z'}$ [27], assuming equal couplings for electrons and muons. The lines labelled by Z'_ψ and Z'_χ are theoretical predictions for the $U(1)_{10+x5}$ models in Table 1 with $x = -3$ and $x = +1$, respectively, for g_z fixed by an E_6 unification condition. The Z'_{SSM} line corresponds to Z' couplings equal to those of the Z boson.

The observation of a dilepton resonance at the LHC would determine the Z' mass and width. A measurement of the total cross section would define a band in the $c_u^\ell - c_d^\ell$ plane. Angular distributions can be used to measure several combinations of Z' parameters (an example of how angular distributions improve the Tevatron sensitivity is given in [16]). Even though the original quark direction in a pp collider is unknown, the leptonic forward-backward asymmetry A_{FB}^ℓ can be extracted from the kinematics of the dilepton system, and is sensitive to parity-violating couplings. A fit to the Z' rapidity distribution can distinguish between the couplings to up and down quarks. These measurements, combined with off-peak observables, have the potential to differentiate among various Z' models [17]. For example, the couplings of a Z' boson with mass below 1.5 TeV

can be well determined with 100 fb^{-1} of data at $\sqrt{s} = 14 \text{ TeV}$. With this amount of data, the spin of the Z' boson may be determined for $M_{Z'} \leq 3 \text{ TeV}$ [18], and the expected sensitivity extends to $M_{Z'} \sim 5 - 6 \text{ TeV}$ for many models [19].

Figure 2: CMS results from Ref. 35. Limits in the $c_d^e - c_d^\mu$ plane ($\ell = e$ or μ) are shown as thin lines for certain $M_{Z'}$ values. For specific sets of charges (described in Ref. 5), parametrized by a mixing angle, the mass limit is given by the intersection of the thick and thin lines.

The Z' decays into e^+e^- and $\mu^+\mu^-$ are useful due to relatively good mass resolution and large acceptance. The Z' decays into $e\mu$ and $\tau^+\tau^-$, along with $t\bar{t}$, $b\bar{b}$ and jj which suffer from larger backgrounds, are also important as they probe various combinations of Z' couplings to fermions.

Z' searches at the Tevatron have been performed by the CDF and D0 Collaborations in the e^+e^- [20], $\mu^+\mu^-$ [21], $e\mu$ [22], $\tau^+\tau^-$ [23], $t\bar{t}$ [24], jj [25] and WW [26] final states. At the 7 TeV LHC, the ATLAS and CMS Collaborations have searched for Z' bosons in the e^+e^- and $\mu^+\mu^-$ channels [27,28], as well as in the $e\mu$ [29], $\tau^+\tau^-$ [30], $t\bar{t}$ [31] and jj [32] final states. The $pp \rightarrow Z'X \rightarrow W^+W^-X$ process may also be explored at the LHC, and is important for disentangling the origin of electroweak symmetry breaking. The Z' boson may be produced in this process through its couplings to either quarks [33] or W bosons [34].

Low-energy constraints. Z' boson properties are also constrained by a variety of low-energy experiments [36]. Polarized electron-nucleon scattering and atomic parity violation are sensitive to electron-quark contact interactions, which get contributions from Z' exchange that can be expressed in terms of the couplings introduced in Eq. (1) and $M_{Z'}$. Further corrections to the electron-quark contact interactions are induced in

the presence of $\tilde{Z} - \tilde{Z}'$ mixing because of the shifts in the Z couplings to quarks and leptons [2]. Deep-inelastic neutrino-nucleon scattering is similarly affected by Z' bosons. Other low-energy observables are discussed in [3]. Interestingly, due to the $\tilde{Z} - \tilde{Z}'$ mixing, the global fit in Z' models often prefers a higher Higgs mass than in the Standard Model [37]. In some models, the lower limits on $M_{Z'}$ set by the low energy data are above 1 TeV [3].

Although the LHC data are most constraining for many Z' models, one should be careful in assessing the relative reach of various experiments given the freedom in Z' couplings. For example, a Z' associated with the $U(1)_{B-xL_e-yL_\mu}$ model (see Table 2) for $x = 0$ and $y \gg 1$ couples only to leptons of the second and third generations, with implications for the muon $g - 2$, neutrino oscillations or τ decays, and would be hard to see in processes involving first-generation fermions. Moreover, the combination of LHC searches and low-energy measurements could allow a precise determination of the Z' parameters [38].

MASS LIMITS for Z' (Heavy Neutral Vector Boson Other Than Z)

Limits for Z'_{SM}

Z'_{SM} is assumed to have couplings with quarks and leptons which are identical to those of Z , and decays only to known fermions. The most recent preliminary results can be found in the "Z'-boson searches" review above.

53 AAD 11AD search for resonances decaying to $e^+e^-, \mu^+\mu^-$ in pp collisions at $\sqrt{s} = 7$ TeV.				
54 CHEUNG 01B limit is derived from bounds on contact interactions in a global electroweak analysis.				
55 AAD 11J search for resonances decaying to e^+e^- or $\mu^+\mu^-$ in pp collisions at $\sqrt{s} = 7$ TeV.				
56 AALTONEN 11i search for resonances decaying to $\mu^+\mu^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.				
57 ABZOV 11A, AALTONEN 09T, AALTONEN 07H, and ABULENCIA 06L search for resonances decaying to e^+e^- in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.				
58 CHATRCHYAN 11 search for resonances decaying to e^+e^- or $\mu^+\mu^-$ in pp collisions at $\sqrt{s} = 7$ TeV.				
59 The quoted limit assumes $g_{WWZ'}/g_{WWZ} = (M_{W'}/M_Z)^2$. See their Fig. 4 for limits in mass-coupling plane.				
60 AALTONEN 09AC search for new particle decaying to dijets.				
61 AALTONEN 09V search for resonances decaying to $\mu^+\mu^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.				
62 ERLER 09 give 95% CL limit on the Z - Z' mixing $-0.0026 < \theta < 0.0006$.				
63 ABDALLAH 06C use data $\sqrt{s} = 130-207$ GeV.				
64 ABULENCIA 05A search for resonances decaying to electron or muon pairs in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.				
65 ACOSTA 05R search for resonances decaying to tau lepton pairs in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.				
66 ABBIENDI 04G give 95% CL limit on Z - Z' mixing $-0.00422 < \theta < 0.00091$. $\sqrt{s} = 91$ to 207 GeV.				
67 ABZOV 01B search for resonances in $p\bar{p} \rightarrow e^+e^-$ at $\sqrt{s}=1.8$ TeV. They find $\sigma \cdot B(Z' \rightarrow ee) < 0.06$ pb for $M_{Z'} > 500$ GeV.				
68 ABREU 00s uses LEP data at $\sqrt{s}=90$ to 189 GeV.				
69 BARATE 00i search for deviations in cross section and asymmetries in $e^+e^- \rightarrow$ fermions at $\sqrt{s}=90$ to 183 GeV. Assume $\theta=0$. Bounds in the mass-mixing plane are shown in their Figure 18.				
70 ERLER 99 give 90%CL limit on the Z - Z' mixing $-0.0041 < \theta < 0.0003$. $\rho_0=1$ is assumed.				
71 ABE 97s find $\sigma(Z') \times B(e^+e^-, \mu^+\mu^-) < 40$ fb for $M_{Z'} > 600$ GeV at $\sqrt{s}=1.8$ TeV.				
72 VILAIN 94B assume $m_t = 150$ GeV.				
73 ALITTI 93 search for resonances in the two-jet invariant mass. The limit assumes $B(Z' \rightarrow q\bar{q})=0.7$. See their Fig. 5 for limits in the $m_{Z'}-B(q\bar{q})$ plane.				
74 RIZZO 93 analyses CDF limit on possible two-jet resonances.				
75 ABE 90F use data for $R, R_{\ell\ell}$, and $A_{\ell\ell}$. They fix $m_{W'} = 80.49 \pm 0.43 \pm 0.24$ GeV and $m_Z = 91.13 \pm 0.03$ GeV.				

Limits for Z_{LR}

Z_{LR} is the extra neutral boson in left-right symmetric models. $g_L = g_R$ is assumed unless noted. Values in parentheses assume stronger constraint on the Higgs sector, usually motivated by specific left-right symmetric models (see the Note on the W'). Values in brackets are from cosmological and astrophysical considerations and assume a light right-handed neutrino. Direct search bounds assume decays to Standard Model fermions only, unless noted.

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

- 76 DEL-AGUILA 10 give 95% CL limit on the Z - Z' mixing $-0.0012 < \theta < 0.0004$.
- 77 ABE 97s find $\sigma(Z') \times B(e^+ e^-, \mu^+ \mu^-) < 40 \text{ fb}$ for $m_{Z'} > 600 \text{ GeV}$ at $\sqrt{s} = 1.8 \text{ TeV}$.
- 78 ERLER 09 give 95% CL limit on the Z - Z' mixing $-0.0013 < \theta < 0.0006$.
- 79 ABDALLAH 06c give 95% CL limit $|\theta| < 0.0028$. See their Fig. 14 for limit contours in the mass-mixing plane.
- 80 ABBIENDI 04g give 95% CL limit on Z - Z' mixing $-0.00098 < \theta < 0.00190$. See their Fig. 20 for the limit contour in the mass-mixing plane. $\sqrt{s} = 91$ to 207 GeV .
- 81 CHEUNG 01b limit is derived from bounds on contact interactions in a global electroweak analysis.
- 82 ABREU 00s give 95% CL limit on Z - Z' mixing $|\theta| < 0.0018$. See their Fig. 6 for the limit contour in the mass-mixing plane. $\sqrt{s} = 90$ to 189 GeV .
- 83 BARATE 00i search for deviations in cross section and asymmetries in $e^+ e^- \rightarrow$ fermions at $\sqrt{s} = 90$ to 183 GeV . Assume $\theta = 0$. Bounds in the mass-mixing plane are shown in their Figure 18.
- 84 CHAY 00 also find $-0.0003 < \theta < 0.0019$. For g_R free, $m_{Z'} > 430 \text{ GeV}$.
- 85 ERLER 00 discuss the possibility that a discrepancy between the observed and predicted values of $Q_W(\text{Cs})$ is due to the exchange of Z' . The data are better described in a certain class of the Z' models including Z_{LR} and Z_χ .
- 86 CASALBUONI 99 discuss the discrepancy between the observed and predicted values of $Q_W(\text{Cs})$. It is shown that the data are better described in a class of models including the Z_{LR} model.
- 87 CZAKON 99 perform a simultaneous fit to charged and neutral sectors. Assumes manifest left-right symmetric model. Finds $|\theta| < 0.0042$.
- 88 ERLER 99 give 90% CL limit on the Z - Z' mixing $-0.0009 < \theta < 0.0017$.
- 89 ERLER 99 assumes 2 Higgs doublets, transforming as 10 of $\text{SO}(10)$, embedded in E_6 .
- 90 BARENBOIM 98 also gives 68% CL limits on the Z - Z' mixing $-0.0005 < \theta < 0.0033$. Assumes Higgs sector of minimal left-right model.
- 91 CONRAD 98 limit is from measurements at CCFR, assuming no Z - Z' mixing.
- 92 VILAIN 94b assume $m_t = 150 \text{ GeV}$ and $\theta = 0$. See Fig. 2 for limit contours in the mass-mixing plane.
- 93 RIZZO 93 analyses CDF limit on possible two-jet resonances.
- 94 GRIFOLS 90 limit holds for $m_{\nu_R} \lesssim 1 \text{ MeV}$. A specific Higgs sector is assumed. See also GRIFOLS 90d, RIZZO 91.
- 95 BARBIERI 89b limit holds for $m_{\nu_R} \leq 10 \text{ MeV}$. Bounds depend on assumed supernova core temperature.

Limits for Z_χ

Z_χ is the extra neutral boson in $\text{SO}(10) \rightarrow \text{SU}(5) \times \text{U}(1)_\chi$. $g_\chi = e/\cos\theta_W$ is assumed unless otherwise stated. We list limits with the assumption $\rho = 1$ but with no further constraints on the Higgs sector. Values in parentheses assume stronger constraint on the Higgs sector motivated by superstring models. Values in brackets are from cosmological and astrophysical considerations and assume a light right-handed neutrino.

- 96 AAD 11AD search for resonances decaying to $e^+ e^-, \mu^+ \mu^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 7 \text{ TeV}$.
- 97 ERLER 09 give 95% CL limit on the Z - Z' mixing $-0.0016 < \theta < 0.0006$.
- 98 AAD 11i search for resonances decaying to $e^+ e^-$ or $\mu^+ \mu^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 7 \text{ TeV}$.
- 99 AALTONEN 11i search for resonances decaying to $\mu^+ \mu^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 1.96 \text{ TeV}$.
- 100 ABAZOV 11A, AALTONEN 09T, AALTONEN 07H, and ABULENCIA 06L search for resonances decaying to $e^+ e^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 1.96 \text{ TeV}$.

- 101 DEL-AGUILA 10 give 95% CL limit on the Z - Z' mixing $-0.0011 < \theta < 0.0007$.
- 102 AALTONEN 09v search for resonances decaying to $\mu^+ \mu^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 1.96 \text{ TeV}$.
- 103 ABDALLAH 06c give 95% CL limit $|\theta| < 0.0031$. See their Fig. 14 for limit contours in the mass-mixing plane.
- 104 ABULENCIA 05A search for resonances decaying to electron or muon pairs in $p\bar{p}$ collisions at $\sqrt{s} = 1.96 \text{ TeV}$.
- 105 ABBIENDI 04g give 95% CL limit on Z - Z' mixing $-0.00099 < \theta < 0.00194$. See their Fig. 20 for the limit contour in the mass-mixing plane. $\sqrt{s} = 91$ to 207 GeV .
- 106 BARGER 03b limit is from the nucleosynthesis bound on the effective number of light neutrino $\delta N_\nu < 1$. The quark-hadron transition temperature $T_C = 150 \text{ MeV}$ is assumed. The limit with $T_C = 400 \text{ MeV}$ is $> 4300 \text{ GeV}$.
- 107 CHEUNG 01b limit is derived from bounds on contact interactions in a global electroweak analysis.
- 108 ABREU 00s give 95% CL limit on Z - Z' mixing $|\theta| < 0.0017$. See their Fig. 6 for the limit contour in the mass-mixing plane. $\sqrt{s} = 90$ to 189 GeV .
- 109 BARATE 00i search for deviations in cross section and asymmetries in $e^+ e^- \rightarrow$ fermions at $\sqrt{s} = 90$ to 183 GeV . Assume $\theta = 0$. Bounds in the mass-mixing plane are shown in their Figure 18.
- 110 CHO 00 use various electroweak data to constrain Z' models assuming $m_H = 100 \text{ GeV}$. See Fig. 3 for limits in the mass-mixing plane.
- 111 ERLER 00 discuss the possibility that a discrepancy between the observed and predicted values of $Q_W(\text{Cs})$ is due to the exchange of Z' . The data are better described in a certain class of the Z' models including Z_{LR} and Z_χ .
- 112 ROSNER 00 discusses the possibility that a discrepancy between the observed and predicted values of $Q_W(\text{Cs})$ is due to the exchange of Z' . The data are better described in a certain class of the Z' models including Z_χ .
- 113 ERLER 99 give 90% CL limit on the Z - Z' mixing $-0.0020 < \theta < 0.0015$.
- 114 ERLER 99 assumes 2 Higgs doublets, transforming as 10 of $\text{SO}(10)$, embedded in E_6 .
- 115 CONRAD 98 limit is from measurements at CCFR, assuming no Z - Z' mixing.
- 116 ABE 97s find $\sigma(Z') \times B(e^+ e^-, \mu^+ \mu^-) < 40 \text{ fb}$ for $m_{Z'} > 600 \text{ GeV}$ at $\sqrt{s} = 1.8 \text{ TeV}$.
- 117 Z - Z' mixing is assumed to be zero. $\sqrt{s} = 57.77 \text{ GeV}$.
- 118 VILAIN 94b assume $m_t = 150 \text{ GeV}$ and $\theta = 0$. See Fig. 2 for limit contours in the mass-mixing plane.
- 119 FARAGGI 91 limit assumes the nucleosynthesis bound on the effective number of neutrinos $\Delta N_\nu < 0.5$ and is valid for $m_{\nu_R} < 1 \text{ MeV}$.
- 120 ABE 90f use data for $R, R_{\ell\ell}$, and $A_{\ell\ell}$. ABE 90f fix $m_W = 80.49 \pm 0.43 \pm 0.24 \text{ GeV}$ and $m_Z = 91.13 \pm 0.03 \text{ GeV}$.
- 121 Assumes the nucleosynthesis bound on the effective number of light neutrinos ($\delta N_\nu < 1$) and that ν_R is light ($\lesssim 1 \text{ MeV}$).
- 122 GRIFOLS 90 limit holds for $m_{\nu_R} \lesssim 1 \text{ MeV}$. See also GRIFOLS 90d, RIZZO 91.

Limits for Z_ψ

Z_ψ is the extra neutral boson in $E_6 \rightarrow \text{SO}(10) \times \text{U}(1)_\psi$. $g_\psi = e/\cos\theta_W$ is assumed unless otherwise stated. We list limits with the assumption $\rho = 1$ but with no further constraints on the Higgs sector. Values in brackets are from cosmological and astrophysical considerations and assume a light right-handed neutrino.

- 127 ABAZOV 11A, AALTONEN 09T, AALTONEN 07H, and ABULENCIA 06L search for resonances decaying to $e^+ e^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 1.96 \text{ TeV}$.

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

- 128 CHATRCHYAN 11 search for resonances decaying to e^+e^- or $\mu^+\mu^-$ in pp collisions at $\sqrt{s} = 7$ TeV.
- 129 AALTONEN 09v search for resonances decaying to $\mu^+\mu^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.
- 130 ERLER 09 give 95% CL limit on the $Z-Z'$ mixing $-0.0018 < \theta < 0.0009$.
- 131 ABDALLAH 06c give 95% CL limit $|\theta| < 0.0027$. See their Fig. 14 for limit contours in the mass-mixing plane.
- 132 ABULENCIA 05A search for resonances decaying to electron or muon pairs in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.
- 133 ABBIENDI 04G give 95% CL limit on $Z-Z'$ mixing $-0.00129 < \theta < 0.00258$. See their Fig. 20 for the limit contour in the mass-mixing plane. $\sqrt{s} = 91$ to 207 GeV.
- 134 BARGER 03B limit is from the nucleosynthesis bound on the effective number of light neutrino $\delta N_\nu < 1$. The quark-hadron transition temperature $T_C = 150$ MeV is assumed. The limit with $T_C = 400$ MeV is > 1100 GeV.
- 135 ABREU 00s give 95% CL limit on $Z-Z'$ mixing $|\theta| < 0.0018$. See their Fig. 6 for the limit contour in the mass-mixing plane. $\sqrt{s} = 90$ to 189 GeV.
- 136 BARATE 00i search for deviations in cross section and asymmetries in $e^+e^- \rightarrow$ fermions at $\sqrt{s} = 90$ to 183 GeV. Assume $\theta = 0$. Bounds in the mass-mixing plane are shown in their Figure 18.
- 137 CHO 00 use various electroweak data to constrain Z' models assuming $m_H = 100$ GeV. See Fig. 3 for limits in the mass-mixing plane.
- 138 ERLER 99 give 90% CL limit on the $Z-Z'$ mixing $-0.0013 < \theta < 0.0024$.
- 139 CONRAD 98 limit is from measurements at CCFR, assuming no $Z-Z'$ mixing.
- 140 ABE 97s find $\sigma(Z') \times B(e^+e^-, \mu^+\mu^-) < 40$ fb for $m_{Z'} > 600$ GeV at $\sqrt{s} = 1.8$ TeV.
- 141 VILAIN 94B assume $m_t = 150$ GeV and $\theta = 0$. See Fig. 2 for limit contours in the mass-mixing plane.
- 142 ABE 90f use data for R , $R_{\ell\ell}$, and $A_{\ell\ell}$. ABE 90f fix $m_W = 80.49 \pm 0.43 \pm 0.24$ GeV and $m_Z = 91.13 \pm 0.03$ GeV.
- 143 Assumes the nucleosynthesis bound on the effective number of light neutrinos ($\delta N_\nu < 1$) and that ν_R is light ($\lesssim 1$ MeV).
- 144 GRIFOLS 90D limit holds for $m_{\nu_R} \lesssim 1$ MeV. See also RIZZO 91.

Limits for Z_η

Z_η is the extra neutral boson in E_6 models, corresponding to $Q_\eta = \sqrt{3/8} Q_\chi - \sqrt{5/8} Q_\psi$. $g_\eta = e/\cos\theta_W$ is assumed unless otherwise stated. We list limits with the assumption $\rho = 1$ but with no further constraints on the Higgs sector. Values in parentheses assume stronger constraint on the Higgs sector motivated by superstring models. Values in brackets are from cosmological and astrophysical considerations and assume a light right-handed neutrino.

- 145 AAD 11AD search for resonances decaying to e^+e^- , $\mu^+\mu^-$ in pp collisions at $\sqrt{s} = 7$ TeV.
- 146 CHO 00 use various electroweak data to constrain Z' models assuming $m_H = 100$ GeV. See Fig. 3 for limits in the mass-mixing plane.
- 147 AAD 11j search for resonances decaying to e^+e^- or $\mu^+\mu^-$ in pp collisions at $\sqrt{s} = 7$ TeV.
- 148 AALTONEN 11i search for resonances decaying to $\mu^+\mu^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.
- 149 ABAZOV 11A, AALTONEN 09T, AALTONEN 07H, and ABULENCIA 06L search for resonances decaying to e^+e^- in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.
- 150 DEL-AGUILA 10 give 95% CL limit on the $Z-Z'$ mixing $-0.0023 < \theta < 0.0027$.
- 151 AALTONEN 09v search for resonances decaying to $\mu^+\mu^-$ in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.
- 152 ERLER 09 give 95% CL limit on the $Z-Z'$ mixing $-0.0047 < \theta < 0.0021$.
- 153 ABDALLAH 06c give 95% CL limit $|\theta| < 0.0092$. See their Fig. 14 for limit contours in the mass-mixing plane.
- 154 ABULENCIA 05A search for resonances decaying to electron or muon pairs in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV.

- 155 ABBIENDI 04G give 95% CL limit on $Z-Z'$ mixing $-0.00447 < \theta < 0.00331$. See their Fig. 20 for the limit contour in the mass-mixing plane. $\sqrt{s} = 91$ to 207 GeV.
- 156 BARGER 03B limit is from the nucleosynthesis bound on the effective number of light neutrino $\delta N_\nu < 1$. The quark-hadron transition temperature $T_C = 150$ MeV is assumed. The limit with $T_C = 400$ MeV is > 3300 GeV.
- 157 ABREU 00s give 95% CL limit on $Z-Z'$ mixing $|\theta| < 0.0024$. See their Fig. 6 for the limit contour in the mass-mixing plane. $\sqrt{s} = 90$ to 189 GeV.
- 158 BARATE 00i search for deviations in cross section and asymmetries in $e^+e^- \rightarrow$ fermions at $\sqrt{s} = 90$ to 183 GeV. Assume $\theta = 0$. Bounds in the mass-mixing plane are shown in their Figure 18.
- 159 ERLER 99 give 90% CL limit on the $Z-Z'$ mixing $-0.0062 < \theta < 0.0011$.
- 160 CONRAD 98 limit is from measurements at CCFR, assuming no $Z-Z'$ mixing.
- 161 ABE 97s find $\sigma(Z') \times B(e^+e^-, \mu^+\mu^-) < 40$ fb for $m_{Z'} > 600$ GeV at $\sqrt{s} = 1.8$ TeV.
- 162 VILAIN 94B assume $m_t = 150$ GeV and $\theta = 0$. See Fig. 2 for limit contours in the mass-mixing plane.
- 163 ABE 90f use data for R , $R_{\ell\ell}$, and $A_{\ell\ell}$. ABE 90f fix $m_W = 80.49 \pm 0.43 \pm 0.24$ GeV and $m_Z = 91.13 \pm 0.03$ GeV.
- 164 These authors claim that the nucleosynthesis bound on the effective number of light neutrinos ($\delta N_\nu < 1$) constrains Z' masses if ν_R is light ($\lesssim 1$ MeV).
- 165 GRIFOLS 90 limit holds for $m_{\nu_R} \lesssim 1$ MeV. See also GRIFOLS 90D, RIZZO 91.

- 166 AAD 11H search for new particle with lepton flavor violating decay in pp collisions at $\sqrt{s} = 7$ TeV. See their Fig. 3 for exclusion plot on the production cross section.
- 167 AAD 11Z search for new particle with lepton flavor violating decay in pp collisions at $\sqrt{s} = 7$ TeV. See their Fig. 3 for limit on $\sigma \cdot B$.
- 168 Search for narrow resonance decaying to $t\bar{t}$. See their Fig. 4 for limit on $\sigma \cdot B$.
- 169 Search for narrow resonance decaying to $t\bar{t}$. See their Fig. 3 for limit on $\sigma \cdot B$.
- 170 CHATRCHYAN 11o search for same-sign top production in pp collisions induced by a hypothetical FCNC Z' at $\sqrt{s} = 7$ TeV. See their Fig. 3 for limit in mass-coupling plane.
- 171 Search for narrow resonance decaying to $t\bar{t}$. See their Fig. 3 for limit on $\sigma \cdot B$.
- 172 ABULENCIA 06M search for new particle with lepton flavor violating decay at $\sqrt{s} = 1.96$ TeV. See their Fig. 4 for an exclusion plot on a mass-coupling plane.
- 173 Search for narrow resonance decaying to $t\bar{t}$. See their Fig. 2 for limit on $\sigma \cdot B$.
- 174 BARGER 03B use the nucleosynthesis bound on the effective number of light neutrino δN_ν . See their Figs. 4-5 for limits in general E_6 motivated models.
- 175 CHO 00 use various electroweak data to constrain Z' models assuming $m_H = 100$ GeV. See Fig. 2 for limits in general E_6 -motivated models.
- 176 CHO 98 study constraints on four-Fermi contact interactions obtained from low-energy electroweak experiments, assuming no $Z-Z'$ mixing.
- 177 Search for Z' decaying to dijets at $\sqrt{s} = 1.8$ TeV. For Z' with electromagnetic strength coupling, no bound is obtained.

Indirect Constraints on Kaluza-Klein Gauge Bosons

Bounds on a Kaluza-Klein excitation of the Z boson or photon in $d=1$ extra dimension. These bounds can also be interpreted as a lower bound on $1/R$, the size of the extra dimension. Unless otherwise stated, bounds assume all fermions live on a single brane and all gauge fields occupy the $4+d$ -dimensional bulk. See also the section on "Extra Dimensions" in the "Searches" Listings in this Review.

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

measurement of $Q_{WW}(Cs)$. Quoted bound assumes all Higgs bosons confined to brane; placing one Higgs doublet in the bulk lowers bound to 2.3 TeV.

¹⁸² Bound is derived from global electroweak analysis assuming the Higgs field is trapped on the matter brane. If the Higgs propagates in the bulk, the bound increases to 3.8 TeV.

¹⁸³ Bound is derived from global electroweak analysis but considering only presence of the KK W bosons.

¹⁸⁴ Global electroweak analysis used to obtain bound independent of position of Higgs on brane or in bulk.

¹⁸⁵ Bounds from effect of KK states on G_F , α , M_W , and M_Z . Hard cutoff at string scale determined using gauge coupling unification. Limits for $d=2,3,4$ rise to 3.5, 5.7, and 7.8 TeV.

¹⁸⁶ Bound obtained for Higgs confined to the matter brane with $m_H=500$ GeV. For Higgs in the bulk, the bound increases to 3.5 TeV.

LEPTOQUARKS

Updated May 2012 by S. Rolli (US Department of Energy) and M. Tanabashi (Nagoya Univ.).

Leptoquarks are hypothetical particles carrying both baryon number (B) and lepton number (L). The possible quantum numbers of leptoquark states can be restricted by assuming that their direct interactions with the ordinary SM fermions are dimensionless and invariant under the standard model (SM) gauge group. Table 1 shows the list of all possible quantum numbers with this assumption [1]. The columns of $SU(3)_C$, $SU(2)_W$, and $U(1)_Y$ in Table 1 indicate the QCD representation, the weak isospin representation, and the weak hypercharge, respectively. The spin of a leptoquark state is taken to be 1 (vector leptoquark) or 0 (scalar leptoquark).

Table 1: Possible leptoquarks and their quantum numbers.

Spin	$3B+L$	$SU(3)_c$	$SU(2)_W$	$U(1)_Y$	Allowed coupling
0	-2	$\bar{3}$	1	1/3	$\bar{q}_L^c \ell_L$ or $\bar{u}_R^c e_R$
0	-2	$\bar{3}$	1	4/3	$\bar{d}_R^c e_R$
0	-2	$\bar{3}$	3	1/3	$\bar{q}_L^c \ell_L$
1	-2	$\bar{3}$	2	5/6	$\bar{q}_L^c \gamma^\mu e_R$ or $\bar{d}_R^c \gamma^\mu \ell_L$
1	-2	$\bar{3}$	2	-1/6	$\bar{u}_R^c \gamma^\mu \ell_L$
0	0	3	2	7/6	$\bar{q}_L e_R$ or $\bar{u}_R \ell_L$
0	0	3	2	1/6	$\bar{d}_R \ell_L$
1	0	3	1	2/3	$\bar{q}_L \gamma^\mu \ell_L$ or $\bar{d}_R \gamma^\mu e_R$
1	0	3	1	5/3	$\bar{u}_R \gamma^\mu e_R$
1	0	3	3	2/3	$\bar{q}_L \gamma^\mu \ell_L$

If we do not require leptoquark states to couple directly with SM fermions, different assignments of quantum numbers become possible [2,3].

Leptoquark states are expected to exist in various extensions of SM. The Pati-Salam model [4] is an example predicting the existence of a leptoquark state. Vector leptoquark states also exist in grand unification theories based on $SU(5)$ [5], $SO(10)$ [6], which includes Pati-Salam color $SU(4)$, and larger gauge groups. Scalar quarks in supersymmetric models with R-parity violation may also have leptoquark-type Yukawa couplings. The bounds on the leptoquark states can therefore be applied to constrain R-parity-violating supersymmetric models. Scalar leptoquarks are expected to exist at TeV scale in extended technicolor models [7,8] where leptoquark states appear as the bound states of techni-fermions. Compositeness of quarks

and leptons also provides examples of models which may have light leptoquark states [9].

Bounds on leptoquark states are obtained both directly and indirectly. Direct limits are from their production cross sections at colliders, while indirect limits are calculated from the bounds on the leptoquark-induced four-fermion interactions, which are obtained from low-energy experiments, or from collider experiments below threshold.

If a leptoquark couples to fermions belonging to more than a single generation in the mass eigenbasis of the SM fermions, it can induce four-fermion interactions causing flavor-changing neutral currents and lepton-family-number violations. The quantum number assignment of Table 1 allows several leptoquark states to couple to both left- and right-handed quarks simultaneously. Such leptoquark states are called non-chiral and may cause four-fermion interactions affecting the $(\pi \rightarrow e\nu)/(\pi \rightarrow \mu\nu)$ ratio [10]. Non-chiral scalar leptoquarks also contribute to the muon anomalous magnetic moment [11,12]. Since indirect limits provide more stringent constraints on these types of leptoquarks, it is often assumed that a leptoquark state couples only to a single generation in a chiral interaction, for which indirect limits become much weaker. Additionally, this assumption gives strong constraints on concrete models of leptoquarks.

Leptoquark states which couple only to left- or right-handed quarks are called chiral leptoquarks. Leptoquark states which couple only to the first (second, third) generation are referred as the first- (second-, third-) generation leptoquarks. Refs. [13,14] give extensive lists of the bounds on the leptoquark-induced four-fermion interactions. For the isoscalar and vector leptoquarks S_0 and V_0 , for example, which couple with the first- (second-) generation left-handed quark, and the first-generation left-handed lepton, the bounds of Ref. 13 read $\lambda^2 < 0.03 \times (M_{LQ}/300 \text{ GeV})^2$ for S_0 , and $\lambda^2 < 0.02 \times (M_{LQ}/300 \text{ GeV})^2$ for V_0 ($\lambda^2 < 5 \times (M_{LQ}/300 \text{ GeV})^2$ for S_0 , and $\lambda^2 < 3 \times (M_{LQ}/300 \text{ GeV})^2$ for V_0) with λ being the leptoquark coupling strength. The e^+e^- experiments are sensitive to the indirect effects coming from t - and u -channel exchanges of leptoquarks in the $e^+e^- \rightarrow q\bar{q}$ process. The HERA experiments give bounds on the leptoquark-induced four-fermion interaction. For detailed bounds obtained in this way, see the Boson Particle Listings for “Indirect Limits for Leptoquarks” and its references.

Collider experiments provide direct limits on the leptoquark states through limits on the pair- and single-production cross sections. The leading-order cross sections of the parton processes

$$q + \bar{q} \rightarrow LQ + \bar{L}\bar{Q}$$

$$g + g \rightarrow LQ + \bar{L}\bar{Q}$$

$$e + q \rightarrow LQ$$

(1)

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

may be written as [15]

$$\begin{aligned}\hat{\sigma}_{\text{LO}}[q\bar{q} \rightarrow \text{LQ} + \overline{\text{LQ}}] &= \frac{2\alpha_s^2\pi}{27\hat{s}}\beta^3, \\ \hat{\sigma}_{\text{LO}}[gg \rightarrow \text{LQ} + \overline{\text{LQ}}] &= \frac{\alpha_s^2\pi}{96\hat{s}} \\ &\times \left[\beta(41 - 31\beta^2) + (18\beta^2 - \beta^4 - 17) \log \frac{1+\beta}{1-\beta} \right], \\ \hat{\sigma}_{\text{LO}}[e\bar{q} \rightarrow \text{LQ}] &= \frac{\pi\lambda^2}{4}\delta(\hat{s} - M_{\text{LQ}}^2)\end{aligned}\quad (2)$$

for a scalar leptoquark. Here $\sqrt{\hat{s}}$ is the invariant energy of the parton subprocess, and $\beta \equiv \sqrt{1 - 4M_{\text{LQ}}^2/\hat{s}}$. The leptoquark Yukawa coupling is given by λ . Leptoquarks are also produced singly at hadron colliders through $g + q \rightarrow \text{LQ} + \ell$ [16], which allows extending to higher masses the collider reach in the leptoquark search [17], depending on the leptoquark Yukawa coupling.

The LHC, Tevatron and LEP experiments search for pair production of the leptoquark states, which arises from the leptoquark gauge interaction. The searches are carried on in signatures including high P_T leptons, E_T jets and large missing transverse energy, due to the typical decay of the leptoquark. The gauge couplings of a scalar leptoquark are determined uniquely according to its quantum numbers in Table 1. Since all of the leptoquark states belong to color-triplet representation, the scalar leptoquark pair-production cross section at the Tevatron and LHC can be determined solely as a function of the leptoquark mass without making further assumptions. This is in contrast to the indirect or single-production limits, which give constraints in the leptoquark mass-coupling plane. For the first- and second-generation scalar leptoquark states with decaying branching fraction $\beta = B(eq) = 1$ and $\beta = B(\mu q) = 1$, the CDF and DØ experiments obtain the lower bounds on the leptoquark mass > 236 GeV (first generation, CDF) [18], > 299 GeV (first generation, DØ) [19], > 226 GeV (second generation, CDF) [20], and > 316 GeV (second generation, DØ) [21] at 95% CL. Third generation leptoquark mass bounds come from the DØ experiment [22] which sets a limit at 247 GeV for a charge $-1/3$ third generation scalar leptoquark, at 95% C.L.

Recent results from the LHC proton-proton collider, running at a center of mass energy of 7 TeV, extend previous Tevatron mass limits for scalar leptoquarks to > 384 GeV (first generation, CMS, $\beta = 1$) [23] and > 339 GeV (first generation, CMS, $\beta = 0.5$) [24]; > 660 GeV (first generation, ATLAS, $\beta = 1$) and > 607 GeV (first generation, ATLAS, $\beta = 0.5$) [25]; > 632 GeV (second generation, CMS, $\beta = 1$) [26] and > 523 GeV (second generation, CMS, $\beta = 0.5$) [26] and; > 685 GeV (second generation, ATLAS, $\beta = 1$) and > 594 GeV (second generation, ATLAS, $\beta = 0.5$) [27]. All limits at 95% C.L. Finally a new measurement performed by the CMS experiment [28] extends the mass limit to 350 GeV for a charge $-1/3$ third generation scalar leptoquark, at 95% C.L.

The magnetic-dipole-type and the electric-quadrupole-type interactions of a vector leptoquark are not determined even if we fix its gauge quantum numbers as listed in the Table [29]. The production of vector leptoquarks depends in general on additional assumptions that the leptoquark couplings and their pair-production cross sections are enhanced relative to the scalar leptoquark contributions. At the Tevatron for instance, since the acceptance for vector and scalar leptoquark detection is similar, limits on the vector leptoquark mass will be more stringent (see for example [35,19]). The leptoquark pair-production cross sections in e^+e^- collisions depend on the leptoquark $SU(2) \times U(1)$ quantum numbers and Yukawa coupling with electron [30]. The OPAL experiment sets mass bounds on various leptoquark states from the pair-production cross sections [31]. For a second-generation weak-isosinglet weak-hypercharge $-4/3$ scalar-leptoquark state, for example, the OPAL pair-production bound is $M_{\text{LQ}} > 100$ GeV/c² at 95% C.L. The LEP experiments also searched for the single production of the leptoquark states from the process $e\gamma \rightarrow \text{LQ} + q$.

The most stringent searches for the leptoquark single production are performed by the HERA experiments. Since the leptoquark single-production cross section depends on its Yukawa coupling, the leptoquark mass limits from HERA are usually displayed in the mass-coupling plane. For leptoquark Yukawa coupling $\lambda = 0.1$, the ZEUS bounds on the first-generation leptoquarks range from 248 to 290 GeV, depending on the leptoquark species [32]. Recently the H1 Collaboration released a comprehensive summary of searches for first generation leptoquarks using the full data sample collected in ep collisions at HERA (446 pb⁻¹). No evidence of production of leptoquarks is observed in final states with a large transverse momentum electron or large missing transverse momentum. For a coupling strength $\lambda = 0.3$, first generation leptoquarks with masses up to 800 GeV are excluded at 95% C.L. [34]

Fig. 1 summarizes ATLAS, CMS, DØ, LEP, and H1 limits on two typical first-generation scalar-leptoquark states in the mass-coupling plane [34].

The search for LQ will be continued with more LHC data. Early feasibility studies by the LHC experiments ATLAS [36] and CMS [37] indicate that clear signals can be established for masses up to about $M(\text{LQ})$ 1.3 to 1.4 TeV for first- and second-generation scalar LQ, with a likely final reach 1.5 TeV, for collisions at 14 TeV in the center of mass.

197	AALTONEN	08P	search for vector leptoquarks using $\tau^+\tau^-b\bar{b}$ events in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. Assuming Yang-Mills (minimal) couplings, the mass limit is >317 GeV (251 GeV) at 95% CL for $B(\tau b) = 1$.
198			Search for pair production of scalar leptoquark state decaying to τb in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. The limit above assumes $B(\tau b) = 1$.
199			Search for scalar leptoquarks using $\nu\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. The limit above assumes $B(\nu q) = 1$.
200	ABAZOV	07I	search for pair productions of scalar leptoquark state decaying to νb in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. The limit above assumes $B(\nu b) = 1$.
201	ABAZOV	06A	search for scalar leptoquarks using $\mu\bar{\mu}jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV and 1.96 TeV. The limit above assumes $B(\mu q) = 1$. For $B(\mu q) = 0.5$, the limit becomes 204 GeV.
202	ABAZOV	06L	search for scalar leptoquarks using $\nu\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV and at 1.96 TeV. The limit above assumes $B(\nu q) = 1$.
203	ABULENCIA	06T	search for scalar leptoquarks using $\mu\bar{\mu}jj$, $\mu\nu jj$, and $\nu\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. The quoted limit assumes $B(\mu q) = 1$. For $B(\mu q) = 0.5$ or 0.1, the bound becomes 208 GeV or 143 GeV, respectively. See their Fig. 4 for the exclusion limit as a function of $B(\mu q)$.
204	ABAZOV	05H	search for scalar leptoquarks using $e\bar{e}jj$ and $e\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV and 1.96 TeV. The limit above assumes $B(eq) = 1$. For $B(eq) = 0.5$ the bound becomes 234 GeV.
205	ACOSTA	05P	search for scalar leptoquarks using $e\bar{e}jj$, $e\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.96$ TeV. The limit above assumes $B(eq) = 1$. For $B(eq) = 0.5$ and 0.1, the bound becomes 205 GeV and 145 GeV, respectively.
206	ABBIENDI	03R	search for scalar/vector leptoquarks in e^+e^- collisions at $\sqrt{s} = 189-209$ GeV. The quoted limits are for charge $-4/3$ isospin 0 scalar-leptoquark with $B(\ell q) = 1$. See their table 12 for other cases.
207	ABAZOV	02	search for scalar leptoquarks using $\nu\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The bound holds for all leptoquark generations. Vector leptoquarks are likewise constrained to lie above 200 GeV.
208	ABAZOV	01D	search for scalar leptoquarks using $e\nu jj$, $e\bar{e}jj$, and $\nu\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The limit above assumes $B(eq) = 1$. For $B(eq) = 0.5$ and 0, the bound becomes 204 and 79 GeV, respectively. Bounds for vector leptoquarks are also given. Supersedes ABBOTT 98E.
209	ABBIENDI	00M	search for scalar/vector leptoquarks in e^+e^- collisions at $\sqrt{s} = 183$ GeV. The quoted limits are for charge $-4/3$ isospin 0 scalar-leptoquarks with $B(\ell q) = 1$. See their Table 8 and Figs. 6-9 for other cases.
210	ABBOTT	00C	search for scalar leptoquarks using $\mu\bar{\mu}jj$, $\mu\nu jj$, and $\nu\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The limit above assumes $B(\mu q) = 1$. For $B(\mu q) = 0.5$ and 0,

						the bound becomes 180 and 79 GeV respectively. Bounds for vector leptoquarks are also given.
211	AFFOLDER	00K	search for scalar leptoquark using $\nu\nu cc$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The quoted limit assumes $B(\nu c) = 1$. Bounds for vector leptoquarks are also given.			
212	AFFOLDER	00K	search for scalar leptoquark using $\nu\nu bb$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The quoted limit assumes $B(\nu b) = 1$. Bounds for vector leptoquarks are also given.			
213	ABBOTT	99I	search for leptoquarks using $\mu\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The quoted limit is for a scalar leptoquark with $B(\mu q) = B(\nu q) = 0.5$. Limits on vector leptoquarks range from 240 to 290 GeV.			
214	ABBOTT	98E	search for scalar leptoquarks using $e\nu jj$, $e\bar{e}jj$, and $\nu\nu jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The limit above assumes $B(eq) = 1$. For $B(eq) = 0.5$ and 0, the bound becomes 204 and 79 GeV, respectively.			
215	ABBOTT	98J	search for charge $-1/3$ third generation scalar and vector leptoquarks in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The quoted limit is for scalar leptoquark with $B(\nu b) = 1$.			
216	ABE	98S	search for scalar leptoquarks using $\mu\bar{\mu}jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The limit is for $B(\mu q) = 1$. For $B(\mu q) = B(\nu q) = 0.5$, the limit is > 160 GeV.			
217	GROSS-PILCHER	98	the combined limit of the CDF and DØ Collaborations as determined by a joint CDF/DØ working group and reported in this FNAL Technical Memo. Original data published in ABE 97X and ABBOTT 98E.			
218	ABE	97F	search for third generation scalar and vector leptoquarks in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The quoted limit is for scalar leptoquark with $B(\tau b) = 1$.			
219	ABE	97X	search for scalar leptoquarks using $e\bar{e}jj$ events in $p\bar{p}$ collisions at $E_{cm} = 1.8$ TeV. The limit is for $B(eq) = 1$.			
220	Limit		is for charge $-1/3$ isospin-0 leptoquark with $B(\ell q) = 2/3$.			
221	First and second generation		leptoquarks are assumed to be degenerate. The limit is slightly lower for each generation.			
222	Limits are for charge $-1/3$, isospin-0		scalar leptoquarks decaying to $\ell^- q$ or νq with any branching ratio. See paper for limits for other charge-isospin assignments of leptoquarks.			
223	KIM	90	assume pair production of charge 2/3 scalar-leptoquark via photon exchange. The decay of the first (second) generation leptoquark is assumed to be any mixture of d^+ and u^+ ($s\mu^+$ and $c\tau$). See paper for limits for specific branching ratios.			
224	BARTEL	87B	limit is valid when a pair of charge 2/3 spinless leptoquarks X is produced with point coupling, and when they decay under the constraint $B(X \rightarrow c\tau_\mu) + B(X \rightarrow s\mu^+) = 1$.			
225	BEHREND	86B	assumed that a charge 2/3 spinless leptoquark, χ , decays either into $s\mu^+$ or $c\tau$: $B(X \rightarrow s\mu^+) + B(X \rightarrow c\tau) = 1$.			

MASS LIMITS for Leptoquarks from Single Production

These limits depend on the q - ℓ -leptoquark coupling g_{LQ} . It is often assumed that $g_{LQ}^2/4\pi = 1/137$. Limits shown are for a scalar, weak isoscalar, charge $-1/3$ leptoquark.

226		CHEKANOV 03B	limit is for a scalar, weak isoscalar, charge $-1/3$ leptoquark coupled with e_R . See their Figs. 11-12 and Table 5 for limits on states with different quantum numbers.	
227		Limit from single production in Z decay. The limit is for a leptoquark coupling of electromagnetic strength and assumes $B(\ell q) = 2/3$. The limit is 77 GeV if first and second leptoquarks are degenerate.		
228		AARON 11A	search for various leptoquarks with lepton-flavor violating couplings. See their Figs. 2-3 and Tables 1-4 for detailed limits.	
229		The quoted limit is for a scalar, weak isoscalar, charge $-1/3$ leptoquark coupled with e_R . See their Figs. 3-5 for limits on states with different quantum numbers.		
230		ABAZOV 07E	search for leptoquark single production through qg fusion process in $p\bar{p}$ collisions. See their Fig. 4 for exclusion plot in mass-coupling plane.	
231		AKTAS 05B	limit is for a scalar, weak isoscalar, charge $-1/3$ leptoquark coupled with e_R . See their Fig. 3 for limits on states with different quantum numbers.	
232		CHEKANOV 05	search for various leptoquarks with lepton-flavor violating couplings. See their Figs. 6-10 and Tables 1-8 for detailed limits.	
233		For limits on states with different quantum numbers and the limits in the mass-coupling plane, see their Fig. 4 and Fig. 5.		
234		CHEKANOV 02	search for various leptoquarks with lepton-flavor violating couplings. See their Figs. 6-7 and Tables 5-6 for detailed limits.	
235		For limits on states with different quantum numbers and the limits in the mass-coupling plane, see their Fig. 3.		
236		See their Fig. 14 for limits in the mass-coupling plane.		
237		BREITWEG 00E	search for $F=0$ leptoquarks in e^+p collisions. For limits in mass-coupling plane, see their Fig. 11.	
238		ABREU 99G	limit obtained from process $e\gamma \rightarrow LQ+q$. For limits on vector and scalar states with different quantum numbers and the limits in the coupling-mass plane, see their Fig. 4 and Table 2.	

See key on page 457

Gauge & Higgs Boson Particle Listings
Heavy Bosons Other than Higgs Bosons

- 239 For limits on states with different quantum numbers and the limits in the mass-coupling plane, see their Fig. 13 and Fig. 14. ADLOFF 99 also search for leptoquarks with lepton-flavor violating couplings. ADLOFF 99 supersedes AID 96b.
- 240 DERRICK 97 search for various leptoquarks with lepton-flavor violating couplings. See their Figs. 5–8 and Table 1 for detailed limits.
- 241 DERRICK 93 search for single leptoquark production in ep collisions with the decay eq and νq . The limit is for leptoquark coupling of electromagnetic strength and assumes $B(eq) = B(\nu q) = 1/2$. The limit for $B(eq) = 1$ is 176 GeV. For limits on states with different quantum numbers, see their Table 3.

- 242 AARON 11c limit is for weak isotriplet spin-0 leptoquark at strong coupling $\lambda = \sqrt{4\pi}$. For the limits of leptoquarks with different quantum numbers, see their Table 3. Limits are derived from bounds of eq contact interactions.
- 243 DORSNER 11 give bounds on scalar, weak singlet, charge 4/3 leptoquark from K, B, τ decays, meson mixings, $L\nu\nu$, $g-2$ and $Z \rightarrow b\bar{b}$.
- 244 AKTAS 07A search for lepton-flavor violation in ep collision. See their Tables 4–7 for limits on lepton-flavor violating four-fermion interactions induced by various leptoquarks.
- 245 SCHAEEL 07A limit is for the weak-isoscalar spin-0 left-handed leptoquark with the coupling of electromagnetic strength. For the limits of leptoquarks with different quantum numbers, see their Table 35.
- 246 SMIRNOV 07 obtains mass limits for the vector and scalar chiral leptoquark states from $K \rightarrow e\mu, B \rightarrow e\tau$ decays.
- 247 CHEKANOV 05 search for various leptoquarks with lepton-flavor violating couplings. See their Figs. 6–10 and Tables 1–8 for detailed limits.
- 248 ADLOFF 03 limit is for the weak isotriplet spin-0 leptoquark at strong coupling $\lambda = \sqrt{4\pi}$. For the limits of leptoquarks with different quantum numbers, see their Table 3. Limits are derived from bounds on $e^\pm q$ contact interactions.
- 249 The bound is derived from $B(B^0 \rightarrow e^\pm \mu^\mp) < 1.7 \times 10^{-7}$.
- 250 CHEKANOV 02 search for lepton-flavor violation in ep collisions. See their Tables 1–4 for limits on lepton-flavor violating and four-fermion interactions induced by various leptoquarks.
- 251 CHEUNG 01b quoted limit is for a scalar, weak isoscalar, charge $-1/3$ leptoquark with a coupling of electromagnetic strength. The limit is derived from bounds on contact interactions in a global electroweak analysis. For the limits of leptoquarks with different quantum numbers, see Table 5.
- 252 ACCIARRI 00P limit is for the weak isoscalar spin-0 leptoquark with the coupling of electromagnetic strength. For the limits of leptoquarks with different quantum numbers, see their Table 4.
- 253 ADLOFF 00 limit is for the weak isotriplet spin-0 leptoquark at strong coupling, $\lambda = \sqrt{4\pi}$. For the limits of leptoquarks with different quantum numbers, see their Table 2. ADLOFF 00 limits are from the Q^2 spectrum measurement of $e^+p \rightarrow e^+X$.
- 254 BARATE 00i search for deviations in cross section and jet-charge asymmetry in $e^+e^- \rightarrow \bar{q}q$ due to t -channel exchange of a leptoquark at $\sqrt{s}=130$ to 183 GeV. Limits for other scalar and vector leptoquarks are also given in their Table 22.
- 255 BARGER 00 explain the deviation of atomic parity violation in cesium atoms from prediction is explained by scalar leptoquark exchange.
- 256 GABRIELLI 00 calculate various process with lepton flavor violation in leptoquark models.
- 257 ZARNECKI 00 limit is derived from data of HERA, LEP, and Tevatron and from various low-energy data including atomic parity violation. Leptoquark coupling with electromagnetic strength is assumed.
- 258 ABBIENDI 99 limits are from $e^+e^- \rightarrow q\bar{q}$ cross section at 130–136, 161–172, 183 GeV. See their Fig. 8 and Fig. 9 for limits in mass-coupling plane.

- 259 ABE 98v quoted limit is from $B(B_s \rightarrow e^\pm \mu^\mp) < 8.2 \times 10^{-6}$. ABE 98v also obtain a similar limit on $M_{LQ} > 20.4$ TeV from $B(B_d \rightarrow e^\pm \mu^\mp) < 4.5 \times 10^{-6}$. Both bounds assume the non-canonical association of the b quark with electrons or muons under $SU(4)$.
- 260 ACCIARRI 98J limit is from $e^+e^- \rightarrow q\bar{q}$ cross section at $\sqrt{s}=130$ –172 GeV which can be affected by the t - and u -channel exchanges of leptoquarks. See their Fig. 4 and Fig. 5 for limits in the mass-coupling plane.
- 261 ACKERSTAFF 98V limits are from $e^+e^- \rightarrow q\bar{q}$ and $e^+e^- \rightarrow b\bar{b}$ cross sections at $\sqrt{s}=130$ –172 GeV, which can be affected by the t - and u -channel exchanges of leptoquarks. See their Fig. 21 and Fig. 22 for limits of leptoquarks in mass-coupling plane.
- 262 DEANDREA 97 limit is for \tilde{R}_2 leptoquark obtained from atomic parity violation (APV). The coupling of leptoquark is assumed to be electromagnetic strength. See Table 2 for limits of the four-fermion interactions induced by various scalar leptoquark exchange. DEANDREA 97 combines APV limit and limits from Tevatron and HERA. See Fig. 1–4 for combined limits of leptoquark in mass-coupling plane.
- 263 DERRICK 97 search for lepton-flavor violation in ep collision. See their Tables 2–5 for limits on lepton-flavor violating four-fermion interactions induced by various leptoquarks.
- 264 GROSSMAN 97 estimate the upper bounds on the branching fraction $B \rightarrow \tau^+\tau^- (X)$ from the absence of the B decay with large missing energy. These bounds can be used to constrain leptoquark induced four-fermion interactions.
- 265 JADACH 97 limit is from $e^+e^- \rightarrow q\bar{q}$ cross section at $\sqrt{s}=172.3$ GeV which can be affected by the t - and u -channel exchanges of leptoquarks. See their Fig. 1 for limits on vector leptoquarks in mass-coupling plane.
- 266 KUZNETSOV 95B use π, K, B, τ decays and μe conversion and give a list of bounds on the leptoquark mass and the fermion mixing matrix in the Pati-Salam model. The quoted limit is from $K_L \rightarrow \mu e$ decay assuming zero mixing.
- 267 MIZUKOSHI 95 calculate the one-loop radiative correction to the Z -physics parameters in various scalar leptoquark models. See their Fig. 4 for the exclusion plot of third generation leptoquark models in mass-coupling plane.
- 268 BHATTACHARYYA 94 limit is from one-loop radiative correction to the leptonic decay width of the Z . $m_H=250$ GeV, $\alpha_s(m_Z)=0.12$, $m_t=180$ GeV, and the electroweak strength of leptoquark coupling are assumed. For leptoquark coupled to $\bar{\nu}_L \ell_R, \bar{\mu} \tau$, and $\bar{\tau}$, see Fig. 2 in BHATTACHARYYA 94b erratum and Fig. 3.
- 269 DAVIDSON 94 gives an extensive list of the bounds on leptoquark-induced four-fermion interactions from π, K, D, B, μ, τ decays and meson mixings, etc. See Table 15 of DAVIDSON 94 for detail.
- 270 KUZNETSOV 94 gives mixing independent bound of the Pati-Salam leptoquark from the cosmological limit on $\pi^0 \rightarrow \nu\nu$.
- 271 LEURER 94, LEURER 94B limits are obtained from atomic parity violation and apply to any chiral leptoquark which couples to the first generation with electromagnetic strength. For a nonchiral leptoquark, universality in $\pi_{\ell 2}$ decay provides a much more stringent bound.
- 272 MAHANTA 94 gives bounds of P - and T -violating scalar-leptoquark couplings from atomic and molecular experiments.
- 273 From $(\pi \rightarrow e\nu)/(\pi \rightarrow \mu\nu)$ ratio. SHANKER 82 assumes the leptoquark induced four-fermion coupling $4g^2/M^2 (\bar{\nu}_L \ell_R u_R) (\bar{\ell}_L e_R)$ with $g=0.004$ for spin-0 leptoquark and $g^2/M^2 (\bar{\nu}_L \ell_R \mu_L) (\bar{\mu}_R \gamma^\mu e_R)$ with $g=0.6$ for spin-1 leptoquark.

Gauge & Higgs Boson Particle Listings

Heavy Bosons Other than Higgs Bosons

- 279 CHATRCHYAN 11y search for new resonance decaying to dijets in pp collisions at $\sqrt{s} = 7$ TeV.
- 280 AALTONEN 10L search for massive color octet non-chiral vector particle decaying into $t\bar{t}$ pair with mass in the range $400 \text{ GeV} < M < 800 \text{ GeV}$. See their Fig. 6 for limit in the mass-coupling plane.
- 281 KHACHATRYAN 10 search for new resonance decaying to dijets in pp collisions at $\sqrt{s} = 7$ TeV.
- 282 AALTONEN 09AC search for new narrow resonance decaying to dijets.
- 283 CHOUDHURY 07 limit is from the $t\bar{t}$ production cross section measured at CDF.
- 284 DONCHESKI 98 compare α_S derived from low-energy data and that from $\Gamma(Z \rightarrow \text{hadrons})/\Gamma(Z \rightarrow \text{leptons})$.
- 285 ABE 97G search for new particle decaying to dijets.
- 286 ABE 95N assume axigluons decaying to quarks in the Standard Model only.
- 287 ABE 93G assume $\Gamma(g_A) = N\alpha_S m_{g_A}/6$ with $N = 10$.
- 288 CUYPERS 91 compare α_S measured in T decay and that from R at PEP/PETRA energies.
- 289 ABE 90H assumes $\Gamma(g_A) = N\alpha_S m_{g_A}/6$ with $N = 5$ ($\Gamma(g_A) = 0.09 m_{g_A}$). For $N = 10$, the excluded region is reduced to 120–150 GeV.
- 290 ROBINETT 89 result demands partial-wave unitarity of $J = 0$ $t\bar{t} \rightarrow t\bar{t}$ scattering amplitude and derives a limit $m_{g_A} > 0.5 m_t$. Assumes $m_t > 56 \text{ GeV}$.
- 291 ALBAJAR 88b result is from the nonobservation of a peak in two-jet invariant mass distribution. $\Gamma(g_A) < 0.4 m_{g_A}$ assumed. See also BAGGER 88.
- 292 CUYPERS 88 requires $\Gamma(T \rightarrow g g_A) < \Gamma(T \rightarrow g g g)$. A similar result is obtained by DONCHESKI 88.
- 293 DONCHESKI 88b requires $\Gamma(T \rightarrow g q \bar{q})/\Gamma(T \rightarrow g g g) < 0.25$, where the former decay proceeds via axigluon exchange. A more conservative estimate of < 0.5 leads to $m_{g_A} > 21 \text{ GeV}$.

X^0 (Heavy Boson) Searches in Z Decays

Searches for radiative transition of Z to a lighter spin-0 state X^0 decaying to hadrons, a lepton pair, a photon pair, or invisible particles as shown in the comments. The limits are for the product of branching ratios.

294 BARATE 98U obtain limits on $B(Z \rightarrow \gamma X^0)B(X^0 \rightarrow \ell\bar{\ell}, q\bar{q}, g\bar{g}, \gamma\gamma, \nu\bar{\nu})$. See their Fig. 17.				
295 See Fig. 4 of ACCIARRI 97Q for the upper limit on $B(Z \rightarrow \gamma X^0; E_{\gamma} > E_{\text{min}})$ as a function of E_{min} .				
296 ACTON 93E give $\sigma(e^+e^- \rightarrow X^0\gamma) \cdot B(X^0 \rightarrow \gamma\gamma) < 0.4 \text{ pb}$ (95%CL) for $m_{X^0} = 60 \pm 2.5 \text{ GeV}$. If the process occurs via s-channel γ exchange, the limit translates to $\Gamma(X^0) \cdot B(X^0 \rightarrow \gamma\gamma)^2 < 20 \text{ MeV}$ for $m_{X^0} = 60 \pm 1 \text{ GeV}$.				
297 ABREU 92D give $\sigma_Z \cdot B(Z \rightarrow \gamma X^0) \cdot B(X^0 \rightarrow \text{hadrons}) < (3-10) \text{ pb}$ for $m_{X^0} = 10-78 \text{ GeV}$. A very similar limit is obtained for spin-1 X^0 .				
298 ADRIANI 92F search for isolated γ in hadronic Z decays. The limit $\sigma_Z \cdot B(Z \rightarrow \gamma X^0) \cdot B(X^0 \rightarrow \text{hadrons}) < (2-10) \text{ pb}$ (95%CL) is given for $m_{X^0} = 25-85 \text{ GeV}$.				
299 ACTON 91 searches for $Z \rightarrow Z^* X^0$, $Z^* \rightarrow e^+e^-, \mu^+\mu^-,$ or $\nu\bar{\nu}$. Excludes any new scalar X^0 with $m_{X^0} < 9.5 \text{ GeV}/c$ if it has the same coupling to ZZ^* as the MSM Higgs boson.				
300 ACTON 91B limits are for $m_{X^0} = 60-85 \text{ GeV}$.				
301 ADEVA 91D limits are for $m_{X^0} = 30-89 \text{ GeV}$.				
302 ADEVA 91D limits are for $m_{X^0} = 30-86 \text{ GeV}$.				
303 AKRAWY 90J give $\Gamma(Z \rightarrow \gamma X^0) \cdot B(X^0 \rightarrow \text{hadrons}) < 1.9 \text{ MeV}$ (95%CL) for $m_{X^0} = 32-80 \text{ GeV}$. We divide by $\Gamma(Z) = 2.5 \text{ GeV}$ to get product of branching ratios. For nonresonant transitions, the limit is $B(Z \rightarrow \gamma q\bar{q}) < 8.2 \text{ MeV}$ assuming three-body phase space distribution.				

MASS LIMITS for a Heavy Neutral Boson Coupling to e^+e^-

VALUE (GeV)	CL%	DOCUMENT ID	TECN	COMMENT

		307 BERGER	85B PLUT	$\Gamma(X^0 \rightarrow e^+e^-) = 10 \text{ keV}$
none 39.8–45.5		308 ADEVA	84 MRKJ	$\Gamma(X^0 \rightarrow e^+e^-) = 4 \text{ MeV}$
> 47.8	95	308 ADEVA	84 MRKJ	$\Gamma(X^0 \rightarrow e^+e^-) = 4 \text{ MeV}$
none 39.8–45.2		308 BEHREND	84C CELL	
> 47	95	308 BEHREND	84C CELL	$\Gamma(X^0 \rightarrow e^+e^-) = 4 \text{ MeV}$

- 304 ODAKA 89 looked for a narrow or wide scalar resonance in $e^+e^- \rightarrow$ hadrons at $E_{\text{cm}} = 55.0-60.8 \text{ GeV}$.
- 305 DERRICK 86 found no deviation from the Standard Model Bhabha scattering at $E_{\text{cm}} = 29 \text{ GeV}$ and set limits on the possible scalar boson e^+e^- coupling. See their figure 4 for excluded region in the $\Gamma(X^0 \rightarrow e^+e^-) \cdot m_{X^0}$ plane. Electronic chiral invariance requires a parity doublet of X^0 , in which case the limit applies for $\Gamma(X^0 \rightarrow e^+e^-) = 3 \text{ MeV}$.
- 306 ADEVA 85 first limit is from $2\gamma, \mu^+\mu^-$, hadrons assuming X^0 is a scalar. Second limit is from e^+e^- channel. $E_{\text{cm}} = 40-47 \text{ GeV}$. Supersedes ADEVA 84.
- 307 BERGER 85B looked for effect of spin-0 boson exchange in $e^+e^- \rightarrow e^+e^-$ and $\mu^+\mu^-$ at $E_{\text{cm}} = 34.7 \text{ GeV}$. See Fig. 5 for excluded region in the $m_{X^0} - \Gamma(X^0)$ plane.
- 308 ADEVA 84 and BEHREND 84c have $E_{\text{cm}} = 39.8-45.5 \text{ GeV}$. MARK-J searched X^0 in $e^+e^- \rightarrow$ hadrons, $2\gamma, \mu^+\mu^-$, e^+e^- and CELLO in the same channels plus τ pair. No narrow or broad X^0 is found in the energy range. They also searched for the effect of X^0 with $m_X > E_{\text{cm}}$. The second limits are from Bhabha data and for spin-0 singlet. The same limits apply for $\Gamma(X^0 \rightarrow e^+e^-) = 2 \text{ MeV}$ if X^0 is a spin-0 doublet. The second limit of BEHREND 84c was read off from their figure 2. The original papers also list limits in other channels.

Search for X^0 Resonance in e^+e^- Collisions

The limit is for $\Gamma(X^0 \rightarrow e^+e^-) \cdot B(X^0 \rightarrow f)$, where f is the specified final state. Spin 0 is assumed for X^0 .

Axions (A^0) and Other Very Light Bosons, Searches for

AXIONS AND OTHER SIMILAR PARTICLES

Revised March 2012 by G.G. Raffelt (MPI Physics, Munich) and L.J. Rosenberg (U. of Washington).

Introduction

In this section, we list coupling-strength and mass limits for light neutral scalar or pseudoscalar bosons that couple weakly to normal matter and radiation. Such bosons may arise from a global spontaneously broken $U(1)$ symmetry, resulting in a massless Nambu-Goldstone (NG) boson. If there is a small explicit symmetry breaking, either already in the Lagrangian or

due to quantum effects such as anomalies, the boson acquires a mass and is called a pseudo-NG boson. Typical examples are axions (A^0) [1,2], familons [3] and Majorons [4], associated, respectively, with a spontaneously broken Peccei-Quinn, family and lepton-number symmetry.

A common characteristic among these light bosons ϕ is that their coupling to Standard-Model particles is suppressed by the energy scale that characterizes the symmetry breaking, *i.e.*, the decay constant f . The interaction Lagrangian is

$$\mathcal{L} = f^{-1} J^\mu \partial_\mu \phi, \quad (1)$$

where J^μ is the Noether current of the spontaneously broken global symmetry. If f is very large, these new particles interact very weakly. Detecting them would provide a window to physics far beyond what can be probed at accelerators.

Axions remain of particular interest because the Peccei-Quinn (PQ) mechanism remains perhaps the most credible scheme to preserve CP in QCD. Moreover, the cold dark matter of the universe may well consist of axions and they are searched for in dedicated experiments with a realistic chance of discovery.

Originally it was assumed that the PQ scale f_A was related to the electroweak symmetry-breaking scale $v_{\text{weak}} = (\sqrt{2}G_F)^{-1/2} = 247$ GeV. However, the associated “standard” and “variant” axions were quickly excluded—we refer to the Listings for detailed limits. Here we focus on “invisible axions” with $f_A \gg v_{\text{weak}}$ as the main possibility.

Axions have a characteristic two-photon vertex, inherited from their mixing with π^0 and η . It allows for the main search strategy based on axion-photon conversion in external magnetic fields [5], an effect that also can be of astrophysical interest. While for axions the product “ $A\gamma\gamma$ interaction strength \times mass” is essentially fixed by the corresponding π^0 properties, one may consider more general axion-like particles (ALPs) where the two parameters are independent. Several experiments have recently explored this more general parameter space.

I. THEORY

I.1 Peccei-Quinn mechanism and axions

The QCD Lagrangian includes a CP-violating term $\mathcal{L}_\Theta = \bar{\Theta}(\alpha_s/8\pi) G^{\mu\nu a} \tilde{G}_{\mu\nu}^a$, where $-\pi \leq \bar{\Theta} \leq +\pi$ is the effective Θ parameter after diagonalizing quark masses, G is the color field strength tensor, and \tilde{G} its dual. Limits on the neutron electric dipole moment [6] imply $|\bar{\Theta}| \lesssim 10^{-10}$ even though $\bar{\Theta} = \mathcal{O}(1)$ is otherwise completely satisfactory. The spontaneously broken global Peccei-Quinn symmetry $U(1)_{\text{PQ}}$ was introduced to solve this “strong CP problem” [1], an axion being the pseudo-NG boson of $U(1)_{\text{PQ}}$ [2]. This symmetry is broken due to the axion’s anomalous triangle coupling to gluons,

$$\mathcal{L} = \left(\bar{\Theta} - \frac{\phi_A}{f_A} \right) \frac{\alpha_s}{8\pi} G^{\mu\nu a} \tilde{G}_{\mu\nu}^a, \quad (2)$$

where ϕ_A is the axion field and f_A the axion decay constant. Color anomaly factors have been absorbed in the normalization of f_A which is defined by this Lagrangian. Thus normalized, f_A

See key on page 457

Gauge & Higgs Boson Particle Listings Axions (A^0) and Other Very Light Bosons

is the quantity that enters all low-energy phenomena [7]. Non-perturbative effects induce a potential for ϕ_A whose minimum is at $\phi_A = \Theta f_A$, thereby canceling the Θ term in the QCD Lagrangian and thus restoring CP symmetry.

The resulting axion mass is given by $m_A f_A \approx m_\pi f_\pi$ where $m_\pi = 135$ MeV and $f_\pi \approx 92$ MeV. In more detail one finds

$$m_A = \frac{z^{1/2}}{1+z} \frac{f_\pi m_\pi}{f_A} = \frac{0.60 \text{ meV}}{f_A/10^{10} \text{ GeV}}, \quad (3)$$

where $z = m_u/m_d$. We have used the canonical value $z = 0.56$ [8], although the range $z = 0.35\text{--}0.60$ is plausible [9].

Originally one assumed $f_A \sim v_{\text{weak}}$ [1,2]. Tree-level flavor conservation fixes the axion properties in terms of a single parameter $\tan\beta$, the ratio of the vacuum expectation values of two Higgs fields that appear as a minimal ingredient. This “standard axion” is excluded after extensive searches [10]. A narrow peak structure observed in positron spectra from heavy ion collisions [11] suggested an axion-like particle of mass 1.8 MeV that decays into e^+e^- , but extensive follow-up searches were negative. “Variant axion models” were proposed which keep $f_A \sim v_{\text{weak}}$ while dropping the constraint of tree-level flavor conservation [12], but these models are also excluded [13].

Axions with $f_A \gg v_{\text{weak}}$ evade all current experimental limits. One generic class of models invokes “hadronic axions” where new heavy quarks carry $U(1)_{\text{PQ}}$ charges, leaving ordinary quarks and leptons without tree-level axion couplings. The prototype is the KSVZ model [14], where in addition the heavy quarks are electrically neutral. Another generic class requires at least two Higgs doublets and ordinary quarks and leptons carry PQ charges, the prototype being the DFSZ model [15]. All of these models contain at least one electroweak singlet scalar that acquires a vacuum expectation value and thereby breaks the PQ symmetry. The KSVZ and DFSZ models are frequently used as generic examples, but other models exist where both heavy quarks and Higgs doublets carry PQ charges.

1.2 Model-dependent axion couplings

Although the generic axion interactions scale approximately with f_π/f_A from the corresponding π^0 couplings, there are non-negligible model-dependent factors and uncertainties. The axion’s two-photon interaction plays a key role for many searches,

$$\mathcal{L}_{A\gamma\gamma} = \frac{G_{A\gamma\gamma}}{4} F_{\mu\nu} \tilde{F}^{\mu\nu} \phi_A = -G_{A\gamma\gamma} \mathbf{E} \cdot \mathbf{B} \phi_A, \quad (4)$$

where F is the electromagnetic field-strength tensor and \tilde{F} its dual. The coupling constant is

$$\begin{aligned} G_{A\gamma\gamma} &= \frac{\alpha}{2\pi f_A} \left(\frac{E}{N} - \frac{2}{3} \frac{4+z}{1+z} \right) \\ &= \frac{\alpha}{2\pi} \left(\frac{E}{N} - \frac{2}{3} \frac{4+z}{1+z} \right) \frac{1+z}{z^{1/2}} \frac{m_A}{m_\pi f_\pi}, \end{aligned} \quad (5)$$

where E and N are the electromagnetic and color anomalies of the axial current associated with the axion. In grand unified models, and notably for DFSZ [15], $E/N = 8/3$, whereas for KSVZ [14] $E/N = 0$ if the electric charge of the new heavy

quark is taken to vanish. In general, a broad range of E/N values is possible [16]. The two-photon decay width is

$$\Gamma_{A \rightarrow \gamma\gamma} = \frac{G_{A\gamma\gamma}^2 m_A^3}{64\pi} = 1.1 \times 10^{-24} \text{ s}^{-1} \left(\frac{m_A}{\text{eV}} \right)^5. \quad (6)$$

The second expression uses Eq. (5) with $z = 0.56$ and $E/N = 0$. Axions decay faster than the age of the universe if $m_A \gtrsim 20$ eV.

The interaction with fermions f has derivative form and is invariant under a shift $\phi_A \rightarrow \phi_A + \phi_0$ as behoves a NG boson,

$$\mathcal{L}_{Aff} = \frac{C_f}{2f_A} \bar{\Psi}_f \gamma^\mu \gamma_5 \Psi_f \partial_\mu \phi_A. \quad (7)$$

Here, Ψ_f is the fermion field, m_f its mass, and C_f a model-dependent coefficient. The dimensionless combination $g_{Aff} \equiv C_f m_f / f_A$ plays the role of a Yukawa coupling and $\alpha_{Aff} \equiv g_{Aff}^2 / 4\pi$ of a “fine-structure constant.” The often-used pseudoscalar form $\mathcal{L}_{Aff} = -i(C_f m_f / f_A) \bar{\Psi}_f \gamma_5 \Psi_f \phi_A$ need not be equivalent to the appropriate derivative structure, for example when two NG bosons are attached to one fermion line as in axion emission by nucleon bremsstrahlung [17].

In the DFSZ model [15], the tree-level coupling coefficient to electrons is

$$C_e = \frac{\cos^2 \beta}{3}, \quad (8)$$

where $\tan\beta$ is the ratio of two Higgs vacuum expectation values that are generic to this and similar models.

For nucleons, $C_{n,p}$ are related to axial-vector current matrix elements by generalized Goldberger-Treiman relations,

$$\begin{aligned} C_p &= (C_u - \eta)\Delta u + (C_d - \eta z)\Delta d + (C_s - \eta w)\Delta s, \\ C_n &= (C_u - \eta)\Delta d + (C_d - \eta z)\Delta u + (C_s - \eta w)\Delta s. \end{aligned} \quad (9)$$

Here, $\eta = (1+z+w)^{-1}$ with $z = m_u/m_d$ and $w = m_u/m_s \ll z$ and the Δq are given by the axial vector current matrix element $\Delta q S_\mu = \langle p | \bar{q} \gamma_\mu \gamma_5 q | p \rangle$ with S_μ the proton spin.

Neutron beta decay and strong isospin symmetry considerations imply $\Delta u - \Delta d = F + D = 1.269 \pm 0.003$, whereas hyperon decays and flavor $SU(3)$ symmetry imply $\Delta u + \Delta d - 2\Delta s = 3F - D = 0.586 \pm 0.031$ [19]. The strange-quark contribution is $\Delta s = -0.08 \pm 0.01_{\text{stat}} \pm 0.05_{\text{sys}}$ from the COMPASS experiment [18], and $\Delta s = -0.085 \pm 0.008_{\text{exp}} \pm 0.013_{\text{theor}} \pm 0.009_{\text{evol}}$ from HERMES [19], in agreement with each other and with an early estimate of $\Delta s = -0.11 \pm 0.03$ [20]. We thus adopt $\Delta u = 0.84 \pm 0.02$, $\Delta d = -0.43 \pm 0.02$ and $\Delta s = -0.09 \pm 0.02$, very similar to what was used in the axion literature.

The uncertainty of the axion-nucleon couplings is dominated by the uncertainty $z = m_u/m_d = 0.35\text{--}0.60$ that we mentioned earlier. For hadronic axions $C_{u,d,s} = 0$ so that $-0.51 < C_p < -0.36$ and $0.10 > C_n > -0.05$. Therefore it is well possible that $C_n = 0$ whereas C_p does not vanish within the plausible z range. In the DFSZ model, $C_u = \frac{1}{3} \sin^2 \beta$ and $C_d = \frac{1}{3} \cos^2 \beta$ and C_n and C_p as functions of β and z do not vanish simultaneously.

The axion-pion interaction is given by the Lagrangian [21]

$$\mathcal{L}_{A\pi} = \frac{C_{A\pi}}{f_\pi f_A} (\pi^0 \pi^+ \partial_\mu \pi^- + \pi^0 \pi^- \partial_\mu \pi^+ - 2\pi^+ \pi^- \partial_\mu \pi^0) \partial_\mu \phi_A, \quad (10)$$

Gauge & Higgs Boson Particle Listings

Axions (A^0) and Other Very Light Bosons

where $C_{A\pi} = (1 - z)/[3(1 + z)]$ in hadronic models. The chiral symmetry-breaking Lagrangian provides an additional term $\mathcal{L}'_{A\pi} \propto (m_\pi^2/f_\pi f_A)(\pi^0\pi^0 + 2\pi^-\pi^+)\pi^0\phi_A$. For hadronic axions it vanishes identically, in contrast to the DFSZ model (Roberto Peccei, private communication).

II. LABORATORY SEARCHES

II.1 Photon regeneration

Searching for “invisible axions” is extremely challenging. The most promising approaches rely on the axion-two-photon vertex, allowing for axion-photon conversion in external electric or magnetic fields [5]. For the Coulomb field of a charged particle, the conversion is best viewed as a scattering process, $\gamma + Ze \leftrightarrow Ze + A$, called Primakoff effect [22]. In the other extreme of a macroscopic field, usually a large-scale B -field, the momentum transfer is small, the interaction coherent over a large distance, and the conversion is best viewed as an axion-photon oscillation phenomenon in analogy to neutrino flavor oscillations [23].

Photons propagating through a transverse magnetic field, with incident \mathbf{E}_γ and magnet \mathbf{B} parallel, may convert into axions. For $m_A^2 L/2\omega \ll 2\pi$, where L is the length of the B field region and ω the photon energy, the resultant axion beam is coherent with the incident photon beam and the conversion probability is $\Pi \sim (1/4)(G_{A\gamma\gamma}BL)^2$. A practical realization uses a laser beam propagating down the bore of a superconducting dipole magnet (like the bending magnets in high-energy accelerators). If another magnet is in line with the first, but shielded by an optical barrier, then photons may be regenerated from the pure axion beam [24]. The overall probability $P(\gamma \rightarrow A \rightarrow \gamma) = \Pi^2$.

The first such experiment utilized two magnets of length $L = 4.4$ m and $B = 3.7$ T and found $G_{A\gamma\gamma} < 6.7 \times 10^{-7}$ GeV $^{-1}$ at 95% CL for $m_A < 1$ meV [25]. More recently, several such experiments were performed (see Listings), improving the limit to $G_{A\gamma\gamma} < 0.7 \times 10^{-7}$ GeV $^{-1}$ at 95% CL for $m_A \lesssim 0.5$ meV [26]. Some of these experiments have also reported limits for scalar bosons where the photon \mathbf{E}_γ must be chosen perpendicular to the magnet \mathbf{B} .

The concept of resonantly enhanced photon regeneration may open unexplored regions of coupling strength [27]. In this scheme, both the production and detection magnets are within Fabry-Perot optical cavities and actively locked in frequency. The $\gamma \rightarrow A \rightarrow \gamma$ rate is enhanced by a factor $2\mathcal{F}\mathcal{F}'/\pi^2$ relative to a single-pass experiment, where \mathcal{F} and \mathcal{F}' are the finesses of the two cavities. The resonant enhancement could be of order $10^{(10-12)}$, improving the $G_{A\gamma\gamma}$ sensitivity by $10^{(2.5-3)}$.

Another new concept involves axion absorption and emission between electromagnetic fields within a high finesse optical cavity [28]. A signal appears as resonant sidebands on the carrier. This technique could be sensitive in the mass range 10^{-6} – 10^{-4} eV and reach the KSVZ line after one year of operation.

II.2 Photon polarization

An alternative to regenerating the lost photons is to use the beam itself to detect conversion: the polarization of light propagating through a transverse B field suffers dichroism and birefringence [29]. Dichroism: The E_\parallel component, but not E_\perp , is depleted by axion production, causing a small rotation of linearly polarized light. For $m_A^2 L/2\omega \ll 2\pi$ the effect is independent of m_A , for heavier axions it oscillates and diminishes as m_A increases, and it vanishes for $m_A > \omega$. Birefringence: This rotation occurs because there is mixing of virtual axions in the E_\parallel state, but not for E_\perp . Hence, linearly polarized light will develop elliptical polarization. Higher-order QED also induces vacuum birefringence. A search for these effects was performed on the same dipole magnets in the early experiment above [30]. The dichroic rotation gave a stronger limit than the ellipticity rotation: $G_{A\gamma\gamma} < 3.6 \times 10^{-7}$ GeV $^{-1}$ at 95% CL for $m_A < 5 \times 10^{-4}$ eV. The ellipticity limits are better at higher masses, as they fall off smoothly and do not terminate at m_A .

In 2006 the PVLAS collaboration reported a signature of magnetically induced vacuum dichroism that could be interpreted as the effect of a pseudoscalar with $m_A = 1$ – 1.5 meV and $G_{A\gamma\gamma} = (1.6$ – $5) \times 10^{-6}$ GeV $^{-1}$ [31]. Since then, these findings are attributed to instrumental artifacts [32]. This particle interpretation is also excluded by the above photon regeneration searches that were perhaps inspired by the original PVLAS result.

II.3 Long-range forces

New bosons would mediate long-range forces, which are severely constrained by “fifth force” experiments [33]. Those looking for new mass-spin couplings provide significant constraints on pseudoscalar bosons [34]. However, they do not yet cover realistic parameters for invisible axion models because they are only sensitive for small m_A . The corresponding coupling strengths scale with $f_A^{-1} \approx m_A/m_\pi f_\pi$ and are too small to be detected. Still, these efforts provide constraints on more general low-mass bosons.

III. AXIONS FROM ASTROPHYSICAL SOURCES

III.1 Stellar energy-loss limits:

Low-mass weakly-interacting particles (neutrinos, gravitons, axions, baryonic or leptonic gauge bosons, *etc.*) are produced in hot astrophysical plasmas, and can thus transport energy out of stars. The coupling strength of these particles with normal matter and radiation is bounded by the constraint that stellar lifetimes or energy-loss rates not conflict with observation [35–37].

We begin this discussion with our Sun and concentrate on hadronic axions. They are produced predominantly by the Primakoff process $\gamma + Ze \rightarrow Ze + A$. Integrating over a standard solar model yields the axion luminosity [51]

$$L_A = G_{10}^2 1.85 \times 10^{-3} L_\odot, \quad (11)$$

See key on page 457

Gauge & Higgs Boson Particle Listings Axions (A^0) and Other Very Light Bosons

where $G_{10} = G_{A\gamma\gamma} \times 10^{10}$ GeV. The maximum of the spectrum is at 3.0 keV, the average at 4.2 keV, and the number flux at Earth is $G_{10}^2 3.75 \times 10^{11}$ cm $^{-2}$ s $^{-1}$. The solar photon luminosity is fixed, so axion losses require enhanced nuclear energy production and thus enhanced neutrino fluxes. The all-flavor measurements by SNO together with a standard solar model imply $L_A \lesssim 0.10 L_\odot$, corresponding to $G_{10} \lesssim 7$ [38], mildly superseding a similar limit from helioseismology [39].

A more restrictive limit derives from globular-cluster (GC) stars that allow for detailed tests of stellar-evolution theory. The stars on the horizontal branch (HB) in the color-magnitude diagram have reached helium burning with a core-averaged energy release of about 80 erg g $^{-1}$ s $^{-1}$, compared to Primakoff axion losses of $G_{10}^2 30$ erg g $^{-1}$ s $^{-1}$. The accelerated consumption of helium reduces the HB lifetime by about $80/(80+30 G_{10}^2)$. Number counts of HB stars in 15 GCs compared with the number of red giants (that are not much affected by Primakoff losses) reveal agreement with expectations within 20–40% in any one GC and overall on the 10% level [36]. Therefore, a reasonably conservative limit is

$$G_{A\gamma\gamma} \lesssim 1 \times 10^{-10} \text{ GeV}^{-1}, \quad (12)$$

although a detailed error budget is not available.

We translate this constraint on $G_{A\gamma\gamma}$ to $f_A > 2.3 \times 10^7$ GeV ($m_A < 0.3$ eV), using $z = 0.56$ and $E/N = 0$ as in the KSVZ model, and show the excluded range in Figure 1. For the DFSZ model with $E/N = 8/3$, the corresponding limits are slightly less restrictive, $f_A > 0.8 \times 10^7$ GeV ($m_A < 0.7$ eV). The exact high-mass end of the exclusion range has not been determined. The relevant temperature is around 10 keV and the average photon energy is therefore around 30 keV. The excluded m_A range thus certainly extends beyond the shown 100 keV.

If axions couple directly to electrons, the dominant emission processes are $\gamma + e^- \rightarrow e^- + A$ and $e^- + Ze \rightarrow Ze + e^- + A$. Moreover, bremsstrahlung is efficient in white dwarfs (WDs), where the Primakoff and Compton processes are suppressed by the large plasma frequency. The enhanced energy losses would delay helium ignition in GC stars, implying $\alpha_{Aee} \lesssim 0.5 \times 10^{-26}$ [40]. Enhanced WD cooling led to a similar limit from the WD luminosity function [41]. Based on much better data and detailed WD cooling treatment, today it appears that the WD luminosity function fits better with a new energy-loss channel that can be interpreted in terms of axion losses corresponding to $\alpha_{Aee} \sim 10^{-27}$ [42]. For pulsationally unstable WDs (ZZ Ceti stars), the period decrease \dot{P}/P is a measure of the cooling speed. A well-studied case is the star G117–B15A, where the measured \dot{P}/P also implies additional cooling that can be interpreted in terms of similar axion losses [43]. At the moment we prefer to interpret these results as an upper limit $\alpha_{Aee} \lesssim 10^{-27}$ shown in Figure 1.

Similar constraints derive from the measured duration of the neutrino signal of the supernova SN 1987A. Numerical simulations for a variety of cases, including axions and Kaluza-Klein gravitons, reveal that the energy-loss rate of a nuclear medium

Figure 1: Exclusion ranges as described in the text. The dark intervals are the approximate CAST and ADMX search ranges. Limits on coupling strengths are translated into limits on m_A and f_A using $z = 0.56$ and the KSVZ values for the coupling strengths. The “Laboratory” bar is a rough representation of the exclusion range for standard or variant axions. The “GC stars and white-dwarf cooling” range uses the DFSZ model with an axion-electron coupling corresponding to $\cos^2 \beta = 1/2$. The Cold Dark Matter exclusion range is particularly uncertain. We show the benchmark case from the misalignment mechanism.

at the density 3×10^{14} g cm $^{-3}$ and temperature 30 MeV should not exceed about 1×10^{19} erg g $^{-1}$ s $^{-1}$ [36]. The energy-loss rate from nucleon bremsstrahlung, $N + N \rightarrow N + N + A$, is $(C_N/2f_A)^2 (T^4/\pi^2 m_N) F$. Here F is a numerical factor that represents an integral over the dynamical spin-density structure function because axions couple to the nucleon spin. For realistic conditions, even after considerable effort, one is limited to a heuristic estimate leading to $F \approx 1$ [37].

The SN 1987A limits are of particular interest for hadronic axions where the bounds on α_{Aee} are moot. Within uncertainties of $z = m_u/m_d$ a reasonable choice for the coupling constants is then $C_p = -0.4$ and $C_n = 0$. Using a proton fraction of 0.3, $F = 1$, and $T = 30$ MeV one finds [37]

$$f_A \gtrsim 4 \times 10^8 \text{ GeV} \quad \text{and} \quad m_A \lesssim 16 \text{ meV}. \quad (13)$$

Gauge & Higgs Boson Particle Listings

Axions (A^0) and Other Very Light Bosons

If axions interact sufficiently strongly they are trapped. Only about three orders of magnitude in g_{ANN} or m_A are excluded, a range shown somewhat schematically in Figure 1. For even larger couplings, the axion flux would have been negligible, yet it would have triggered additional events in the detectors, excluding a further range [44]. A possible gap between these two SN 1987A arguments was discussed as the “hadronic axion window” under the assumption that $G_{A\gamma\gamma}$ was anomalously small [45]. This range is now excluded by hot dark matter bounds (see below).

The very tentative indication for additional WD cooling by axion emission described above is not in conflict with SN 1987A bounds. Still, if the WD interpretation were correct, SNe would lose a large fraction of their energy as axions. This would lead to a diffuse SN axion background (DSAB) in the universe with an energy density comparable to the extra-galactic background light [46]. However, there is no apparent way of detecting it or the axion burst from the next nearby SN.

III.2 Searches for solar axions

Instead of using stellar energy losses to derive axion limits, one can also search directly for these fluxes, notably from the Sun. The main focus has been on axion-like particles with a two-photon vertex. They are produced by the Primakoff process with a flux given by Equation 11 and can be detected at Earth with the reverse process in a macroscopic B -field (“axion helioscope”) [5]. The average energy of solar axions of 4.2 keV implies a photon-axion oscillation length in vacuum of $2\pi(2\omega/m_A^2) \sim \mathcal{O}(1 \text{ mm})$, precluding the vacuum mixing from achieving its theoretical maximum in any practical magnet. However, one can endow the photon with an effective mass in a gas, $m_\gamma = \omega_{\text{plas}}$, thus matching the axion and photon dispersion relations [47].

An early implementation of these ideas used a conventional dipole magnet, with a conversion volume of variable-pressure gas with a xenon proportional chamber as x-ray detector [48]. The conversion magnet was fixed in orientation and collected data for about 1000 s/day. Axions were excluded for $G_{A\gamma\gamma} < 3.6 \times 10^{-9} \text{ GeV}^{-1}$ for $m_A < 0.03 \text{ eV}$, and $G_{A\gamma\gamma} < 7.7 \times 10^{-9} \text{ GeV}^{-1}$ for $0.03 < m_A < 0.11 \text{ eV}$ at 95% CL.

Later, the Tokyo axion helioscope used a superconducting magnet on a tracking mount, viewing the Sun continuously. They reported $G_{A\gamma\gamma} < 6 \times 10^{-10} \text{ GeV}^{-1}$ for $m_A < 0.3 \text{ eV}$ [49]. Recently this experiment was recommissioned and a similar limit for masses around 1 eV was reported [50]. These exclusion ranges are shown in Figure 2.

The most recent helioscope CAST (CERN Axion Solar Telescope) uses a decommissioned LHC dipole magnet on a tracking mount. The hardware includes grazing-incidence x-ray optics with solid-state x-ray detectors, as well as a novel x-ray Micromegas position-sensitive gaseous detector. CAST has established a 95% CL limit $G_{A\gamma\gamma} < 8.8 \times 10^{-11} \text{ GeV}^{-1}$ for $m_A < 0.02 \text{ eV}$ [51]. To cover larger masses, the magnet bores are filled with a gas at varying pressure. The runs with

Figure 2: Solar exclusion plot for axion-like particles (adapted from [53]). The green solid line corresponds to KSVZ axions.

^4He cover masses up to about 0.4 eV [52], providing the ^4He limits shown in Figure 2. To cover yet larger masses to about 1.15 eV, ^3He was used to achieve a larger pressure at cryogenic temperatures. First limits up to 0.64 eV were recently published [53], allowing CAST to “cross the axion line” for the KSVZ model (Figure 2).

Going to yet larger masses in a helioscope search is not well motivated because of the cosmic hot dark matter bound of $m_A \lesssim 0.7 \text{ eV}$ (see below). Sensitivity to significantly smaller values of $G_{A\gamma\gamma}$ can be achieved with a next-generation axion helioscope with a much larger magnetic-field cross section. Realistic design options for this “International Axion Observatory” (IAXO) have been studied in some detail [54].

Other Primakoff searches for solar axions have been carried out using crystal detectors, exploiting the coherent conversion of axions into photons when the axion angle of incidence satisfies a Bragg condition with a crystal plane [55]. However, none of these limits is more restrictive than the one derived from solar neutrinos that was discussed earlier.

Another idea is to look at the Sun with an x-ray satellite when the Earth is in between. Solar axions would convert in the Earth magnetic field on the far side and could be detected [56]. The sensitivity to $G_{A\gamma\gamma}$ could be comparable to CAST, but only for much smaller m_A . Deep solar x-ray measurements with existing satellites, using the solar magnetosphere as conversion region, have reported preliminary limits on $G_{A\gamma\gamma}$ [57].

III.3 Conversion of astrophysical photon fluxes

Large-scale B fields exist in astrophysics that can induce axion-photon oscillations. In practical cases, B is much smaller than in the laboratory, whereas the conversion region L is much

See key on page 457

Gauge & Higgs Boson Particle Listings Axions (A^0) and Other Very Light Bosons

larger. Therefore, while the product BL can be large, realistic sensitivities are usually restricted to very low-mass particles, far away from the “axion line” in a plot like Figure 2.

One example is SN 1987A, which would have emitted a burst of axion-like particles due to the Primakoff production in its core. They would have partially converted into γ -rays in the galactic B -field. The absence of a γ -ray burst in coincidence with SN 1987A neutrinos provides a limit $G_{A\gamma\gamma} \lesssim 1 \times 10^{-11} \text{ GeV}^{-1}$ for $m_A \lesssim 10^{-9} \text{ eV}$ [58], the most restrictive limit for very small m_A . Axion-like particles from other stars (e.g. magnetic white dwarfs or neutron stars) can be converted to photons, but no tangible new limits or signatures seem to have appeared, except perhaps from solar x-ray observations (see above).

Magnetically induced oscillations between photons and axion-like particles (ALPs) can modify the photon fluxes from distant sources in various ways: (i) Frequency-dependent dimming. (ii) Modified polarization. (iii) Avoiding absorption by propagation in the form of axions. For example, dimming of SNe Ia could influence the interpretation in terms of cosmic acceleration [59], although it has become clear that photon-ALP conversion could only be a subdominant effect [60]. More recently, it appears that the universe could be too transparent to TeV γ -rays that should be absorbed by pair production on the extra-galactic background light [61]. The situation is not conclusive at present, but the possible role of photon-ALP oscillations in TeV γ -ray astronomy is tantalizing [62].

IV. COSMIC AXIONS

IV.1 Cosmic axion populations

In the early universe, axions are produced by processes involving quarks and gluons [63]. After color confinement, the dominant thermalization process is $\pi + \pi \leftrightarrow \pi + A$ [21]. The resulting axion population would contribute a hot dark matter component in analogy to massive neutrinos. Cosmological precision data provide restrictive constraints on a possible hot dark-matter fraction that translate into $m_A < 0.7 \text{ eV}$ at the 95% statistical CL [64], but in detail depend on the used data set and assumed cosmological model.

For $m_A \gtrsim 20 \text{ eV}$, axions decay fast on a cosmic time scale, removing the axion population while injecting photons. This excess radiation provides additional limits up to very large axion masses [65]. An anomalously small $G_{A\gamma\gamma}$ provides no loophole because suppressing decays leads to thermal axions overdominating the mass density of the universe.

The main cosmological interest in axions derives from their possible role as cold dark matter (CDM). In addition to thermal processes, axions are abundantly produced by the “misalignment mechanism” [66]. After the breakdown of the PQ symmetry, the axion field relaxes somewhere in the “bottom of the wine bottle” potential. Near the QCD epoch, instanton effects explicitly break the PQ symmetry, the very effect that causes dynamical PQ symmetry restoration. This “tilting of the wine

bottle” drives the axion field toward the CP-conserving minimum, thereby exciting coherent oscillations of the axion field that ultimately represent a condensate of CDM. The cosmic mass density in this homogeneous field mode is [67]

$$\Omega_A h^2 \approx 0.7 \left(\frac{f_A}{10^{12} \text{ GeV}} \right)^{7/6} \left(\frac{\bar{\Theta}_i}{\pi} \right)^2, \quad (14)$$

where h is the present-day Hubble expansion parameter in units of $100 \text{ km s}^{-1} \text{ Mpc}^{-1}$, and $-\pi \leq \bar{\Theta}_i \leq \pi$ is the initial “misalignment angle” relative to the CP-conserving position. If the PQ symmetry breakdown takes place after inflation, $\bar{\Theta}_i$ will take on different values in different patches of the universe. The average contribution is [67]

$$\Omega_A h^2 \approx 0.3 \left(\frac{f_A}{10^{12} \text{ GeV}} \right)^{7/6}. \quad (15)$$

Comparing with the measured CDM density of $\Omega_{\text{CDM}} h^2 \approx 0.13$ implies that axions with $m_A \approx 10 \text{ } \mu\text{eV}$ provide the dark matter, whereas smaller masses are excluded (Figure 1).

This density sets only a rough scale for the expected m_A . The mass of CDM axions could be significantly smaller or larger than $10 \text{ } \mu\text{eV}$. Apart from the overall particle physics uncertainties, the cosmological sequence of events is crucial. Assuming axions make up CDM, much smaller masses are possible if inflation took place after the PQ transition and the initial value $\bar{\Theta}_i$ was small (“anthropic axion window” [68]). The oscillating galactic dark matter axion field induces extremely small oscillating nuclear electric dipole moments. Conceivably, these could be measured by extremely tiny energy shifts in cold molecules [69].

Conversely, if the PQ transition took place after inflation, there are additional sources for nonthermal axions, notably the decay of cosmic strings and domain walls. According to Sikivie and collaborators, these populations are comparable to the misalignment contribution [67]. Other groups find a significantly enhanced axion density [70] or rather, a larger m_A value for axions providing CDM. Moreover, the spatial axion density variations are large at the QCD transition and they are not erased by free streaming. When matter begins to dominate the universe, gravitationally bound “axion mini clusters” form promptly [71]. A significant fraction of CDM axions can reside in these bound objects.

If the reheat temperature after inflation is too small to restore PQ symmetry, the axion field is present during inflation. It is subject to quantum fluctuations, leading to isocurvature fluctuations that are severely constrained [72].

IV.2 Telescope searches

The two-photon decay is extremely slow for axions with masses in the CDM regime, but could be detectable for eV masses. The signature would be a quasi-monochromatic emission line from galaxies and galaxy clusters. The expected optical line intensity for DFSZ axions is similar to the continuum night emission. An early search in three rich Abell clusters [73],

Gauge & Higgs Boson Particle Listings

Axions (A^0) and Other Very Light Bosons

and a recent search in two rich Abell clusters [74], exclude the “Telescope” range in Figure 1 unless the axion-photon coupling is strongly suppressed. Of course, axions in this mass range would anyway provide an excessive hot DM contribution.

Very low-mass axions in halos produce a weak quasi-monochromatic radio line. Virial velocities in undisrupted dwarf galaxies are very low, and the axion decay line would therefore be extremely narrow. A search with the Haystack radio telescope on three nearby dwarf galaxies provided a limit $G_{A\gamma\gamma} < 1.0 \times 10^{-9} \text{ GeV}^{-1}$ at 96% CL for $298 < m_A < 363 \mu\text{eV}$ [75]. However, this combination of m_A and $G_{A\gamma\gamma}$ does not exclude plausible axion models.

IV.3 Microwave cavity experiments

The limits of Figure 1 suggest that axions, if they exist, provide a significant fraction or even perhaps all of the cosmic CDM. In a broad range of the plausible m_A range for CDM, galactic halo axions may be detected by their resonant conversion into a quasi-monochromatic microwave signal in a high-Q electromagnetic cavity permeated by a strong static B field [5,76]. The cavity frequency is tunable, and the signal is maximized when the frequency is the total axion energy, rest mass plus kinetic energy, of $\nu = (m_A/2\pi) [1 + \mathcal{O}(10^{-6})]$, the width above the rest mass representing the virial distribution in the galaxy. The frequency spectrum may also contain finer structure from axions more recently fallen into the galactic potential and not yet completely virialized [77].

Figure 3: Exclusion region reported from the microwave cavity experiments RBF and UF [78] and ADMX [79]. A local dark-matter density of 450 MeV cm^{-3} is assumed.

The feasibility of this technique was established in early experiments of relatively small sensitive volume, $\mathcal{O}(1 \text{ liter})$, with HFET-based amplifiers, setting limits in the range $4.5 < m_A < 16.3 \mu\text{eV}$ [78], but lacking by 2–3 orders of magnitude the sensitivity required to detect realistic axions.

Later, ADMX ($B \sim 8 \text{ T}$, $V \sim 200 \text{ liters}$) has achieved sensitivity to KSVZ axions, assuming they saturate the local dark matter density and are well virialized, over the mass range $1.9\text{--}3.3 \mu\text{eV}$ [79]. Should halo axions have a component not yet virialized, ADMX is sensitive to DFSZ axions [80]. The corresponding 90% CL exclusion regions shown in Figure 3 are normalized to an assumed local CDM density of $7.5 \times 10^{-25} \text{ g cm}^{-3}$ (450 MeV cm^{-3}). More recently the ADMX experiment commissioned an upgrade [81] that replaces the microwave HFET amplifiers by near quantum-limited low-noise dc SQUID microwave amplifiers [82], allowing for a significantly improved sensitivity [83]. This apparatus is also sensitive to other hypothetical light bosons over a limited parameter space [84]. Alternatively, a Rydberg atom single-photon detector [85] can in principle evade the standard quantum limit for coherent photon detection.

Conclusions

Experimental, astrophysical, and cosmological limits have been refined and indicate that axions, if they exist, very likely have very low mass, $m_A \lesssim 10 \text{ meV}$, suggesting that axions are a non-negligible fraction of the cosmic CDM. The upgraded versions of the ADMX experiment will ultimately cover the range $1\text{--}100 \mu\text{eV}$ with a sensitivity allowing one to detect such axions, unless the local DM density is unexpectedly small or the axion-photon coupling anomalously weak. Other experimental techniques remain of interest to search for axion-like particles, although at present no method besides the DM search is known that could detect realistic axions obeying the astrophysical and cosmological limits, and fulfilling the QCD-implied relationship between mass and coupling strength.

³ This limit applies for a mass near 180 MeV. For other masses in the range $m_{X^0} = 150-250$ MeV the limit is less restrictive, but still improves ADLER 02c and ATIYA 93b.

⁴ ANISIMOVSKY 04 bound is for $m_{X^0} = 0$.

⁵ ADLER 02c bound is for $m_{X^0} < 60$ MeV. See Fig. 2 for limits at higher masses.

⁶ The quoted limit is for $m_{X^0} = 0-80$ MeV. See their Fig. 5 for the limit at higher mass. The branching fraction limit assumes pure phase space decay distributions.

⁷ ALTEGOER 98 looked for X^0 from π^0 decay which penetrate the shielding and convert to π^0 in the external Coulomb field of a nucleus.

⁸ KITCHING 97 limit is for $B(K^+ \rightarrow \pi^+ X^0) \cdot B(X^0 \rightarrow \gamma\gamma)$ and applies for $m_{X^0} \approx 50$ MeV, $\tau_{X^0} < 10^{-10}$ s. Limits are provided for $0 < m_{X^0} < 100$ MeV, $\tau_{X^0} < 10^{-8}$ s.

⁹ ADLER 96 looked for a peak in missing-mass distribution. This work is an update of ATIYA 93. The limit is for massless stable X^0 particles and extends to $m_{X^0} = 80$ MeV at the same level. See paper for dependence on finite lifetime.

¹⁰ AMSLER 94B and AMSLER 96B looked for a peak in missing-mass distribution.

¹¹ The MEIJERDREES 94 limit is based on inclusive photon spectrum and is independent of X^0 decay modes. It applies to $\tau(X^0) > 10^{-23}$ sec.

¹² ATIYA 93B looked for a peak in missing mass distribution. The bound applies for stable X^0 of $m_{X^0} = 150-250$ MeV, and the limit becomes stronger (10^{-8}) for $m_{X^0} = 180-240$ MeV.

¹³ NG 93 studied the production of X^0 via $\gamma\gamma \rightarrow \pi^0 \rightarrow \gamma X^0$ in the early universe at $T \approx 1$ MeV. The bound on extra neutrinos from nucleosynthesis $\Delta N_\nu < 0.3$ (WALKER 91) is employed. It applies to $m_{X^0} \ll 1$ MeV in order to be relativistic down to nucleosynthesis temperature. See paper for heavier X^0 .

¹⁴ ALLIEGRO 92 limit applies for $m_{X^0} = 150-340$ MeV and is the branching ratio times the decay probability. Limit is $< 1.5 \times 10^{-8}$ at 99%CL.

¹⁵ ATIYA 92 looked for a peak in missing mass distribution. The limit applies to $m_{X^0} = 0-130$ MeV in the narrow resonance limit. See paper for the dependence on lifetime. Covariance requires X^0 to be a vector particle.

¹⁶ MEIJERDREES 92 limit applies for $\tau_{X^0} = 10^{-23}-10^{-11}$ sec. Limits between 2×10^{-4} and 4×10^{-6} are obtained for $m_{X^0} = 25-120$ MeV. Angular momentum conservation requires that X^0 has spin ≥ 1 .

¹⁷ ATIYA 90B limit is for $B(K^+ \rightarrow \pi^+ X^0) \cdot B(X^0 \rightarrow \gamma\gamma)$ and applies for $m_{X^0} = 50$ MeV, $\tau_{X^0} < 10^{-10}$ s. Limits are also provided for $0 < m_{X^0} < 100$ MeV, $\tau_{X^0} < 10^{-8}$ s.

¹⁸ KORENCHENKO 87 limit assumes $m_{A^0} = 1.7$ MeV, $\tau_{A^0} \lesssim 10^{-12}$ s, and $B(A^0 \rightarrow e^+ e^-) = 1$.

A^0 (Axion) MASS LIMITS from Astrophysics and Cosmology

These bounds depend on model-dependent assumptions (i.e. — on a combination of axion parameters).

VALUE (MeV)	DOCUMENT ID	TECN	COMMENT

See key on page 457

Gauge & Higgs Boson Particle Listings

Axions (A^0) and Other Very Light Bosons

- ¹⁹EICHLER 86 looked for $\pi^+ \rightarrow e^+ \nu A^0$ followed by $A^0 \rightarrow e^+ e^-$. Limits on the branching fraction depend on the mass and lifetime of A^0 . The quoted limits are valid when $\tau(A^0) \gtrsim 3 \times 10^{-10}$ s if the decays are kinematically allowed.
- ²⁰YAMAZAKI 84 looked for a discrete line in $K^+ \rightarrow \pi^+ X$. Sensitive to wide mass range (5–300 MeV), independent of whether X decays promptly or not.
- ²¹ASANO 82 at KEK set limits for $B(K^+ \rightarrow \pi^+ X^0)$ for $m_{X^0} < 100$ MeV as BR $< 4 \times 10^{-8}$ for $\tau(X^0 \rightarrow n\gamma)$'s $> 1 \times 10^{-9}$ s, BR $< 1.4 \times 10^{-6}$ for $\tau < 1 \times 10^{-9}$ s.
- ²²ASANO 81b is KEK experiment. Set $B(K^+ \rightarrow \pi^+ X^0) < 3.8 \times 10^{-8}$ at CL = 90%.
- ²³ZHITNITSKII 79 argue that a heavy axion predicted by YANG 78 ($3 < m < 40$ MeV) contradicts experimental muon anomalous magnetic moments.

A^0 (Axion) Searches in Quarkonium Decays

Decay or transition of quarkonium. Limits are for branching ratio.

VALUE	CL%	DOCUMENT ID	TECN	COMMENT
●●● We do not use the following data for averages, fits, limits, etc. ●●●				
$< 5 \times 10^{-5}$	90	²⁴ DRUZHININ 87	ND	$\phi \rightarrow A^0 \gamma (A^0 \rightarrow e^+ e^-)$
$< 2 \times 10^{-3}$	90	²⁵ DRUZHININ 87	ND	$\phi \rightarrow A^0 \gamma (A^0 \rightarrow \gamma \gamma)$
$< 7 \times 10^{-6}$	90	²⁶ DRUZHININ 87	ND	$\phi \rightarrow A^0 \gamma (A^0 \rightarrow \text{missing})$
$< 1.4 \times 10^{-5}$	90	²⁷ EDWARDS 82	CBAL	$J/\psi \rightarrow A^0 \gamma$
²⁴ The first DRUZHININ 87 limit is valid when $\tau_{A^0}/m_{A^0} < 3 \times 10^{-13}$ s/MeV and $m_{A^0} < 20$ MeV.				
²⁵ The second DRUZHININ 87 limit is valid when $\tau_{A^0}/m_{A^0} < 5 \times 10^{-13}$ s/MeV and $m_{A^0} < 20$ MeV.				
²⁶ The third DRUZHININ 87 limit is valid when $\tau_{A^0}/m_{A^0} > 7 \times 10^{-12}$ s/MeV and $m_{A^0} < 200$ MeV.				
²⁷ EDWARDS 82 looked for $J/\psi \rightarrow \gamma A^0$ decays by looking for events with a single γ [of energy $\sim 1/2$ the $J/\psi(1S)$ mass], plus nothing else in the detector. The limit is inconsistent with the axion interpretation of the FAISSNER 81b result.				

A^0 (Axion) Searches in Positronium Decays

Decay or transition of positronium. Limits are for branching ratio.

³⁷ JAIN 07 claims evidence for $A^0 \rightarrow e^+ e^-$ produced in ^{207}Pb collision on nuclear emulsion (Ag/Br) for $m(A^0) = 7 \pm 1$ or 19 ± 1 MeV and $\tau(A^0) \leq 10^{-13}$ s.				
³⁸ AHMAD 97 reports a result of APEX Collaboration which studied positron production in $^{238}\text{U} + ^{232}\text{Th}$ and $^{238}\text{U} + ^{181}\text{Ta}$ collisions, without requiring a coincident electron. No narrow lines were found for $250 < E_{e^+} < 750$ keV.				
³⁹ LEINBERGER 97 (ORANGE Collaboration) at GSI looked for a narrow sum-energy $e^+ e^-$ line at ~ 635 keV in $^{238}\text{U} + ^{181}\text{Ta}$ collision. Limits on the production probability for a narrow sum-energy $e^+ e^-$ line are set. See their Table 2.				
⁴⁰ GANZ 96 (EPoS II Collaboration) has placed upper bounds on the production cross section of $e^+ e^-$ pairs from $^{238}\text{U} + ^{181}\text{Ta}$ and $^{238}\text{U} + ^{232}\text{Th}$ collisions at GSI. See Table 2 for limits both for back-to-back and isotropic configurations of $e^+ e^-$ pairs. These limits rule out the existence of peaks in the $e^+ e^-$ sum-energy distribution, reported by an earlier version of this experiment.				
⁴¹ KAMEL 96 looked for $e^+ e^-$ pairs from the collision of ^{32}S (200 GeV/nucleon) and emulsion. No evidence of mass peaks is found in the region of sensitivity $m_{e^+ e^-} > 2$ MeV.				
⁴² BLUEMLEIN 92 is a proton beam dump experiment at Serpukhov with a secondary target to induce Bethe-Heitler production of $e^+ e^-$ or $\mu^+ \mu^-$ from the produce A^0 . See Fig. 5 for the excluded region in m_{A^0} - x plane. For the standard axion, $0.3 < x < 25$ is excluded at 95% CL. If combined with BLUEMLEIN 91, $0.008 < x < 32$ is excluded.				
⁴³ MEIJERDREES 92 give $\Gamma(\pi^- p \rightarrow n A^0) / \Gamma(\pi^- p \rightarrow \text{all}) < 10^{-5}$ (90% CL) for $m_{A^0} = 100$ MeV, $\tau_{A^0} = 10^{-11}\text{--}10^{-23}$ sec. Limits ranging from 2.5×10^{-3} to 10^{-7} are given for $m_{A^0} = 25\text{--}136$ MeV.				
⁴⁴ BLUEMLEIN 91 is a proton beam dump experiment at Serpukhov. No candidate event for $A^0 \rightarrow e^+ e^-, 2\gamma$ are found. Fig. 6 gives the excluded region in m_{A^0} - x plane ($x = \tan\beta = v_2/v_1$). Standard axion is excluded for $0.2 < m_{A^0} < 3.2$ MeV for most $x > 1$, $0.2\text{--}11$ MeV for most $x < 1$.				
⁴⁵ FAISSNER 89 searched for $A^0 \rightarrow e^+ e^-$ in a proton beam dump experiment at SIN. No excess of events was observed over the background. A standard axion with mass $2m_e\text{--}20$ MeV is excluded. Lower limit on f_{A^0} of $\approx 10^4$ GeV is given for $m_{A^0} = 2m_e\text{--}20$ MeV.				
⁴⁶ DEBOER 88 reanalyze EL-NADI 88 data and claim evidence for three distinct states with mass $\sim 1.1, \sim 2.1$, and ~ 9 MeV, lifetimes $10^{-16}\text{--}10^{-15}$ s decaying to $e^+ e^-$ and note the similarity of the data with those of a cosmic-ray experiment by Bristol group (B.M. Anand, Proc. of the Royal Society of London, Section A A22 183 (1953)). For a criticism see PERKINS 89, who suggests that the events are compatible with π^0 Dalitz decay. DEBOER 89b is a reply which contests the criticism.				
⁴⁷ EL-NADI 88 claim the existence of a neutral particle decaying into $e^+ e^-$ with mass 1.60 ± 0.59 MeV, lifetime $(0.15 \pm 0.01) \times 10^{-14}$ s, which is produced in heavy ion interactions with emulsion nuclei at ~ 4 GeV/c/nucleon.				
⁴⁸ FAISSNER 88 is a proton beam dump experiment at SIN. They found no candidate event for $A^0 \rightarrow \gamma\gamma$. A standard axion decaying to 2γ is excluded except for a region $x \approx 1$. Lower limit on f_{A^0} of $10^2\text{--}10^3$ GeV is given for $m_{A^0} = 0.1\text{--}1$ MeV.				

Gauge & Higgs Boson Particle Listings

Axions (A^0) and Other Very Light Bosons

- ⁴⁹BADIER 86 did not find long-lived A^0 in 300 GeV π^- Beam Dump Experiment that decays into e^+e^- in the mass range $m_{A^0} = (20-200)$ MeV, which excludes the A^0 decay constant $f(A^0)$ in the interval (60-600) GeV. See their figure 6 for excluded region on $f(A^0)-m_{A^0}$ plane.
- ⁵⁰BERGSM 85 look for $A^0 \rightarrow 2\gamma, e^+e^-, \mu^+\mu^-$. First limit above is for $m_{A^0} = 1$ MeV; second is for 200 MeV. See their figure 4 for excluded region on $f_{A^0}-m_{A^0}$ plane, where f_{A^0} is A^0 decay constant. For Peccei-Quinn PECCEI 77 $A^0, m_{A^0} < 180$ keV and $\tau > 0.037$ s. (CL = 90%). For the axion of FAISSNER 81B at 250 keV, BERGSM 85 expect 15 events but observe zero.
- ⁵¹FAISSNER 83 observed 19 $1-\gamma$ and 12 $2-\gamma$ events where a background of 4.8 and 2.3 respectively is expected. A small-angle peak is observed even if iron wall is set in front of the decay region.
- ⁵²FAISSNER 83B extrapolate SIN γ signal to LAMPF ν experimental condition. Resulting 370 γ 's are not at variance with LAMPF upper limit of 450 γ 's. Derived from LAMPF limit that $[d\sigma(A^0)/d\omega \text{ at } 90^\circ] m_{A^0}^2/\tau_{A^0} < 14 \times 10^{-35} \text{ cm}^2 \text{ sr}^{-1} \text{ MeV ms}^{-1}$. See comment on FRANK 83B.
- ⁵³FRANK 83B stress the importance of LAMPF data bins with negative net signal. By statistical analysis say that LAMPF and SIN-A0 are at variance when extrapolation by phase-space model is done. They find LAMPF upper limit is 248 not 450 γ 's. See comment on FAISSNER 83B.
- ⁵⁴HOFFMAN 83 set CL = 90% limit $d\sigma/dt \text{ B}(e^+e^-) < 3.5 \times 10^{-32} \text{ cm}^2/\text{GeV}^2$ for 140 $< m_{A^0} < 160$ MeV. Limit assumes $\tau(A^0) < 10^{-9}$ s.
- ⁵⁵FETSCHER 82 reanalyzes SIN beam-dump data of FAISSNER 81. Claims no evidence for axion since $2-\gamma$ peak rate remarkably decreases if iron wall is set in front of the decay region.
- ⁵⁶FAISSNER 81 see excess μe events. Suggest axion interactions.
- ⁵⁷FAISSNER 81B is SIN 590 MeV proton beam dump. Observed 14.5 ± 5.0 events of 2γ decay of long-lived neutral penetrating particle with $m_{2\gamma} \lesssim 1$ MeV. Axion interpretation with $\eta-A^0$ mixing gives $m_{A^0} = 250 \pm 25$ keV, $\tau(2\gamma) = (7.3 \pm 3.7) \times 10^{-3}$ s from above rate. See critical remarks below in comments of FETSCHER 82, FAISSNER 83, FAISSNER 83B, FRANK 83B, and BERGSM 85. Also see in the next subsection ALEKSEEV 82B, CAVAIAGNAC 83, and ANANEV 85.
- ⁵⁸KIM 81 analyzed 8 candidates for $A^0 \rightarrow 2\gamma$ obtained by Aachen-Padova experiment at CERN with 26 GeV protons on Be. Estimated axion mass is about 300 keV and lifetime is $(0.86 \sim 5.6) \times 10^{-3}$ s depending on models. Faissner (private communication), says axion production underestimated and mass overestimated. Correct value around 200 keV.
- ⁵⁹FAISSNER 80 is SIN beam dump experiment with 590 MeV protons looking for $A^0 \rightarrow e^+e^-$ decay. Assuming $A^0/\pi^0 = 5.5 \times 10^{-7}$, obtained decay rate limit $20/(A^0 \text{ mass}) \text{ MeV/s}$ (CL = 90%), which is about 10^{-7} below theory and interpreted as upper limit to $m_{A^0} < 2m_{e^-}$.
- ⁶⁰JACQUES 80 is a BNL beam dump experiment. First limit above comes from nonobservation of excess neutral-current-type events $[\sigma(\text{production})\sigma(\text{interaction}) < 7. \times 10^{-68} \text{ cm}^4, \text{ CL} = 90\%]$. Second limit is from nonobservation of axion decays into 2γ 's or e^+e^- , and for axion mass a few MeV.
- ⁶¹SOUKAS 80 at BNL observed no excess of neutral-current-type events in beam dump.
- ⁶²BECHIS 79 looked for the axion production in low energy electron Bremsstrahlung and the subsequent decay into either 2γ or e^+e^- . No signal found. CL = 90% limits for model parameter(s) are given.
- ⁶³COTEUS 79 is a beam dump experiment at BNL.
- ⁶⁴DISHAW 79 is a calorimetric experiment and looks for low energy tail of energy distributions due to energy lost to weakly interacting particles.
- ⁶⁵BELLOTTI 78 first value comes from search for $A^0 \rightarrow e^+e^-$. Second value comes from search for $A^0 \rightarrow 2\gamma$, assuming mass $< 2m_{e^-}$. For any mass satisfying this, limit is above value $\times (\text{mass}^{-4})$. Third value uses data of PL 60B 401 and quotes $\sigma(\text{production})\sigma(\text{interaction}) < 10^{-67} \text{ cm}^4$.
- ⁶⁶BOSETTI 78B quotes $\sigma(\text{production})\sigma(\text{interaction}) < 2. \times 10^{-67} \text{ cm}^4$.
- ⁶⁷DONNELLY 78 examines data from reactor neutrino experiments of REINES 76 and GURR 74 as well as SLAC beam dump experiment. Evidence is negative.
- ⁶⁸MICELMACHER 78 finds no evidence of axion existence in reactor experiments of REINES 76 and GURR 74. (See reference under DONNELLY 78 below).
- ⁶⁹VYSOTSII 78 derived lower limit for the axion mass 25 keV from luminosity of the sun and 200 keV from red supergiants.

A^0 (Axion) Searches in Reactor Experiments

VALUE	DOCUMENT ID	TECN	COMMENT
• • • We do not use the following data for averages, fits, limits, etc. • • •			
	70 CHANG 07		Primakoff or Compton
	71 ALTMANN 95	CNTR	Reactor; $A^0 \rightarrow e^+e^-$
	72 KETOV 86	SPEC	Reactor; $A^0 \rightarrow \gamma\gamma$
	73 KOCH 86	SPEC	Reactor; $A^0 \rightarrow \gamma\gamma$
	74 DATAR 82	CNTR	Light water reactor
	75 VUILLEUMIER 81	CNTR	Reactor; $A^0 \rightarrow 2\gamma$
⁷⁰ CHANG 07 looked for monochromatic photons from Primakoff or Compton conversion of axions from the Kuo-Sheng reactor due to axion coupling to photon or electron, respectively. The search places model-independent limits on the products $G_{A\gamma\gamma}G_{ANN}$ and $G_{Aee}G_{ANN}$ for $m(A^0)$ less than the MeV range.			
⁷¹ ALTMANN 95 looked for A^0 decaying into e^+e^- from the Bugey5 nuclear reactor. They obtain an upper limit on the A^0 production rate of $\omega(A^0)/\omega(\gamma) \times \text{B}(A^0 \rightarrow e^+e^-) < 10^{-16}$ for $m_{A^0} = 1.5$ MeV at 90% CL. The limit is weaker for heavier A^0 . In the case of a standard axion, this limit excludes a mass in the range $2m_e < m_{A^0} < 4.8$ MeV at 90% CL. See Fig. 5 of their paper for exclusion limits of axion-like resonances Z^0 in the (m_{X^0}, f_{X^0}) plane.			
⁷² KETOV 86 searched for A^0 at the Rovno nuclear power plant. They found an upper limit on the A^0 production probability of $0.8 [100 \text{ keV}/m_{A^0}]^6 \times 10^{-6}$ per fission. In			

- the standard axion model, this corresponds to $m_{A^0} > 150$ keV. Not valid for $m_{A^0} \gtrsim 1$ MeV.
- ⁷³KOCH 86 searched for $A^0 \rightarrow \gamma\gamma$ at nuclear power reactor Biblis A. They found an upper limit on the A^0 production rate of $\omega(A^0)/\omega(\gamma(M1)) < 1.5 \times 10^{-10}$ (CL=95%). Standard axion with $m_{A^0} = 250$ keV gives 10^{-5} for the ratio. Not valid for $m_{A^0} > 1022$ keV.
- ⁷⁴DATAR 82 looked for $A^0 \rightarrow 2\gamma$ in neutron capture ($np \rightarrow dA^0$) at Tarapur 500 MW reactor. Sensitive to sum of $l = 0$ and $l = 1$ amplitudes. With ZEHNDER 81 [$l = 0$ ($l = 1$)] result, assert nonexistence of standard A^0 .
- ⁷⁵VUILLEUMIER 81 is at Grenoble reactor. Set limit $m_{A^0} < 280$ keV.

A^0 (Axion) and Other Light Boson (X^0) Searches in Nuclear Transitions

Limits are for branching ratio.

- ⁷⁶DERBIN 02 looked for the axion emission in an M1 transition in ^{125m}Te decay. They looked for a possible presence of a shifted energy spectrum in gamma rays due to the undetected axion.
- ⁷⁷DEBOER 97c reanalyzed the existent data on Nuclear M1 transitions and find that a 9 MeV boson decaying into e^+e^- would explain the excess of events with large opening angles. See also DEBOER 01 for follow-up experiments.
- ⁷⁸TSUNODA 95 looked for axion emission when ^{252}Cf undergoes a spontaneous fission, with the axion decaying into e^+e^- . The bound is for $m_{A^0}=40$ MeV. It improves to 2.5×10^{-5} for $m_{A^0}=200$ MeV.
- ⁷⁹MINOWA 93 studied chain process, $^{139}\text{Ce} \rightarrow ^{139}\text{La}^*$ by electron capture and M1 transition of $^{139}\text{La}^*$ to the ground state. It does not assume decay modes of A^0 . The bound applies for $m_{A^0} < 166$ keV.
- ⁸⁰HICKS 92 bound is applicable for $\tau_{X^0} < 4 \times 10^{-11}$ sec.
- ⁸¹The ASANUMA 90 limit is for the branching fraction of X^0 emission per ^{241}Am α decay and valid for $\tau_{X^0} < 3 \times 10^{-11}$ s.
- ⁸²The DEBOER 90 limit is for the branching ratio $^8\text{Be}^* (18.15 \text{ MeV}, 1^+) \rightarrow ^8\text{Be} A^0, A^0 \rightarrow e^+e^-$ for the mass range $m_{A^0} = 4-15$ MeV.
- ⁸³The BINI 89 limit is for the branching fraction of $^{16}\text{O}^* (6.05 \text{ MeV}, 0^+) \rightarrow ^{16}\text{O} X^0, X^0 \rightarrow e^+e^-$ for $m_X = 1.5-3.1$ MeV. $\tau_{X^0} \lesssim 10^{-11}$ s is assumed. The spin-parity of X is restricted to 0^+ or 1^- .
- ⁸⁴AVIGNONE 88 looked for the 1115 keV transition $\text{C}^* \rightarrow \text{Cu} A^0$, either from $A^0 \rightarrow 2\gamma$ in-flight decay or from the secondary A^0 interactions by Compton and by Primakoff processes. Limits for axion parameters are obtained for $m_{A^0} < 1.1$ MeV.
- ⁸⁵DATAR 88 rule out light pseudoscalar particle emission through its decay $A^0 \rightarrow e^+e^-$ in the mass range 1.02-2.5 MeV and lifetime range $10^{-13}-10^{-8}$ s. The above limit is for $\tau = 5 \times 10^{-13}$ s and $m = 1.7$ MeV; see the paper for the τ - m dependence of the limit.
- ⁸⁶The limit is for the branching fraction of $^{16}\text{O}^* (6.05 \text{ MeV}, 0^+) \rightarrow ^{16}\text{O} X^0, X^0 \rightarrow e^+e^-$ against internal pair conversion for $m_{X^0} = 1.7$ MeV and $\tau_{X^0} < 10^{-11}$ s. Similar limits are obtained for $m_{X^0} = 1.3-3.2$ MeV. The spin parity of X^0 must be either 0^+ or 1^- . The limit at 1.7 MeV is translated into a limit for the X^0 -nucleon coupling constant: $g_{X^0 NN}^2/4\pi < 2.3 \times 10^{-9}$.
- ⁸⁷The DOEHNER 88 limit is for $m_{A^0} = 1.7$ MeV, $\tau(A^0) < 10^{-10}$ s. Limits less than 10^{-4} are obtained for $m_{A^0} = 1.2-2.2$ MeV.
- ⁸⁸SAVAGE 88 looked for A^0 that decays into e^+e^- in the decay of the 9.17 MeV $J^P = 2^+$ state in ^{14}N , 17.64 MeV state $J^P = 1^+$ in ^8Be , and the 18.15 MeV state $J^P =$

See key on page 457

Gauge & Higgs Boson Particle Listings Axions (A^0) and Other Very Light Bosons

- 1^+ in ^8Be . This experiment constrains the isovector coupling of A^0 to hadrons, if $m_{A^0} = (1.1 \rightarrow 2.2)$ MeV and the isoscalar coupling of A^0 to hadrons, if $m_{A^0} = (1.1 \rightarrow 2.6)$ MeV. Both limits are valid only if $\tau(A^0) \lesssim 1 \times 10^{-11}$ s.
- ⁸⁹Limits are for $\Gamma(A^0(1.8 \text{ MeV}))/\Gamma(\pi M1)$; i.e., for 1.8 MeV axion emission normalized to the rate for internal emission of e^+e^- pairs. Valid for $\tau_{A^0} < 2 \times 10^{-11}$ s. ^6Li isovector decay data strongly disfavor PECCEI 86 model I, whereas the ^{10}B and ^{14}N isoscalar decay data strongly reject PECCEI 86 model II and III.
- ⁹⁰SAVAGE 86B looked for A^0 that decays into e^+e^- in the decay of the 9.17 MeV $J^P = 2^+$ state in ^{14}N . Limit on the branching fraction is valid if $\tau_{A^0} \lesssim 1 \times 10^{-11}$ s for $m_{A^0} = (1.1-1.7)$ MeV. This experiment constrains the iso-vector coupling of A^0 to hadrons.
- ⁹¹ANANEV 85 with IBR-2 pulsed reactor exclude standard A^0 at CL = 95% masses below 470 keV (Li^* decay) and below $2m_e$ for deuteron* decay.
- ⁹²CAVAIGNAC 83 at Bugey reactor exclude axion at any $m_{97\text{Nb}^*}$ decay and axion with m_{A^0} between 275 and 288 keV (deuteron* decay).
- ⁹³ALEKSEEV 82 with IBR-2 pulsed reactor exclude standard A^0 at CL = 95% mass-ranges $m_{A^0} < 400$ keV (Li^* decay) and 330 keV $< m_{A^0} < 2.2$ MeV. (deuteron* decay).
- ⁹⁴LEHMANN 82 obtained $A^0 \rightarrow 2\gamma$ rate $< 6.2 \times 10^{-5}/\text{s}$ (CL = 95%) excluding m_{A^0} between 100 and 1000 keV.
- ⁹⁵ZEHNDER 82 used Gosgen 2.8GW light-water reactor to check A^0 production. No 2γ peak in Li^* , Nb^* decay (both single p transition) nor in n capture (combined with previous Ba^* negative result) rules out standard A^0 . Set limit $m_{A^0} < 60$ keV for any A^0 .
- ⁹⁶ZEHNDER 81 looked for $\text{Ba}^* \rightarrow A^0\text{Ba}$ transition with $A^0 \rightarrow 2\gamma$. Obtained 2γ coincidence rate $< 2.2 \times 10^{-5}/\text{s}$ (CL = 95%) excluding $m_{A^0} > 160$ keV (or 200 keV depending on Higgs mixing). However, see BARROSO 81.
- ⁹⁷CALAPRICE 79 saw no axion emission from excited states of carbon. Sensitive to axion mass between 1 and 15 MeV.

A^0 (Axion) Limits from Its Electron Coupling

Limits are for $\tau(A^0 \rightarrow e^+e^-)$.

VALUE (s)	CL%	DOCUMENT ID	TECN	COMMENT
• • • We do not use the following data for averages, fits, limits, etc. • • •				
none 4×10^{-16} - 4.5×10^{-12}	90	98 BROSS	91 BDMP	$eN \rightarrow eA^0N$ ($A^0 \rightarrow ee$)
		99 GUO	90 BDMP	$eN \rightarrow eA^0N$ ($A^0 \rightarrow ee$)
		100 BJORKEN	88 CALO	$A \rightarrow e^+e^-$ or 2γ
		101 BLINOV	88 MD1	$ee \rightarrow eeA^0$ ($A^0 \rightarrow ee$)

none 6×10^{-14} - 9×10^{-11}	95	104 DAVIER	86 BDMP	$eN \rightarrow eA^0N$ ($A^0 \rightarrow ee$)
none 3×10^{-13} - 1×10^{-7}	90	105 KONAKA	86 BDMP	$eN \rightarrow eA^0N$ ($A^0 \rightarrow ee$)
⁹⁸ The listed BROSS 91 limit is for $m_{A^0} = 1.14$ MeV. $B(A^0 \rightarrow e^+e^-) = 1$ assumed. Excluded domain in the $\tau_{A^0}-m_{A^0}$ plane extends up to $m_{A^0} \approx 7$ MeV (see Fig. 5). Combining with electron $g-2$ constraint, axions coupling only to e^+e^- ruled out for $m_{A^0} < 4.8$ MeV (90% CL).				
⁹⁹ GUO 90 use the same apparatus as BROWN 86 and improve the previous limit in the shorter lifetime region. Combined with $g-2$ constraint, axions coupling only to e^+e^- are ruled out for $m_{A^0} < 2.7$ MeV (90% CL).				
¹⁰⁰ BJORKEN 88 reports limits on axion parameters (f_A, m_A, τ_A) for $m_{A^0} < 200$ MeV from electron beam-dump experiment with production via Primakoff photoproduction, bremsstrahlung from electrons, and resonant annihilation of positrons on atomic electrons.				
¹⁰¹ BLINOV 88 assume zero spin, $m = 1.8$ MeV and lifetime $< 5 \times 10^{-12}$ s and find $\Gamma(A^0 \rightarrow \gamma\gamma)B(A^0 \rightarrow e^+e^-) < 2$ eV (CL=90%).				
¹⁰² Assumes $A^0\gamma\gamma$ coupling is small and hence Primakoff production is small. Their figure 2 shows limits on axions for $m_{A^0} < 15$ MeV.				
¹⁰³ Uses electrons in hadronic showers from an incident 800 GeV proton beam. Limits for $m_{A^0} < 15$ MeV are shown in their figure 3.				
¹⁰⁴ $m_{A^0} = 1.8$ MeV assumed. The excluded domain in the $\tau_{A^0}-m_{A^0}$ plane extends up to $m_{A^0} \approx 14$ MeV, see their figure 4.				
¹⁰⁵ The limits are obtained from their figure 3. Also given is the limit on the $A^0\gamma\gamma-A^0e^+e^-$ coupling plane by assuming Primakoff production.				

Search for A^0 (Axion) Resonance in Bhabha Scattering

The limit is for $\Gamma(A^0)B(A^0 \rightarrow e^+e^-)^2$.

- ¹⁰⁶HALLIN 92 quote limits on lifetime, $8 \times 10^{-14} - 5 \times 10^{-13}$ sec depending on mass, assuming $B(A^0 \rightarrow e^+e^-) = 100\%$. They say that TSERTOS 91 overstated their sensitivity by a factor of 3.
- ¹⁰⁷HENDERSON 92c exclude axion with lifetime $\tau_{A^0} = 1.4 \times 10^{-12} - 4.0 \times 10^{-10}$ s, assuming $B(A^0 \rightarrow e^+e^-) = 100\%$. HENDERSON 92c also exclude a vector boson with $\tau = 1.4 \times 10^{-12} - 6.0 \times 10^{-10}$ s.
- ¹⁰⁸WU 92 quote limits on lifetime $> 3.3 \times 10^{-13}$ s assuming $B(A^0 \rightarrow e^+e^-) = 100\%$. They say that TSERTOS 89 overestimate the limit by a factor of $\pi/2$. WU 92 also quote a bound for vector boson, $\tau > 8.2 \times 10^{-13}$ s.
- ¹⁰⁹WIDMANN 91 bound applies exclusively to the case $B(A^0 \rightarrow e^+e^-) = 1$, since the detection efficiency varies substantially as $\Gamma(A^0)_{\text{total}}$ changes. See their Fig. 6.
- ¹¹⁰JUDGE 90 excludes an elastic pseudoscalar e^+e^- resonance for $4.5 \times 10^{-13} \text{ s} < \tau(A^0) < 7.5 \times 10^{-12} \text{ s}$ (95% CL) at $m_{A^0} = 1.832$ MeV. Comparable limits can be set for $m_{A^0} = 1.776-1.856$ MeV.
- ¹¹¹See also TSERTOS 88B in references.
- ¹¹²The upper limit listed in TSERTOS 88 is too large by a factor of 4. See TSERTOS 88B, footnote 3.
- ¹¹³VANKLINKEN 88 looked for relatively long-lived resonance ($\tau = 10^{-10}-10^{-12}$ s). The sensitivity is not sufficient to exclude such a narrow resonance.
- ¹¹⁴MAIER 87 obtained limits $R\Gamma \lesssim 60$ eV (100 eV) at $m_{A^0} \approx 1.64$ MeV (1.83 MeV) for energy resolution $\Delta E_{\text{cm}} \approx 3$ keV, where R is the resonance cross section normalized to that of Bhabha scattering, and $\Gamma = \Gamma_{ee}^2/\Gamma_{\text{total}}$. For a discussion implying that $\Delta E_{\text{cm}} \approx 10$ keV, see TSERTOS 89.
- ¹¹⁵VONWIMMERSPERG 87 measured Bhabha scattering for $E_{\text{cm}} = 1.37-1.86$ MeV and found a possible peak at 1.73 with $\int \sigma dE_{\text{cm}} = 14.5 \pm 6.8$ keV-b. For a comment and a reply, see VANKLINKEN 88B and VONWIMMERSPERG 88. Also see CONNELL 88.

Search for A^0 (Axion) Resonance in $e^+e^- \rightarrow \gamma\gamma$

The limit is for $\Gamma(A^0 \rightarrow e^+e^-)\Gamma(A^0 \rightarrow \gamma\gamma)/\Gamma_{\text{total}}$

VALUE (10^{-3} eV)	CL%	DOCUMENT ID	TECN	COMMENT

- • • We do not use the following data for averages, fits, limits, etc. • • •
- 122 MITSUI 96 looked for a monochromatic γ . The bound applies for a vector X^0 with $C=-1$ and $m_{X^0} < 200$ keV. They derive an upper bound on $e e X^0$ coupling and hence on the branching ratio $B(\rho\text{-Ps} \rightarrow \gamma\gamma X^0) < 6.2 \times 10^{-6}$. The bounds weaken for heavier X^0 .
- 123 SKALSEY 95 looked for a monochromatic γ without an accompanying γ in e^+e^- annihilation. The bound applies for scalar and vector X^0 with $C = -1$ and $m_{X^0} = 100\text{--}1000$ keV.
- 124 SKALSEY 95 reinterpreted the bound on γA^0 decay of ρ -Ps by ASA1 91 where 3% of delayed annihilations are not from 3S_1 states. The bound applies for scalar and vector X^0 with $C = -1$ and $m_{X^0} = 0\text{--}800$ keV.
- 125 ADACHI 94 looked for a peak in the $\gamma\gamma$ invariant mass distribution in $\gamma\gamma\gamma\gamma$ production from e^+e^- annihilation. The bound applies for $m_{X^0} = 70\text{--}800$ keV.
- 126 ADACHI 94 looked for a peak in the missing-mass mass distribution in $\gamma\gamma$ channel, using $\gamma\gamma\gamma\gamma$ production from e^+e^- annihilation. The bound applies for $m_{X^0} < 800$ keV.
- 127 ADACHI 94 looked for a peak in the missing mass distribution in $\gamma\gamma\gamma$ channel, using $\gamma\gamma\gamma\gamma$ production from e^+e^- annihilation. The bound applies for $m_{X^0} = 200\text{--}900$ keV.

Searches for Goldstone Bosons (X^0)

(Including Horizontal Bosons and Majorons.) Limits are for branching ratios.

- • • We do not use the following data for averages, fits, limits, etc. • • •
- 128 LESSA 07 consider decays of the form Meson $\rightarrow \ell\nu$ Majoron and $\ell \rightarrow \ell'\nu\pi$ Majoron and use existing data to derive limits on the neutrino-Majoron Yukawa couplings $g_{\alpha\beta}$ ($\alpha, \beta = e, \mu, \tau$). Their best limits are $|g_{e\alpha}|^2 < 5.5 \times 10^{-6}$, $|g_{\mu\alpha}|^2 < 4.5 \times 10^{-5}$, $|g_{\tau\alpha}|^2 < 5.5 \times 10^{-2}$ at CL = 90%.
- 129 DIAZ 98 studied models of spontaneously broken lepton number with both singlet and triplet Higgses. They obtain limits on the parameter space from invisible decay $Z \rightarrow H^0 A^0 \rightarrow X^0 X^0 X^0 X^0$ and $e^+e^- \rightarrow ZH^0$ with $H^0 \rightarrow X^0 X^0$.
- 130 BOBRÁKOV 91 searched for anomalous magnetic interactions between polarized electrons expected from the exchange of a massless pseudoscalar boson (arion). A limit $\chi_e^2 < 2 \times 10^{-4}$ (95%CL) is found for the effective anomalous magneton parametrized as $\chi_e(G_F/8\pi\sqrt{2})^{1/2}$.
- 131 ALBRECHT 90E limits are for $B(\tau \rightarrow \ell X^0)/B(\tau \rightarrow \ell\nu\pi)$. Valid for $m_{X^0} < 100$ MeV. The limits rise to 7.1% (for μ), 5.0% (for e) for $m_{X^0} = 500$ MeV.
- 132 ATIYA 90 limit is for $m_{X^0} = 0$. The limit $B < 1 \times 10^{-8}$ holds for $m_{X^0} < 95$ MeV. For the reduction of the limit due to finite lifetime of X^0 , see their Fig. 3.
- 133 BOLTON 88 limit corresponds to $F > 3.1 \times 10^9$ GeV, which does not depend on the chirality property of the coupling.
- 134 CHANDA 88 find $v_T < 10$ MeV for the weak-triplet Higgs vacuum expectation value in Gelmini-Roncadelli model, and $v_S > 5.8 \times 10^6$ GeV in the singlet Majoron model.
- 135 CHOI 88 used the observed neutrino flux from the supernova SN 1987A to exclude the neutrino Majoron Yukawa coupling h in the range $2 \times 10^{-5} < h < 3 \times 10^{-4}$ for the interaction $L_{\text{int}} = \frac{1}{2} i h \bar{\psi}_\nu \gamma_5 \psi_\nu \phi_X$. For several families of neutrinos, the limit applies for $(\Sigma h^2)^{1/4}$.
- 136 PICCIOTTO 88 limit applies when $m_{X^0} < 55$ MeV and $\tau_{X^0} > 2$ ns, and it decreases to 4×10^{-7} at $m_{X^0} = 125$ MeV, beyond which no limit is obtained.
- 137 GOLDMAN 87 limit corresponds to $F > 2.9 \times 10^9$ GeV for the family symmetry breaking scale from the Lagrangian $L_{\text{int}} = (1/F) \bar{\psi}_\mu \gamma^\mu (\alpha + b\gamma_5) \psi_e \phi_\mu \phi_{X^0}$ with $\alpha^2 + b^2 = 1$. This is not as sensitive as the limit $F > 9.9 \times 10^9$ GeV derived from the search for $\mu^+ \rightarrow e^+ X^0$ by JODIDIO 86, but does not depend on the chirality property of the coupling.

- 138 Limits are for $\Gamma(\mu \rightarrow e X^0)/\Gamma(\mu \rightarrow e\nu\pi)$. Valid when $m_{X^0} = 0\text{--}93.4, 98.1\text{--}103.5$ MeV.
- 139 EICHLER 86 looked for $\mu^+ \rightarrow e^+ X^0$ followed by $X^0 \rightarrow e^+ e^-$. Limits on the branching fraction depend on the mass and lifetime of X^0 . The quoted limits are valid when $\tau_{X^0} \lesssim 3 \times 10^{-10}$ s if the decays are kinematically allowed.
- 140 JODIDIO 86 corresponds to $F > 9.9 \times 10^9$ GeV for the family symmetry breaking scale with the parity-conserving effective Lagrangian $L_{\text{int}} = (1/F) \bar{\psi}_\mu \gamma^\mu \psi_e \phi_\mu \phi_{X^0}$.
- 141 BALTRUSAITIS 85 search for light Goldstone boson (X^0) of broken U(1). CL = 95% limits are $B(\tau \rightarrow \mu^+ X^0)/B(\tau \rightarrow \mu^+ \nu\nu) < 0.125$ and $B(\tau \rightarrow e^+ X^0)/B(\tau \rightarrow e^+ \nu\nu) < 0.04$. Inferred limit for the symmetry breaking scale is $m > 3000$ TeV.
- 142 The primordial heavy neutrino must decay into ν and familon, f_A , early so that the red-shifted decay products are below critical density, see their table. In addition, $K \rightarrow \pi f_A$ and $\mu \rightarrow e f_A$ are unobserved. Combining these excludes $m_{\text{heavy}\nu}$ between 5×10^{-5} and 5×10^{-4} MeV (μ decay) and $m_{\text{heavy}\nu}$ between 5×10^{-5} and 0.1 MeV (K -decay).

Majoron Searches in Neutrinoless Double β Decay

Limits are for the half-life of neutrinoless $\beta\beta$ decay with a Majoron emission.

No experiment currently claims any such evidence. Only the best or comparable limits for each isotope are reported. Also see the reviews ZUBER 98 and FAESSLER 98b.

- 143 BERNATOWICZ 92 studied double- β decays of ¹²⁸Te and ¹³⁰Te, and found the ratio $\tau(^{130}\text{Te})/\tau(^{128}\text{Te}) = (3.52 \pm 0.11) \times 10^{-4}$ in agreement with relatively stable theoretical predictions. The bound is based on the requirement that Majoron-emitting decay cannot be larger than the observed double-beta rate of ¹²⁸Te of $(7.7 \pm 0.4) \times 10^{24}$ year. We calculated 90% CL limit as $(7.7 \pm 1.28 \times 0.4 = 7.2) \times 10^{24}$.
- 144 ARNOLD 11 use the NEMO-3 detector to obtain the reported limit on Majoron emission. It implies that the coupling constant $g_{\nu\chi} < 0.6\text{--}1.6 \times 10^{-4}$ depending on the nuclear matrix element used. Supersedes ARNABOLDI 03.
- 145 ARGYRIADES 10 use the NEMO-3 tracking detector and ⁹⁶Zr to derive the reported limit. No limit for the Majoron electron coupling is given.
- 146 ARGYRIADES 09 use ¹⁵⁰Nd data taken with the NEMO-3 tracking detector. The reported limit corresponds to $\langle g_{\nu\chi} \rangle < 1.7\text{--}3.0 \times 10^{-4}$ using a range of nuclear matrix elements that include the effect of nuclear deformation.
- 147 ARNOLD 06 use ¹⁰⁰Mo data taken with the NEMO-3 tracking detector. The reported limit corresponds to $\langle g_{\nu\chi} \rangle < (0.4\text{--}1.8) \times 10^{-4}$ using a range of matrix element calculations. Supersedes ARNOLD 04.
- 148 NEMO-3 tracking calorimeter is used in ARNOLD 06. Reported half-life limit for ⁸²Se corresponds to $\langle g_{\nu\chi} \rangle < (0.66\text{--}1.9) \times 10^{-4}$ using a range of matrix element calculations. Supersedes ARNOLD 04.
- 149 ARNOLD 04 use the NEMO-3 tracking detector. The limit corresponds to $\langle g_{\nu\chi} \rangle < (0.5\text{--}0.9) \times 10^{-4}$ using the matrix elements of SIMKOVIĆ 99, STOICA 01 and CIVITARESE 03.
- 150 ARNOLD 04 use the NEMO-3 tracking detector. The limit corresponds to $\langle g_{\nu\chi} \rangle < (0.7\text{--}1.6) \times 10^{-4}$ using the matrix elements of SIMKOVIĆ 99, STOICA 01 and CIVITARESE 03.
- 151 Supersedes ALESSANDRELLO 00. Array of TeO₂ crystals in high resolution cryogenic calorimeter. Some enriched in ¹³⁰Te. Derive $\langle g_{\nu\chi} \rangle < 17\text{--}33 \times 10^{-5}$ depending on matrix element.
- 152 Supersedes ALESSANDRELLO 00. Cryogenic calorimeter search.
- 153 Limit for the $0\nu\chi$ decay with Majoron emission of ¹¹⁶Cd using enriched CdWO₄ scintillators. $\langle g_{\nu\chi} \rangle < 4.6\text{--}8.1 \times 10^{-5}$ depending on the matrix element. Supersedes DANEVICH 00.
- 154 Limit for the $0\nu2\chi$ decay of ¹¹⁶Cd. Supersedes DANEVICH 00.
- 155 BERNABEI 02b obtain limit for $0\nu\chi$ decay with Majoron emission of ¹³⁶Xe using liquid Xe scintillation detector. They derive $\langle g_{\nu\chi} \rangle < 2.0\text{--}3.0 \times 10^{-5}$ with several nuclear matrix elements.

See key on page 457

Gauge & Higgs Boson Particle Listings

Axions (A^0) and Other Very Light Bosons

- 156 Replaces TANAKA 93. FUSHIMI 02 derive half-life limit for the $0\nu\chi$ decay by means of tracking calorimeter ELEGANT V. Considering various matrix element calculations, a range of limits for the Majoron-neutrino coupling is given: $\langle g_{\nu\chi} \rangle < (6.3-360) \times 10^{-5}$.
- 157 ASHITKOV 01 result for $0\nu\chi$ of ^{100}Mo is less stringent than ARNOLD 00.
- 158 DANEVICH 01 obtain limit for the $0\nu\chi$ decay with Majoron emission of ^{160}Gd using $\text{Gd}_2\text{SiO}_5:\text{Ce}$ crystal scintillators.
- 159 DANEVICH 01 obtain limit for the $0\nu2\chi$ decay with 2 Majoron emission of ^{160}Gd .
- 160 ARNOLD 00 reports limit for the $0\nu\chi$ decay with Majoron emission derived from tracking calorimeter NEMO 2. Using ^{82}Se source: $\langle g_{\nu\chi} \rangle < 1.6 \times 10^{-4}$. Matrix element from GUENTHER 96.
- 161 Using ^{96}Zr source: $\langle g_{\nu\chi} \rangle < 2.6 \times 10^{-4}$. Matrix element from ARNOLD 99.
- 162 ARNOLD 00 reports limit for the $0\nu2\chi$ decay with two Majoron emission derived from tracking calorimeter NEMO 2.
- 163 ARNOLD 98 determine the limit for $0\nu\chi$ decay with Majoron emission of ^{82}Se using the NEMO-2 tracking detector. They derive $\langle g_{\nu\chi} \rangle < 2.3-4.3 \times 10^{-4}$ with several nuclear matrix elements.
- 164 LUESCHER 98 report a limit for the 0ν decay with Majoron emission of ^{136}Xe using Xe TPC. This result is more stringent than BARABASH 89. Using the matrix elements of ENGEL 88, they obtain a limit on $\langle g_{\nu\chi} \rangle$ of 2.0×10^{-4} .
- 165 See Table 1 in GUENTHER 96 for limits on the Majoron coupling in different models.

Invisible A^0 (Axion) MASS LIMITS from Astrophysics and Cosmology

$v_1 = v_2$ is usually assumed ($v_i =$ vacuum expectation values). For a review of these limits, see RAFFELT 91 and TURNER 90. In the comment lines below, D and K refer to DFSZ and KSVZ axion types, discussed in the above minireview.

- 166 CADAMURO 11 use the deuterium abundance to show that the m_{A^0} range $0.7\text{eV} - 300\text{keV}$ is excluded for axions, complementing HANNESTAD 10.
- 167 DERBIN 11A look for solar axions produced by Compton and bremsstrahlung processes, in the resonant excitation of ^{169}Tm , constraining the axion-electron \times axion-nucleon couplings.
- 168 ANDRIAMONJE 10 search for solar axions produced from ^7Li (478 keV) and $\text{D}(\rho,\gamma)^3\text{He}$ (5.5 MeV) nuclear transitions. They show limits on the axion-photon coupling for two reference values of the axion-nucleon coupling for $m_A < 100\text{eV}$.
- 169 This is an update of HANNESTAD 08 including 7 years of WMAP data.
- 170 ANDRIAMONJE 09 look for solar axions produced from the thermally excited 14.4 keV level of ^{57}Fe . They show limits on the axion-nucleon \times axion-photon coupling assuming $m_A < 0.03\text{eV}$.
- 171 DERBIN 09A look for Primakoff-produced solar axions in the resonant excitation of ^{169}Tm , constraining the axion-photon \times axion-nucleon couplings.
- 172 KEKEZ 09 look at axio-electric effect of solar axions in HPGe detectors. The one-loop axion-electron coupling for hadronic axions is used.
- 173 This is an update of HANNESTAD 07 including 5 years of WMAP data.
- 174 This is an update of HANNESTAD 05A with new cosmological data, notably WMAP (3 years) and baryon acoustic oscillations (BAO). Lyman- α data are left out, in contrast to HANNESTAD 05A and MELCHIORRI 07A, because it is argued that systematic errors are large. It uses Bayesian statistics and marginalizes over a possible neutrino hot dark matter component.
- 175 MELCHIORRI 07A is analogous to HANNESTAD 05A, with updated cosmological data, notably WMAP (3 years). Uses Bayesian statistics and marginalizes over a possible neutrino hot dark matter component. Leaving out Lyman- α data, a conservative limit is 1.4eV .
- 176 HANNESTAD 05A puts an upper limit on the mass of hadronic axion because in this mass range it would have been thermalized and contribute to the hot dark matter component of the universe. The limit is based on the CMB anisotropy from WMAP, SDSS large scale structure, Lyman α , and the prior Hubble parameter from HST Key Project. A χ^2 statistic is used. Neutrinos are assumed not to contribute to hot dark matter.
- 177 MOROI 98 points out that a KSVZ axion of this mass range (see CHANG 93) can be a viable hot dark matter of Universe, as long as the model-dependent $g_{A\gamma}$ is accidentally small enough as originally emphasized by KAPLAN 85; see Fig. 1.
- 178 BORISOV 97 bound is on the axion-electron coupling $g_{ae} < 1 \times 10^{-13}$ from the photo-production of axions off of magnetic fields in the outer layers of neutron stars.
- 179 KACHELRIESS 97 bound is on the axion-electron coupling $g_{ae} < 1 \times 10^{-10}$ from the production of axions in strongly magnetized neutron stars. The authors also quote a stronger limit, $g_{ae} < 9 \times 10^{-13}$ which is strongly dependent on the strength of the magnetic field in white dwarfs.
- 180 KEIL 97 uses new measurements of the axial-vector coupling strength of nucleons, as well as a reanalysis of many-body effects and pion-emission processes in the core of the neutron star, to update limits on the invisible-axion mass.
- 181 RAFFELT 95 reexamined the constraints on axion emission from red giants due to the axion-electron coupling. They improve on DEARBORN 86 by taking into proper account degeneracy effects in the bremsstrahlung rate. The limit comes from requiring the red giant core mass at helium ignition not to exceed its standard value by more than 5% (0.025 solar masses).
- 182 ALTHERR 94 bound is on the axion-electron coupling $g_{ae} < 1.5 \times 10^{-13}$, from energy loss via axion emission.
- 183 CHANG 93 updates ENGEL 90 bound with the Kaplan-Manohar ambiguity in $z=m_\mu/m_d$ (see the Note on the Quark Masses in the Quark Particle Listings). It leaves the window $f_A=3 \times 10^5-3 \times 10^6\text{GeV}$ open. The constraint from Big-Bang Nucleosynthesis is satisfied in this window as well.
- 184 BERSHADY 91 searched for a line at wave length from 3100-8300 \AA expected from 2γ decays of relic thermal axions in intergalactic light of three rich clusters of galaxies.
- 185 KIM 91c argues that the bound from the mass density of the universe will change drastically for the supersymmetric models due to the entropy production of saxion (scalar component in the axionic chiral multiplet) decay. Note that it is an *upperbound* rather than a lowerbound.
- 186 RAFFELT 91B argue that previous SN 1987A bounds must be relaxed due to corrections to nucleon bremsstrahlung processes.
- 187 RESSELL 91 uses absence of any intracluster line emission to set limit.
- 188 ENGEL 90 rule out $10^{-10} \lesssim g_{AN} \lesssim 10^{-3}$, which for a hadronic axion with EMC motivated axion-nucleon couplings corresponds to $2.5 \times 10^{-3}\text{eV} \lesssim m_{A^0} \lesssim 2.5 \times 10^4\text{eV}$. The constraint is loose in the middle of the range, i.e. for $g_{AN} \sim 10^{-6}$.
- 189 RAFFELT 90D is a re-analysis of DEARBORN 86.
- 190 The region $m_{A^0} \gtrsim 2\text{eV}$ is also allowed.
- 191 ERICSON 89 considered various nuclear corrections to axion emission in a supernova core, and found a reduction of the previous limit (MAYLE 88) by a large factor.
- 192 MAYLE 89 limit based on naive quark model couplings of axion to nucleons. Limit based on couplings motivated by EMC measurements is 2-4 times weaker. The limit from axion-electron coupling is weak: see HATSUDA 88B.
- 193 RAFFELT 88B derives a limit for the energy generation rate by exotic processes in helium-burning stars $\epsilon < 100\text{erg g}^{-1}\text{s}^{-1}$, which gives a firmer basis for the axion limits based on red giant cooling.
- 194 RAFFELT 87 also gives a limit $g_{A\gamma} < 1 \times 10^{-10}\text{GeV}^{-1}$.
- 195 DEARBORN 86 also gives a limit $g_{A\gamma} < 1.4 \times 10^{-11}\text{GeV}^{-1}$.
- 196 RAFFELT 86 gives a limit $g_{A\gamma} < 1.1 \times 10^{-10}\text{GeV}^{-1}$ from red giants and $< 2.4 \times 10^{-9}\text{GeV}^{-1}$ from the sun.
- 197 KAPLAN 85 says $m_{A^0} < 23\text{eV}$ is allowed for a special choice of model parameters.
- 198 FUKUGITA 82 gives a limit $g_{A\gamma} < 2.3 \times 10^{-10}\text{GeV}^{-1}$.

Search for Relic Invisible Axions

Limits are for $[G_{A\gamma\gamma}/m_{A^0}]^2\rho_A$ where $G_{A\gamma\gamma}$ denotes the axion two-photon coupling, $L_{\text{int}} = \frac{G_{A\gamma\gamma}}{4}\phi_A F_{\mu\nu}\tilde{F}^{\mu\nu} = G_{A\gamma\gamma}\phi_A\mathbf{E}\cdot\mathbf{B}$, and ρ_A is the axion energy density near the earth.

Axions (A^0) and Other Very Light Bosons

$<3.5 \times 10^{-43}$	199	HOSKINS	11	ADMX	$m_{A^0} = 3.3\text{--}3.69 \times 10^{-6}$ eV
$<2.9 \times 10^{-43}$	90	200 ASZTALOS	10	ADMX	$m_{A^0} = 3.34\text{--}3.53 \times 10^{-6}$ eV
$<1.9 \times 10^{-43}$	97.7	201 DUFFY	06	ADMX	$m_{A^0} = 1.98\text{--}2.17 \times 10^{-6}$ eV
$<5.5 \times 10^{-43}$	90	202 ASZTALOS	04	ADMX	$m_{A^0} = 1.9\text{--}3.3 \times 10^{-6}$ eV
		203 KIM	98	THEO	
$<2 \times 10^{-41}$		204 HAGMANN	90	CNTR	$m_{A^0} = (5.4\text{--}5.9)10^{-6}$ eV
$<1.3 \times 10^{-42}$	95	205 WUENSCH	89	CNTR	$m_{A^0} = (4.5\text{--}10.2)10^{-6}$ eV
$<2 \times 10^{-41}$	95	205 WUENSCH	89	CNTR	$m_{A^0} = (11.3\text{--}16.3)10^{-6}$ eV

199 HOSKINS 11 is analogous to DUFFY 06. See Fig. 4 for the mass-dependent limit in terms of the local density.

200 ASZTALOS 10 used the upgraded detector of ASZTALOS 04 to search for halo axions. See their Fig. 5 for the m_{A^0} dependence of the limit.

201 DUFFY 06 used the upgraded detector of ASZTALOS 04, while assuming a smaller velocity dispersion than the isothermal model as in Eq. (8) of their paper. See Fig. 10 of their paper on the axion mass dependence of the limit.

202 ASZTALOS 04 looked for a conversion of halo axions to microwave photons in magnetic field. At 90% CL, the KSVZ axion cannot have a local halo density more than 0.45 GeV/cm^3 in the quoted mass range. See Fig. 7 of their paper on the axion mass dependence of the limit.

203 KIM 98 calculated the axion-to-photon couplings for various axion models and compared them to the HAGMANN 90 bounds. This analysis demonstrates a strong model dependence of $G_{A\gamma\gamma}$ and hence the bound from relic axion search.

204 HAGMANN 90 experiment is based on the proposal of SIKIVIE 83.

205 WUENSCH 89 looks for condensed axions near the earth that could be converted to photons in the presence of an intense electromagnetic field via the Primakoff effect, following the proposal of SIKIVIE 83. The theoretical prediction with $[G_{A\gamma\gamma}/m_{A^0}]^2 = 2 \times 10^{-14} \text{ MeV}^{-4}$ (the three generation DFSZ model) and $\rho_A = 300 \text{ MeV/cm}^3$ that makes up galactic halos gives $(G_{A\gamma\gamma}/m_{A^0})^2 \rho_A = 4 \times 10^{-44}$. Note that our definition of $G_{A\gamma\gamma}$ is $(1/4\pi)$ smaller than that of WUENSCH 89.

Invisible A^0 (Axion) Limits from Photon Coupling

Limits are for the axion-two-photon coupling $G_{A\gamma\gamma}$ defined by $L = G_{A\gamma\gamma}\phi_A^2 \mathbf{E} \cdot \mathbf{B}$.

For scalars S^0 the limit is on the coupling constant in $L = G_{S\gamma\gamma}\phi_S(\mathbf{E}^2 - \mathbf{B}^2)$.

206 ARIK 11 search for solar axions using ^3He buffer gas in CAST, continuing from the ^4He version of ARIK 09. See Fig. 2 for the exact mass-dependent limits.

207 ALPS is a photon regeneration experiment. See their Fig. 4 for mass-dependent limits on scalar and pseudoscalar bosons.

208 AHMED 09A is analogous to AVIGNONE 98.

209 ARIK 09 is the ^4He filling version of the CAST axion helioscope in analogy to INOUE 02 and INOUE 08. See their Fig. 7 for mass-dependent limits.

210 CHOU 09 use the GammeV apparatus in the afterglow mode to search for chameleons, (pseudo)scalar bosons with a mass depending on the environment. For pseudoscalars they exclude at 3σ the range $2.6 \times 10^{-7} \text{ GeV}^{-1} < G_{A\gamma\gamma} < 4.2 \times 10^{-6} \text{ GeV}^{-1}$ for vacuum m_{A^0} roughly below 6 meV for density scaling index exceeding 0.8.

211 GONDOLO 09 use the all-flavor measured solar neutrino flux to constrain solar interior temperature and thus energy losses.

212 LIPSS photon regeneration experiment, assuming scalar particle S^0 . See Fig. 4 for mass-dependent limits.

213 CHOU 08 perform a variable-baseline photon regeneration experiment. See their Fig. 3 for mass-dependent limits. Excludes the PVLAS result of ZAVATTINI 06.

214 FOUCHE 08 is an update of ROBILLIARD 07. See their Fig. 12 for mass-dependent limits.

215 INOUE 08 is an extension of INOUE 02 to larger axion masses, using the Tokyo axion helioscope. See their Fig. 4 for mass-dependent limits.

216 ZAVATTINI 08 is an upgrade of ZAVATTINI 06, see their Fig. 8 for mass-dependent limits. They now exclude the parameter range where ZAVATTINI 06 had seen a positive signature.

217 ANDRIAMONJE 07 looked for Primakoff conversion of solar axions in 9T superconducting magnet into X-rays. Supersedes ZIOUTAS 05.

218 ROBILLIARD 07 perform a photon regeneration experiment with a pulsed laser and pulsed magnetic field. See their Fig. 4 for mass-dependent limits. Excludes the PVLAS result of ZAVATTINI 06 with a CL exceeding 99.9%.

219 ZAVATTINI 06 propagate a laser beam in a magnetic field and observe dichroism and birefringence effects that could be attributed to an axion-like particle. This result is now excluded by ROBILLIARD 07, ZAVATTINI 08, and CHOU 08.

220 INOUE 02 looked for Primakoff conversion of solar axions in 4T superconducting magnet into X-ray.

221 MORALES 02B looked for the coherent conversion of solar axions to photons via the Primakoff effect in Germanium detector.

222 BERNABEI 01B looked for Primakoff coherent conversion of solar axions into photons via Bragg scattering in NaI crystal in DAMA dark matter detector.

223 ASTIER 00B looked for production of axions from the interaction of high-energy photons with the horn magnetic field and their subsequent re-conversion to photons via the interaction with the NOMAD dipole magnetic field.

224 MASSO 00 studied limits on axion-proton coupling using the induced axion-photon coupling through the proton loop and CAMERON 93 bound on the axion-photon coupling using optical rotation. They obtained the bound $g_P^2/4\pi < 1.7 \times 10^{-9}$ for the coupling $g_P \bar{p} \gamma_5 p \phi_A$.

225 AVIGNONE 98 result is based on the coherent conversion of solar axions to photons via the Primakoff effect in a single crystal germanium detector.

226 Based on the conversion of solar axions to X-rays in a strong laboratory magnetic field.

227 Experiment based on proposal by MAIANI 86.

228 Experiment based on proposal by VANBIBBER 87.

229 LAZARUS 92 experiment is based on proposal found in VANBIBBER 89.

230 RUOSO 92 experiment is based on the proposal by VANBIBBER 87.

231 SEMERTZIDIS 90 experiment is based on the proposal of MAIANI 86. The limit is obtained by taking the noise amplitude as the upper limit. Limits extend to $m_{A^0} = 4 \times 10^{-3}$ where $G_{A\gamma\gamma} < 1 \times 10^{-4} \text{ GeV}^{-1}$.

Limit on Invisible A^0 (Axion) Electron Coupling

The limit is for $G_{Aee}\partial_\mu\phi_A\bar{e}\gamma^\mu\gamma_5e$ in GeV^{-1} , or equivalently, the dipole-dipole

potential $\frac{G_{Aee}^2}{4\pi}((\sigma_1 \cdot \sigma_2) - 3(\sigma_1 \cdot \mathbf{n})(\sigma_2 \cdot \mathbf{n}))/r^3$ where $\mathbf{n} = \mathbf{r}/r$.

232 AALSETH 11 assume keV-mass pseudoscalars are the local dark matter and constrain the axio-electric effect in the CoGeNT detector. See their Fig. 4 for mass-dependent limits.

233 AHMED 09A is analogous to AALSETH 08, using the CDMS detector. See their Fig. 5 for mass-dependent limits.

234 DAVOUDI ASL 09 use geophysical constraints on Earth cooling by axion emission.

235 These experiments measured induced magnetization of a bulk material by the spin-dependent potential generated from other bulk material with aligned electron spins, where the magnetic field is shielded with superconductor.

236 These experiments used a torsion pendulum to measure the potential between two bulk matter objects where the spins are polarized but without a net magnetic field in either of them.

237 WINELAND 91 looked for an effect of bulk matter with aligned electron spins on atomic hyperfine splitting using nuclear magnetic resonance.

Invisible A^0 (Axion) Limits from Nucleon Coupling

Limits are for the axion mass in eV.

Gauge & Higgs Boson Particle Listings
Axions (A^0) and Other Very Light Bosons

- 238 DERBIN 11 looked for solar axions emitted by the M1 transition of thermally excited ^{57}Fe nuclei in the Sun, using their possible resonant capture on ^{57}Fe in the laboratory. The mass bound assumes $m_u/m_d = 0.56$ and the flavor-singlet axial vector matrix element $S = 3F - D \approx 0.5$.
- 239 BELLINI 08a is analogous to KRCMAR 01 and DERBIN 05.
- 240 BELLINI 08 consider solar axions emitted in the M1 transition of $^7\text{Li}^*$ (478 keV) and look for a peak at 478 keV in the energy spectra of the Counting Test Facility (CTF), a Borexino prototype. For $m_{A^0} < 450$ keV they find mass-dependent limits on products of axion couplings to photons, electrons, and nucleons.
- 241 ADELBERGER 07 use precision tests of Newton's law to constrain a force contribution from the exchange of two pseudoscalars. See their Fig. 5 for limits on the pseudoscalar coupling to nucleons, relevant for m_{A^0} below about 1 meV.
- 242 DERBIN 05 bound is based on the same principle as KRCMAR 01.
- 243 LJUBICIC 04 looked for ejection of K-shell electrons by the axioelectric effect of 14.4 keV solar axions in a Germanium detector. The limit assumes the hadronic axion model and the same solar axion flux as in KRCMAR 98 and KRCMAR 01.
- 244 KRCMAR 01 looked for solar axions emitted by the M1 transition of ^7Li after the electron capture by ^7Be and the emission of 384 keV line neutrino, using their resonant capture on ^7Li in the laboratory. The mass bound assumes $m_u/m_d = 0.56$ and the flavor-singlet axial-vector matrix element $S=0.4$.

Axion Limits from T-violating Medium-Range Forces

The limit is for the coupling $g = g_P g_S$ in a T-violating potential between nucleons or nucleon and electron of the form $V = \frac{g\hbar^2}{8\pi m_P} (\boldsymbol{\sigma} \cdot \hat{\mathbf{r}}) \left(\frac{1}{r^2} + \frac{1}{r\lambda} \right) e^{-r/\lambda}$, where g_P and g_S are dimensionless scalar and pseudoscalar coupling constants and $\lambda = \hbar/(m_{A^0} c)$ is the range of the force.

VALUE	DOCUMENT ID	TECN	COMMENT

255	RITTER 93		torsion pendulum
256	VENEMA 92		nuclear spin-precession frequencies
257	WINELAND 91	NMR	

- 245 HOEDL 11 use a novel torsion pendulum to study the force by the polarized electrons of an external magnet. In their Fig. 3 they show restrictive limits on g in the approximate m_{A^0} range 0.03–10 meV.
- 246 PETUKHOV 10 use spin relaxation of polarized ^3He and find $g < 3 \times 10^{-23} \text{ (cm}/\lambda)^2$ at 95% CL for the force range $\lambda = 10^{-4}$ –1 cm.
- 247 SEREBROV 10 use spin precession of ultracold neutrons close to bulk matter and find $g < 2 \times 10^{-21} \text{ (cm}/\lambda)^2$ at 95% CL for the force range $\lambda = 10^{-4}$ –1 cm.
- 248 IGNATOVICH 09 use data on depolarization of ultracold neutrons in material traps. They show λ -dependent limits in their Fig. 1.
- 249 SEREBROV 09 uses data on depolarization of ultracold neutrons stored in material traps and finds $g < 2.96 \times 10^{-21} \text{ (cm}/\lambda)^2$ for the force range $\lambda = 10^{-3}$ –1 cm and $g < 3.9 \times 10^{-22} \text{ (cm}/\lambda)^2$ for $\lambda = 10^{-4}$ – 10^{-3} cm, each time at 95% CL, significantly improving on BAESSLER 07.
- 250 BAESSLER 07 use the observation of quantum states of ultracold neutrons in the Earth's gravitational field to constrain g for an interaction range $1 \mu\text{m}$ –a few mm. See their Fig. 3 for results.
- 251 HECKEL 06 studied the influence of unpolarized bulk matter, including the laboratory's surroundings or the Sun, on a torsion pendulum containing about 9×10^{22} polarized electrons. See their Fig. 4 for limits on g as a function of interaction range.
- 252 NI 99 searched for a T-violating medium-range force acting on paramagnetic Tb F_3 salt. See their Fig. 1 for the result.
- 253 POSPELOV 98 studied the possible contribution of T-violating Medium-Range Force to the neutron electric dipole moment, which is possible when axion interactions violate CP. The size of the force among nucleons must be smaller than gravity by a factor of 2×10^{-10} ($1 \text{ cm}/\lambda_A$), where $\lambda_A = \hbar/m_{A^0} c$.
- 254 YOUNG 96 compared the precession frequencies of atomic ^{199}Hg and Cs when a large mass is positioned near the cells, relative to an applied magnetic field. See Fig. 3 for their limits.
- 255 RITTER 93 studied the influence of bulk mass with polarized electrons on an unpolarized torsion pendulum, providing limits in the interaction range from 1 to 100 cm.
- 256 VENEMA 92 looked for an effect of Earth's gravity on nuclear spin-precession frequencies of ^{199}Hg and ^{201}Hg atoms.
- 257 WINELAND 91 looked for an effect of bulk matter with aligned electron spins on atomic hyperfine resonances in stored $^9\text{Be}^+$ ions using nuclear magnetic resonance.

e MASS (atomic mass units u)

The primary determination of an electron's mass comes from measuring the ratio of the mass to that of a nucleus, so that the result is obtained in u (atomic mass units). The conversion factor to MeV is more uncertain than the mass of the electron in u; indeed, the recent improvements in the mass determination are not evident when the result is given in MeV. In this datablock we give the result in u, and in the following datablock in MeV.

VALUE (10 ⁻⁶ u)	DOCUMENT ID	TECN	COMMENT
548.5799046 ± 0.0000022	MOHR 12	RVUE	2010 CODATA value
• • • We do not use the following data for averages, fits, limits, etc. • • •			
548.5799043 ± 0.0000023	MOHR 08	RVUE	2006 CODATA value

548.5799110 ± 0.0000012	MOHR 99	RVUE	1998 CODATA value
548.5799111 ± 0.0000012	² FARNHAM 95	CNTR	Penning trap
548.579903 ± 0.000013	COHEN 87	RVUE	1986 CODATA value

¹ BEIER 02 compares Larmor frequency of the electron bound in a ¹²C⁵⁺ ion with the cyclotron frequency of a single trapped ¹²C⁵⁺ ion.

² FARNHAM 95 compares cyclotron frequency of trapped electrons with that of a single trapped ¹²C⁶⁺ ion.

e MASS

2010 CODATA (MOHR 12) gives the conversion factor from u (atomic mass units, see the above datablock) to MeV as 931.494 061 (21). Earlier values use the then-current conversion factor. The conversion error dominates the uncertainty of the masses given below.

VALUE (MeV)	DOCUMENT ID	TECN	COMMENT
0.510998928 ± 0.00000011	MOHR 12	RVUE	2010 CODATA value

¹⁴ HUDSON 11 gives a measurement corresponding to this limit as $(-2.4 \pm 5.7 \pm 1.5) \times 10^{-28}$ ecm.

¹⁵ ABDULLAH 90, COMMINS 94, and REGAN 02 use the relativistic enhancement of a valence electron's electric dipole moment in a high-Z atom.

e⁻ MEAN LIFE / BRANCHING FRACTION

A test of charge conservation. See the "Note on Testing Charge Conservation and the Pauli Exclusion Principle" following this section in our 1992 edition (Physical Review **D45** S1 (1992), p. VI.10).

Most of these experiments are one of three kinds: Attempts to observe (a) the 25.5 keV gamma ray produced in $e^- \rightarrow \nu_e \gamma$, (b) the (K) shell x-ray produced when an electron decays without additional energy deposit, e.g., $e^- \rightarrow \nu_e \bar{\nu}_e \nu_e$ ("disappearance" experiments), and (c) nuclear de-excitation gamma rays after the electron disappears from an atomic shell and the nucleus is left in an excited state. The last can include both weak boson and photon mediating processes. We use the best $e^- \rightarrow \nu_e \gamma$ limit for the Summary Tables.

Note that we use the mean life rather than the half life, which is often reported.

 μ MASS (atomic mass units u)

The muon's mass is obtained from the muon-electron mass ratio as determined from the measurement of Zeeman transition frequencies in muonium (μ^+e^- atom). Since the electron's mass is most accurately known in u, the muon's mass is also most accurately known in u. The conversion factor to MeV has approximately the same relative uncertainty as the mass of the muon in u. In this datablock we give the result in u, and in the following datablock in MeV.

 μ MASS

2010 CODATA (MOHR 12) gives the conversion factor from u (atomic mass units, see the above datablock) to MeV as 931.494 061 (21). Earlier values use the then-current conversion factor. The conversion error contributes significantly to the uncertainty of the masses given below.

μ/p MAGNETIC MOMENT RATIO

This ratio is used to obtain a precise value of the muon mass and to reduce experimental muon Larmor frequency measurements to the muon magnetic moment anomaly. Measurements with an error > 0.00001 have been omitted. By convention, the minus sign on this ratio is omitted. CODATA values were fitted using their selection of data, plus other data from multiparameter fits.

THE MUON ANOMALOUS MAGNETIC MOMENT

Updated July 2011 by A. Hoecker (CERN), and W.J. Marciano (BNL).

The Dirac equation predicts a muon magnetic moment, $\vec{M} = g_\mu \frac{e}{2m_\mu} \vec{S}$, with gyromagnetic ratio $g_\mu = 2$. Quantum loop effects lead to a small calculable deviation from $g_\mu = 2$, parameterized by the anomalous magnetic moment

$$a_\mu \equiv \frac{g_\mu - 2}{2}. \quad (1)$$

That quantity can be accurately measured and, within the Standard Model (SM) framework, precisely predicted. Hence, comparison of experiment and theory tests the SM at its quantum loop level. A deviation in a_μ^{exp} from the SM expectation would signal effects of new physics, with current sensitivity reaching up to mass scales of $\mathcal{O}(\text{TeV})$ [1,2]. For recent and very thorough muon $g - 2$ reviews, see Refs. [3,4].

The E821 experiment at Brookhaven National Lab (BNL) studied the precession of μ^+ and μ^- in a constant external magnetic field as they circulated in a confining storage ring. It found [6]¹

$$\begin{aligned} a_{\mu^+}^{\text{exp}} &= 11\,659\,204(6)(5) \times 10^{-10}, \\ a_{\mu^-}^{\text{exp}} &= 11\,659\,215(8)(3) \times 10^{-10}, \end{aligned} \quad (2)$$

where the first errors are statistical and the second systematic. Assuming CPT invariance and taking into account correlations between systematic errors, one finds for their average [6]

$$a_\mu^{\text{exp}} = 11\,659\,208.9(5.4)(3.3) \times 10^{-10}. \quad (3)$$

These results represent about a factor of 14 improvement over the classic CERN experiments of the 1970's [7]. Improvement of the measurement in Eq. (3) by a factor of four by moving

¹ The original results reported by the experiment have been updated in Eqs. (2) and (3) to the newest value for the absolute muon-to-proton magnetic ratio $\lambda = 3.183345137(85)$ [5]. The change induced in a_μ^{exp} with respect to the value of $\lambda = 3.18334539(10)$ used in Ref. 6 amounts to $+0.92 \times 10^{-10}$.

the E821 storage ring to Fermilab, and utilizing a cleaner and more intense muon beam has been proposed.

The SM prediction for a_μ^{SM} is generally divided into three parts (see Fig. 1 for representative Feynman diagrams)

$$a_\mu^{\text{SM}} = a_\mu^{\text{QED}} + a_\mu^{\text{EW}} + a_\mu^{\text{Had}}. \quad (4)$$

Figure 1: Representative diagrams contributing to a_μ^{SM} . From left to right: first order QED (Schwinger term), lowest-order weak, lowest-order hadronic.

The QED part includes all photonic and leptonic (e, μ, τ) loops starting with the classic $\alpha/2\pi$ Schwinger contribution. It has been computed through 4 loops and estimated at the 5-loop level [8]

$$\begin{aligned} a_\mu^{\text{QED}} &= \frac{\alpha}{2\pi} + 0.765857410(27) \left(\frac{\alpha}{\pi}\right)^2 + 24.05050964(43) \left(\frac{\alpha}{\pi}\right)^3 \\ &\quad + 130.8055(80) \left(\frac{\alpha}{\pi}\right)^4 + 663(20) \left(\frac{\alpha}{\pi}\right)^5 + \dots \end{aligned} \quad (5)$$

Employing $\alpha^{-1} = 137.035999084(51)$, determined [8,9] from the electron a_e measurement, leads to

$$a_\mu^{\text{QED}} = 116\,584\,718.09(0.15) \times 10^{-11}, \quad (6)$$

where the error results from uncertainties in the coefficients of Eq. (5) and in α .

Loop contributions involving heavy W^\pm, Z or Higgs particles are collectively labeled as a_μ^{EW} . They are suppressed by at least a factor of $\frac{\alpha}{\pi} \frac{m_\mu^2}{M_W^2} \simeq 4 \times 10^{-9}$. At 1-loop order [10]

$$\begin{aligned} a_\mu^{\text{EW}}[1\text{-loop}] &= \frac{G_\mu m_\mu^2}{8\sqrt{2}\pi^2} \left[\frac{5}{3} + \frac{1}{3} (1 - 4\sin^2\theta_W)^2 \right. \\ &\quad \left. + \mathcal{O}\left(\frac{m_\mu^2}{M_W^2}\right) + \mathcal{O}\left(\frac{m_\mu^2}{M_H^2}\right) \right], \\ &= 194.8 \times 10^{-11}, \end{aligned} \quad (7)$$

for $\sin^2\theta_W \equiv 1 - M_W^2/M_Z^2 \simeq 0.223$, and where $G_\mu \simeq 1.166 \times 10^{-5} \text{ GeV}^{-2}$ is the Fermi coupling constant. Two-loop corrections are relatively large and negative [11]

$$a_\mu^{\text{EW}}[2\text{-loop}] = -40.7(1.0)(1.8) \times 10^{-11}, \quad (8)$$

where the errors stem from quark triangle loops and the assumed Higgs mass range between 100 and 500 GeV. The 3-loop leading logarithms are negligible [11,12], $\mathcal{O}(10^{-12})$, implying in total

$$a_\mu^{\text{EW}} = 154(1)(2) \times 10^{-11}. \quad (9)$$

Hadronic (quark and gluon) loop contributions to a_μ^{SM} give rise to its main theoretical uncertainties. At present, those effects

Lepton Particle Listings

μ

are not calculable from first principles, but such an approach, at least partially, may become possible as lattice QCD matures. Instead, one currently relies on a dispersion relation approach to evaluate the lowest-order (*i.e.*, $\mathcal{O}(\alpha^2)$) hadronic vacuum polarization contribution $a_\mu^{\text{Had}}[\text{LO}]$ from corresponding cross section measurements [13]

$$a_\mu^{\text{Had}}[\text{LO}] = \frac{1}{3} \left(\frac{\alpha}{\pi} \right)^2 \int_{m_\pi^2}^{\infty} ds \frac{K(s)}{s} R^{(0)}(s), \quad (10)$$

where $K(s)$ is a QED kernel function [14], and where $R^{(0)}(s)$ denotes the ratio of the bare² cross section for e^+e^- annihilation into hadrons to the pointlike muon-pair cross section at center-of-mass energy \sqrt{s} . The function $K(s) \sim 1/s$ in Eq. (10) gives a strong weight to the low-energy part of the integral. Hence, $a_\mu^{\text{Had}}[\text{LO}]$ is dominated by the $\rho(770)$ resonance.

Currently, the available $\sigma(e^+e^- \rightarrow \text{hadrons})$ data give a leading-order hadronic vacuum polarization (representative) contribution of [15]

$$a_\mu^{\text{Had}}[\text{LO}] = 6\,923(42)(3) \times 10^{-11}, \quad (11)$$

where the first error is experimental (dominated by systematic uncertainties), and the second due to perturbative QCD, which is used at intermediate and large energies to predict the contribution from the quark-antiquark continuum. New multi-hadron data from the BABAR experiment have increased the constraints on unmeasured exclusive final states and led to a small reduction in the hadronic contribution compared to the 2009 PDG value.

Alternatively, one can use precise vector spectral functions from $\tau \rightarrow \nu_\tau + \text{hadrons}$ decays [16] that can be related to isovector $e^+e^- \rightarrow \text{hadrons}$ cross sections by isospin symmetry. Replacing e^+e^- data in the two-pion and four-pion channels by the corresponding isospin-transformed τ data, and applying isospin-violating corrections (from QED and $m_d - m_u \neq 0$), one finds [15]

$$a_\mu^{\text{Had}}[\text{LO}] = 7\,015(42)(19)(3) \times 10^{-11} (\tau), \quad (12)$$

where the first error is experimental, the second estimates the uncertainty in the isospin-breaking corrections applied to the τ data, and the third error is due to perturbative QCD. The current discrepancy between the e^+e^- and τ -based determinations of $a_\mu^{\text{Had}}[\text{LO}]$ has been reduced to 1.8σ with respect to earlier evaluations. New e^+e^- and τ data from the B -factory experiments BABAR and Belle have increased the experimental information. Reevaluated isospin-breaking corrections have also contributed to this improvement [17]. BABAR recently

² The bare cross section is defined as the measured cross section corrected for initial-state radiation, electron-vertex loop contributions and vacuum-polarization effects in the photon propagator. However, QED effects in the hadron vertex and final state, as photon radiation, are included.

reported good agreement with the τ data in the most important two-pion channel [18]. The remaining discrepancy with the older e^+e^- and τ datasets may be indicative of problems with one or both data sets. It may also suggest the need for additional isospin-violating corrections to the τ data.

Higher order, $\mathcal{O}(\alpha^3)$, hadronic contributions are obtained from dispersion relations using the same $e^+e^- \rightarrow \text{hadrons}$ data [16,19,22], giving $a_\mu^{\text{Had,Disp}}[\text{NLO}] = (-98.4 \pm 0.6) \times 10^{-11}$, along with model-dependent estimates of the hadronic light-by-light scattering contribution, $a_\mu^{\text{Had,LBL}}[\text{NLO}]$, motivated by large- N_C QCD [23–29].³ Following [27], one finds for the sum of the two terms

$$a_\mu^{\text{Had}}[\text{NLO}] = 7(26) \times 10^{-11}, \quad (13)$$

where the error is dominated by hadronic light-by-light uncertainties.

Adding Eqs. (6), (9), (11) and (13) gives the representative e^+e^- data based SM prediction

$$a_\mu^{\text{SM}} = 116\,591\,802(2)(42)(26) \times 10^{-11}, \quad (14)$$

where the errors are due to the electroweak, lowest-order hadronic, and higher-order hadronic contributions, respectively. The difference between experiment and theory

$$\Delta a_\mu = a_\mu^{\text{exp}} - a_\mu^{\text{SM}} = 287(63)(49) \times 10^{-11}, \quad (15)$$

(with all errors combined in quadrature) represents an interesting but not yet conclusive discrepancy of 3.6 times the estimated 1σ error. All the recent estimates for the hadronic contribution compiled in Fig. 2 exhibit similar discrepancies. Switching to τ data reduces the discrepancy to 2.4σ , assuming the isospin-violating corrections are under control within the estimated uncertainties.

An alternate interpretation is that Δa_μ may be a new physics signal with supersymmetric particle loops as the leading candidate explanation. Such a scenario is quite natural, since generically, supersymmetric models predict [1] an additional contribution to a_μ^{SM}

$$a_\mu^{\text{SUSY}} \simeq \pm 130 \times 10^{-11} \cdot \left(\frac{100 \text{ GeV}}{m_{\text{SUSY}}} \right)^2 \tan\beta, \quad (16)$$

where m_{SUSY} is a representative supersymmetric mass scale, and $\tan\beta \simeq 3\text{--}40$ is a potential enhancement factor. Supersymmetric particles in the mass range 100–500 GeV could be the source of the deviation Δa_μ . If so, those particles could be directly observed at the next generation of high energy colliders.

New physics effects [1] other than supersymmetry could also explain a non-vanishing Δa_μ . A recent popular scenario involves the “dark photon”, a relatively light hypothetical vector boson from the dark matter sector that couples to our world of particle

³ Some representative recent estimates of the hadronic light-by-light scattering contribution, $a_\mu^{\text{Had,LBL}}[\text{NLO}]$, that followed after the sign correction of [25], are: $105(26) \times 10^{-11}$ [27], $110(40) \times 10^{-11}$ [23], $136(25) \times 10^{-11}$ [24].

Figure 2: Compilation of recently published results for a_μ (in units of 10^{-11}), subtracted by the central value of the experimental average (3). The shaded band indicates the experimental error. The SM predictions are taken from: JN [4], DHMZ [15], and HMNT [19]. Note that the quoted errors do not include the uncertainty on the subtracted experimental value. To obtain for each theory calculation a result equivalent to Eq. (15), the errors from theory and experiment must be added in quadrature.

physics through mixing with the ordinary photon [30,31]. As a result, it couples to ordinary charged particles with strength $\varepsilon \cdot e$ and gives rise to an additional muon anomalous magnetic moment contribution

$$a_\mu^{\text{dark photon}} = \frac{\alpha}{2\pi} \varepsilon^2 F(m_V/m_\mu), \quad (17)$$

where $F(x) = \int_0^1 2z(1-z)^2 / [(1-z)^2 + x^2z] dz$. For values of $\varepsilon \sim 1-2 \cdot 10^{-3}$ and $m_V \sim 10-100$ MeV, the dark photon, which was originally motivated by cosmology, can provide a viable solution to the muon $g-2$ discrepancy. Searches for the dark photon in that mass range are currently underway at Jefferson Lab, USA, and MAMI in Mainz, Germany.

 μ MAGNETIC MOMENT ANOMALY

The parity-violating decay of muons in a storage ring is observed. The difference frequency ω_a between the muon spin precession and the orbital angular frequency $(e/m_\mu c)\langle B \rangle$ is measured, as is the free proton NMR frequency ω_p , thus determining the ratio $R = \omega_a/\omega_p$. Given the magnetic moment ratio $\lambda = \mu_\mu/\mu_p$ (from hyperfine structure in muonium), $(g-2)/2 = R/(\lambda-R)$.

$$\mu_\mu/(e\hbar/2m_\mu) - 1 = (g_\mu - 2)/2$$

⁷BENNETT 06 reports $(g_\mu - 2)/2 = (11659208.0 \pm 5.4 \pm 3.3) \times 10^{-10}$. We rescaled this value using μ/p magnetic moment ratio of 3.183345137(85) from MOHR 08.

⁸BAILEY 79 values recalculated by HUGHES 99 using the COHEN 87 μ/p magnetic moment. The improved MOHR 99 value does not change the result.

$$(g_{\mu^+} - g_{\mu^-}) / g_{\text{average}}$$

¹¹MEYER 00 measure the 1s-2s muonium interval, and then interpret the result in terms of muon-electron charge ratio q_{μ^+}/q_{e^-} .

 μ^- DECAY MODES

μ^+ modes are charge conjugates of the modes below.

Mode	Fraction (Γ_i/Γ)	Confidence level
Γ_1 $e^- \bar{\nu}_e \bar{\nu}_\mu$	≈ 100%	
Γ_2 $e^- \bar{\nu}_e \nu_\mu \gamma$	[a] (1.4 ± 0.4) %	
Γ_3 $e^- \bar{\nu}_e \nu_\mu e^+ e^-$	[b] (3.4 ± 0.4) × 10 ⁻⁵	

Lepton Family number (LF) violating modes

Γ_i	Mode	LF	[c]	%	90%
Γ_4	$e^- \nu_e \bar{\nu}_\mu$	LF	< 1.2		90%
Γ_5	$e^- \gamma$	LF	< 2.4	× 10 ⁻¹²	90%
Γ_6	$e^- e^+ e^-$	LF	< 1.0	× 10 ⁻¹²	90%
Γ_7	$e^- 2\gamma$	LF	< 7.2	× 10 ⁻¹¹	90%

[a] This only includes events with the γ energy > 10 MeV. Since the $e^- \bar{\nu}_e \nu_\mu$ and $e^- \bar{\nu}_e \nu_\mu \gamma$ modes cannot be clearly separated, we regard the latter mode as a subset of the former.

[b] See the Particle Listings below for the energy limits used in this measurement.

[c] A test of additive vs. multiplicative lepton family number conservation.

MUON DECAY PARAMETERS

Revised January 2012 by W. Fetscher and H.-J. Gerber (ETH Zürich).

Introduction: All measurements in direct muon decay, $\mu^- \rightarrow e^- + 2$ neutrals, and its inverse, $\nu_\mu + e^- \rightarrow \mu^- + \text{neutral}$, are successfully described by the “V-A interaction,” which is a particular case of a local, derivative-free, lepton-number-conserving, four-fermion interaction [1]. As shown below, within this framework, the Standard Model assumptions, such as the V-A form and the nature of the neutrals (ν_μ and $\bar{\nu}_e$), and hence the doublet assignments ($\nu_e e^-$)_L and ($\nu_\mu \mu^-$)_L, have been determined from experiments [2,3]. All considerations on muon decay are valid for the leptonic tau decays $\tau \rightarrow \ell + \nu_\tau + \bar{\nu}_e$ with the replacements $m_\mu \rightarrow m_\tau$, $m_e \rightarrow m_\ell$.

Parameters: The differential decay probability to obtain an e^\pm with (reduced) energy between x and $x + dx$, emitted in the direction \hat{x}_3 at an angle between ϑ and $\vartheta + d\vartheta$ with respect to the muon polarization vector \mathbf{P}_μ , and with its spin parallel to the arbitrary direction $\hat{\zeta}$, neglecting radiative corrections, is given by

$$\frac{d^2\Gamma}{dx d\cos\vartheta} = \frac{m_\mu}{4\pi^3} W_{e\mu}^4 G_F^2 \sqrt{x^2 - x_0^2} \times (F_{\text{IS}}(x) \pm P_\mu \cos\vartheta F_{\text{AS}}(x)) \times [1 + \hat{\zeta} \cdot \mathbf{P}_e(x, \vartheta)] \quad (1)$$

Here, $W_{e\mu} = \max(E_e) = (m_\mu^2 + m_e^2)/2m_\mu$ is the maximum e^\pm energy, $x = E_e/W_{e\mu}$ is the reduced energy, $x_0 = m_e/W_{e\mu} = 9.67 \times 10^{-3}$, and $P_\mu = |\mathbf{P}_\mu|$ is the degree of muon polarization. $\hat{\zeta}$ is the direction in which a perfect polarization-sensitive electron detector is most sensitive. The isotropic part of the spectrum, $F_{\text{IS}}(x)$, the anisotropic part $F_{\text{AS}}(x)$, and the electron polarization, $\mathbf{P}_e(x, \vartheta)$, may be parametrized by the Michel parameter ρ [1], by η [4], by ξ and δ [5,6], etc. These are bilinear combinations of the coupling constants $g_{2\mu}^2$, which occur in the matrix element (given below).

Lepton Particle Listings

μ

If the masses of the neutrinos as well as x_0^2 are neglected, the energy and angular distribution of the electron in the rest frame of a muon (μ^\pm) measured by a polarization insensitive detector, is given by

$$\frac{d^2\Gamma}{dx d\cos\vartheta} \sim x^2 \cdot \left\{ 3(1-x) + \frac{2\rho}{3}(4x-3) + 3\eta x_0(1-x)/x \pm P_\mu \cdot \xi \cdot \cos\vartheta \left[1-x + \frac{2\delta}{3}(4x-3) \right] \right\}. \quad (2)$$

Here, ϑ is the angle between the electron momentum and the muon spin, and $x \equiv 2E_e/m_\mu$. For the Standard Model coupling, we obtain $\rho = \xi\delta = 3/4$, $\xi = 1$, $\eta = 0$ and the differential decay rate is

$$\frac{d^2\Gamma}{dx d\cos\vartheta} = \frac{G_F^2 m_\mu^5}{192\pi^3} [3 - 2x \pm P_\mu \cos\vartheta(2x-1)] x^2. \quad (3)$$

The coefficient in front of the square bracket is the total decay rate.

If only the neutrino masses are neglected, and if the e^\pm polarization is detected, then the functions in Eq. (1) become

$$\begin{aligned} F_{\text{IS}}(x) &= x(1-x) + \frac{2}{9}\rho(4x^2 - 3x - x_0^2) + \eta \cdot x_0(1-x) \\ F_{\text{AS}}(x) &= \frac{1}{3}\xi \sqrt{x^2 - x_0^2} \\ &\quad \times [1-x + \frac{2}{3}\delta(4x-3 + (\sqrt{1-x_0^2}-1))] \\ \mathbf{P}_e(x, \vartheta) &= P_{T_1} \cdot \hat{\mathbf{x}}_1 + P_{T_2} \cdot \hat{\mathbf{x}}_2 + P_L \cdot \hat{\mathbf{x}}_3. \end{aligned} \quad (4)$$

Here $\hat{\mathbf{x}}_1$, $\hat{\mathbf{x}}_2$, and $\hat{\mathbf{x}}_3$ are orthogonal unit vectors defined as follows:

$$\begin{aligned} \hat{\mathbf{x}}_3 &\text{ is along the } e \text{ momentum } \mathbf{p}_e \\ \frac{\hat{\mathbf{x}}_3 \times \mathbf{P}_\mu}{|\hat{\mathbf{x}}_3 \times \mathbf{P}_\mu|} &= \hat{\mathbf{x}}_2 \text{ is transverse to } \mathbf{p}_e \text{ and perpendicular to the "decay plane"} \\ \hat{\mathbf{x}}_2 \times \hat{\mathbf{x}}_3 &= \hat{\mathbf{x}}_1 \text{ is transverse to the } \mathbf{p}_e \text{ and in the "decay plane."} \end{aligned}$$

The components of \mathbf{P}_e then are given by

$$\begin{aligned} P_{T_1}(x, \vartheta) &= P_\mu \sin\vartheta \cdot F_{T_1}(x) / (F_{\text{IS}}(x) \pm P_\mu \cos\vartheta \cdot F_{\text{AS}}(x)) \\ P_{T_2}(x, \vartheta) &= P_\mu \sin\vartheta \cdot F_{T_2}(x) / (F_{\text{IS}}(x) \pm P_\mu \cos\vartheta \cdot F_{\text{AS}}(x)) \\ P_L(x, \vartheta) &= (\pm F_{\text{IP}}(x) + P_\mu \cos\vartheta \\ &\quad \times F_{\text{AP}}(x)) / (F_{\text{IS}}(x) \pm P_\mu \cos\vartheta \cdot F_{\text{AS}}(x)), \end{aligned}$$

where

$$\begin{aligned} F_{T_1}(x) &= \frac{1}{12} \left\{ -2 \left[\xi'' + 12(\rho - \frac{3}{4}) \right] (1-x)x_0 \right. \\ &\quad \left. - 3\eta(x^2 - x_0^2) + \eta''(-3x^2 + 4x - x_0^2) \right\} \\ F_{T_2}(x) &= \frac{1}{3} \sqrt{x^2 - x_0^2} \left\{ 3\frac{\alpha'}{A}(1-x) + 2\frac{\beta'}{A}\sqrt{1-x_0^2} \right\} \\ F_{\text{IP}}(x) &= \frac{1}{54} \sqrt{x^2 - x_0^2} \left\{ 9\xi' \left(-2x + 2 + \sqrt{1-x_0^2} \right) \right. \\ &\quad \left. + 4\xi(\delta - \frac{3}{4})(4x - 4 + \sqrt{1-x_0^2}) \right\} \\ F_{\text{AP}}(x) &= \frac{1}{6} \left\{ \xi''(2x^2 - x - x_0^2) + 4(\rho - \frac{3}{4})(4x^2 - 3x - x_0^2) \right. \\ &\quad \left. + 2\eta''(1-x)x_0 \right\}. \end{aligned} \quad (5)$$

For the experimental values of the parameters ρ , ξ , ξ' , ξ'' , δ , η , η'' , α/A , β/A , α'/A , β'/A , which are not all independent, see the Data Listings below. Experiments in the past have also been analyzed using the parameters a , b , c , a' , b' , c' , α/A , β/A , α'/A , β'/A (and $\eta = (\alpha - 2\beta)/2A$), as defined by Kinoshita and Sirlin [5,6]. They serve as a model-independent summary of all possible measurements on the decay electron (see Listings below). The relations between the two sets of parameters are

$$\begin{aligned} \rho - \frac{3}{4} &= \frac{3}{4}(-a + 2c)/A, \\ \eta &= (\alpha - 2\beta)/A, \\ \eta'' &= (3\alpha + 2\beta)/A, \\ \delta - \frac{3}{4} &= \frac{9}{4} \cdot \frac{(a' - 2c')/A}{1 - [a + 3a' + 4(b + b') + 6c - 14c']/A}, \\ 1 - \xi \frac{\delta}{\rho} &= 4 \frac{[(b + b') + 2(c - c')]/A}{1 - (a - 2c)/A}, \\ 1 - \xi' &= [(a + a') + 4(b + b') + 6(c + c')]/A, \\ 1 - \xi'' &= (-2a + 20c)/A, \end{aligned}$$

where

$$A = a + 4b + 6c. \quad (6)$$

The differential decay probability to obtain a *left-handed* ν_e with (reduced) energy between y and $y + dy$, neglecting radiative corrections as well as the masses of the electron and of the neutrinos, is given by [7]

$$\frac{d\Gamma}{dy} = \frac{m_\mu^5 G_F^2}{16\pi^3} \cdot Q_L^{\nu_e} \cdot y^2 \left\{ (1-y) - \omega_L \cdot (y - \frac{3}{4}) \right\}. \quad (7)$$

Here, $y = 2 E_{\nu_e}/m_\mu$. $Q_L^{\nu_e}$ and ω_L are parameters. ω_L is the neutrino analog of the spectral shape parameter ρ of Michel. Since in the Standard Model, $Q_L^{\nu_e} = 1$, $\omega_L = 0$, the measurement of $d\Gamma/dy$ has allowed a null-test of the Standard Model (see Listings below).

Matrix element: All results in direct muon decay (energy spectra of the electron and of the neutrinos, polarizations, and angular distributions), and in inverse muon decay (the reaction cross section) at energies well below $m_W c^2$, may be parametrized in terms of amplitudes $g_{\varepsilon\mu}^{\nu_e}$ and the Fermi coupling constant G_F , using the matrix element

$$\frac{4G_F}{\sqrt{2}} \sum_{\substack{\gamma=S,V,T \\ \varepsilon,\mu=R,L}} g_{\varepsilon\mu}^{\nu_e} \langle \bar{e}_\varepsilon | \Gamma^\gamma | (\nu_e)_n \rangle \langle (\bar{\nu}_\mu)_m | \Gamma_\gamma | \mu_\mu \rangle. \quad (8)$$

We use the notation of Fetscher *et al.* [2], who in turn use the sign conventions and definitions of Scheck [8]. Here, $\gamma = S, V, T$ indicates a scalar, vector, or tensor interaction; and $\varepsilon, \mu = R, L$ indicate a right- or left-handed chirality of the electron or muon. The chiralities n and m of the ν_e and $\bar{\nu}_\mu$ are then determined by the values of γ, ε , and μ . The particles are represented by fields of definite chirality [9].

As shown by Langacker and London [10], explicit lepton-number nonconservation still leads to a matrix element equivalent to Eq. (8). They conclude that it is not possible, even in

principle, to test lepton-number conservation in (leptonic) muon decay if the final neutrinos are massless and are not observed.

The ten complex amplitudes $g_{\varepsilon\mu}^{\tilde{\gamma}}$ (g_{RR}^T and g_{LL}^T are identically zero) and G_F constitute 19 independent (real) parameters to be determined by experiment. The Standard Model interaction corresponds to one single amplitude g_{LL}^V being unity and all the others being zero.

The (direct) muon decay experiments are compatible with an arbitrary mix of the scalar and vector amplitudes g_{LL}^S and g_{LL}^V – in the extreme even with purely scalar $g_{LL}^S = 2$, $g_{LL}^V = 0$. The decision in favour of the Standard Model comes from the quantitative observation of inverse muon decay, which would be forbidden for pure g_{LL}^S [2].

Experimental determination of V–A: In order to determine the amplitudes $g_{\varepsilon\mu}^{\tilde{\gamma}}$ uniquely from experiment, the following set of equations, where the left-hand sides represent experimental results, has to be solved.

$$\begin{aligned} a &= 16(|g_{RL}^V|^2 + |g_{LR}^V|^2) + |g_{RR}^S + 6g_{RR}^T|^2 + |g_{LR}^S + 6g_{LR}^T|^2 \\ a' &= 16(|g_{RL}^V|^2 - |g_{LR}^V|^2) + |g_{RR}^S + 6g_{RR}^T|^2 - |g_{LR}^S + 6g_{LR}^T|^2 \\ \alpha &= 8\text{Re} \left\{ g_{RL}^V (g_{LR}^{S*} + 6g_{LR}^{T*}) + g_{LR}^V (g_{RR}^{S*} + 6g_{RR}^{T*}) \right\} \\ \alpha' &= 8\text{Im} \left\{ g_{LR}^V (g_{RR}^{S*} + 6g_{RR}^{T*}) - g_{RR}^V (g_{LR}^{S*} + 6g_{LR}^{T*}) \right\} \\ b &= 4(|g_{RR}^V|^2 + |g_{LL}^V|^2) + |g_{RR}^S|^2 + |g_{LL}^S|^2 \\ b' &= 4(|g_{RR}^V|^2 - |g_{LL}^V|^2) + |g_{RR}^S|^2 - |g_{LL}^S|^2 \\ \beta &= -4\text{Re} \left\{ g_{RR}^V g_{LL}^{S*} + g_{LL}^V g_{RR}^{S*} \right\} \\ \beta' &= 4\text{Im} \left\{ g_{RR}^V g_{LL}^{S*} - g_{LL}^V g_{RR}^{S*} \right\} \\ c &= \frac{1}{2} \left\{ |g_{RL}^S - 2g_{RL}^T|^2 + |g_{LR}^S - 2g_{LR}^T|^2 \right\} \\ c' &= \frac{1}{2} \left\{ |g_{RL}^S - 2g_{RL}^T|^2 - |g_{LR}^S - 2g_{LR}^T|^2 \right\} \end{aligned}$$

and

$$\begin{aligned} Q_L^{\nu e} &= 1 - \left\{ \frac{1}{4}|g_{LR}^S|^2 + \frac{1}{4}|g_{LL}^S|^2 + |g_{RR}^V|^2 + |g_{RL}^V|^2 + 3|g_{LR}^T|^2 \right\} \\ \omega_L &= \frac{3}{4} \frac{\{|g_{RR}^S|^2 + 4|g_{LR}^V|^2 + |g_{RR}^S + 2g_{RR}^T|^2\}}{|g_{RR}^S|^2 + |g_{RR}^T|^2 + 4|g_{LL}^V|^2 + 4|g_{LR}^V|^2 + 12|g_{RL}^T|^2} \end{aligned}$$

It has been noted earlier by C. Jarlskog [11], that certain experiments observing the decay electron are especially informative if they yield the V–A values. The complete solution is now found as follows. Fetscher *et al.* [2] introduced four probabilities $Q_{\varepsilon\mu}(\varepsilon, \mu = R, L)$ for the decay of a μ -handed muon into an ε -handed electron, and showed that there exist upper bounds on Q_{RR} , Q_{LR} , and Q_{RL} , and a lower bound on Q_{LL} . These probabilities are given in terms of the $g_{\varepsilon\mu}^{\tilde{\gamma}}$'s by

$$Q_{\varepsilon\mu} = \frac{1}{4}|g_{\varepsilon\mu}^S|^2 + |g_{\varepsilon\mu}^V|^2 + 3(1 - \delta_{\varepsilon\mu})|g_{\varepsilon\mu}^T|^2, \quad (9)$$

where $\delta_{\varepsilon\mu} = 1$ for $\varepsilon = \mu$, and $\delta_{\varepsilon\mu} = 0$ for $\varepsilon \neq \mu$. They are related to the parameters a , b , c , a' , b' , and c' by

$$\begin{aligned} Q_{RR} &= 2(b + b')/A, \\ Q_{LR} &= [(a - a') + 6(c - c')]/2A, \\ Q_{RL} &= [(a + a') + 6(c + c')]/2A, \\ Q_{LL} &= 2(b - b')/A, \end{aligned} \quad (10)$$

with $A = 16$. In the Standard Model, $Q_{LL} = 1$ and the others are zero.

Since the upper bounds on Q_{RR} , Q_{LR} , and Q_{RL} are found to be small, and since the helicity of the ν_μ in pion decay is known from experiment [12,13] to very high precision to be -1 [14], the cross section S of *inverse* muon decay, normalized to the V–A value, yields [2]

$$|g_{LL}^S|^2 \leq 4(1 - S) \quad (11)$$

and

$$|g_{LL}^V|^2 = S. \quad (12)$$

Thus the Standard Model assumption of a pure V–A leptonic charged weak interaction of e and μ is derived (within errors) from experiments at energies far below mass of the W^\pm : Eq. (12) gives a lower limit for V–A, and Eqs. (9) and (11) give upper limits for the other four-fermion interactions. The existence of such upper limits may also be seen from $Q_{RR} + Q_{RL} = (1 - \xi')/2$ and $Q_{RR} + Q_{LR} = \frac{1}{2}(1 + \xi/3 - 16 \xi\delta/9)$. Table 1 gives the current experimental limits on the magnitudes of the $g_{\varepsilon\mu}^{\tilde{\gamma}}$'s. More stringent limits on the six coupling constants g_{LR}^V , g_{LR}^T , g_{RR}^S , g_{RR}^T , g_{RL}^S , and g_{RL}^T have been derived from upper limits on the neutrino mass [18]. Limits on the ‘‘charge retention’’ coordinates, as used in the older literature (*e.g.*, Ref. 19), are given by Burkard *et al.* [20].

Table 1. Coupling constants $g_{\varepsilon\mu}^{\tilde{\gamma}}$ and some combinations of them. Ninety-percent confidence level experimental limits. The limits on $|g_{LL}^S|$ and $|g_{LL}^V|$ are from Ref. 15, and the others from a general analysis of muon decay measurements. Top two rows: Ref. 22, next two rows: Ref. 16, bottom three rows: Ref. 17, last row: Ref. 21. The experimental uncertainty on the muon polarization in pion decay is included. Note that, by definition, $|g_{\varepsilon\mu}^S| \leq 2$, $|g_{\varepsilon\mu}^V| \leq 1$ and $|g_{\varepsilon\mu}^T| \leq 1/\sqrt{3}$.

$ g_{RR}^S < 0.035$	$ g_{RR}^V < 0.017$	$ g_{RR}^T \equiv 0$
$ g_{LR}^S < 0.050$	$ g_{LR}^V < 0.023$	$ g_{LR}^T < 0.015$
$ g_{RL}^S < 0.412$	$ g_{RL}^V < 0.104$	$ g_{RL}^T < 0.103$
$ g_{LL}^S < 0.550$	$ g_{LL}^V > 0.960$	$ g_{LL}^T \equiv 0$
$ g_{LR}^S + 6g_{LR}^T < 0.143$	$ g_{RR}^S + 6g_{RR}^T < 0.418$	
$ g_{LR}^S + 2g_{LR}^T < 0.108$	$ g_{RR}^S + 2g_{RR}^T < 0.417$	
$ g_{LR}^S - 2g_{LR}^T < 0.070$	$ g_{RR}^S - 2g_{RR}^T < 0.418$	
$Q_{RR} + Q_{LR} < 8.2 \times 10^{-4}$

τ

$$J = \frac{1}{2}$$

τ discovery paper was PERL 75. $e^+e^- \rightarrow \tau^+\tau^-$ cross-section threshold behavior and magnitude are consistent with pointlike spin-1/2 Dirac particle. BRANDELIK 78 ruled out pointlike spin-0 or spin-1 particle. FELDMAN 78 ruled out $J = 3/2$. KIRKBY 79 also ruled out $J = \text{integer}$, $J = 3/2$.

- AUBERT 09AK and BELOUS 07 fit τ pseudomass spectrum in $\tau \rightarrow \pi^+\pi^-\nu_\tau$ decays. Result assumes $m_{\nu_\tau} = 0$.
- ABBIENDI 00A fit τ pseudomass spectrum in $\tau \rightarrow \pi^\pm \leq 2\pi^0 \nu_\tau$ and $\tau \rightarrow \pi^\pm \pi^+ \pi^- \leq 1\pi^0 \nu_\tau$ decays. Result assumes $m_{\nu_\tau} = 0$.
- BAI 96 fit $\sigma(e^+e^- \rightarrow \tau^+\tau^-)$ at different energies near threshold.
- ALBRECHT 92M fit τ pseudomass spectrum in $\tau^- \rightarrow 2\pi^-\pi^+\nu_\tau$ decays. Result assumes $m_{\nu_\tau} = 0$.
- BACINO 78B value comes from $e^\pm X^\mp$ threshold. Published mass 1782 MeV increased by 1 MeV using the high precision $\psi(2S)$ mass measurement of ZHOLENTZ 80 to eliminate the absolute SPEAR energy calibration uncertainty.
- BALEST 93 fit spectra of minimum kinematically allowed τ mass in events of the type $e^+e^- \rightarrow \tau^+\tau^- \rightarrow (\pi^+ n\pi^0 \nu_\tau)(\pi^- m\pi^0 \nu_\tau)$ $n \leq 2, m \leq 2, 1 \leq n+m \leq 3$. If $m_{\nu_\tau} \neq 0$, result increases by $(m_{\nu_\tau}^2/1100)$ MeV.
- BAI 92 fit $\sigma(e^+e^- \rightarrow \tau^+\tau^-)$ near threshold using $e\mu$ events.

$$(m_{\tau^+} - m_{\tau^-})/m_{\text{average}}$$

A test of CPT invariance.

- ABDALLAH 04K limit is derived from $e^+e^- \rightarrow e^+e^-\tau^+\tau^-$ total cross-section measurements at \sqrt{s} between 183 and 208 GeV. In addition to the limits, the authors also quote a value of -0.018 ± 0.017 .
- ACHARD 04G limit is derived from $e^+e^- \rightarrow e^+e^-\tau^+\tau^-$ total cross-section measurements at \sqrt{s} between 189 and 206 GeV, and is on the absolute value of the magnetic moment anomaly.
- GONZALEZ-SPRINBERG 00 use data on tau lepton production at LEP1, SLC, and LEP2, and data from colliders and LEP2 to determine limits. Assume imaginary component is zero.
- ACCIARRI 98E use $Z \rightarrow \tau^+\tau^-\gamma$ events. In addition to the limits, the authors also quote a value of $0.004 \pm 0.027 \pm 0.023$.
- ACKERSTAFF 98N use $Z \rightarrow \tau^+\tau^-\gamma$ events. The limit applies to an average of the form factor for off-shell τ 's having p^2 ranging from m_τ^2 to $(M_Z - m_\tau)^2$.
- ESCRIBANO 97 use preliminary experimental results.
- ESCRIBANO 93 limit derived from $\Gamma(Z \rightarrow \tau^+\tau^-)$, and is on the absolute value of the magnetic moment anomaly.
- SILVERMAN 83 limit is derived from $e^+e^- \rightarrow \tau^+\tau^-$ total cross-section measurements for q^2 up to $(37 \text{ GeV})^2$.

τ ELECTRIC DIPOLE MOMENT (d_τ)

A nonzero value is forbidden by both T invariance and P invariance.

The q^2 dependence is expected to be small providing no thresholds are nearby.

Re(d_τ)

< 1.6	90	DELAGUILA 90	RVUE	$e^+ e^- \rightarrow \tau^+ \tau^-$ $E_{cm}^{ee} = 35$ GeV

- ¹ INAMI 03 use $e^+ e^- \rightarrow \tau^+ \tau^-$ events.
² GROZIN 09A calculate the contribution to the electron electric dipole moment from the τ electric dipole moment appearing in loops, which is $\Delta d_e = 6.9 \times 10^{-12} d_\tau$. Dividing the REGAN 02 upper limit $|d_e| \leq 1.6 \times 10^{-27}$ e cm at CL=90% by 6.9×10^{-12} gives this limit.
³ ABDALLAH 04K limit is derived from $e^+ e^- \rightarrow e^+ e^- \tau^+ \tau^-$ total cross-section measurements at \sqrt{s} between 183 and 208 GeV and is on the absolute value of d_τ .
⁴ ACHARD 04G limit is derived from $e^+ e^- \rightarrow e^+ e^- \tau^+ \tau^-$ total cross-section measurements at \sqrt{s} between 189 and 206 GeV, and is on the absolute value of d_τ .
⁵ ALBRECHT 00 use $e^+ e^- \rightarrow \tau^+ \tau^-$ events. Limit is on the absolute value of $\text{Re}(d_\tau)$.
⁶ ACKERSTAFF 98N use $Z \rightarrow \tau^+ \tau^- \gamma$ events. The limit applies to an average of the form factor for off-shell τ 's having p^2 ranging from m_τ^2 to $(M_Z - m_\tau)^2$.
⁷ ESCRIBANO 97 derive the relationship $|d_\tau| = \cot \theta_W |d_\tau^W|$ using effective Lagrangian methods, and use a conference result $|d_\tau^W| < 5.8 \times 10^{-18}$ e cm at 95% CL (L. Silvestris, ICHEP96) to obtain this result.
⁸ ESCRIBANO 97 use preliminary experimental results.
⁹ ESCRIBANO 93 limit derived from $\Gamma(Z \rightarrow \tau^+ \tau^-)$, and is on the absolute value of the electric dipole moment.

τ^- DECAY MODES

τ^+ modes are charge conjugates of the modes below. " h^\pm " stands for π^\pm or K^\pm . " l " stands for e or μ . "Neutrals" stands for γ 's and/or π^0 's.

Mode	Fraction (Γ_i/Γ)	Scale factor/ Confidence level
Modes with one charged particle		
Γ_1 particle $^- \geq 0$ neutrals $\geq 0 K^0 \nu_\tau$ ("1-prong")	(85.35 \pm 0.07) %	S=1.3
Γ_2 particle $^- \geq 0$ neutrals $\geq 0 K_L^0 \nu_\tau$	(84.71 \pm 0.08) %	S=1.3

Lepton Particle Listings

T

Lepton Family number (LF), Lepton number (L), or Baryon number (B) violating modes

L means lepton number violation (e.g. tau minus to e plus pi minus pi minus). Following common usage, LF means lepton family violation and not lepton number violation (e.g. tau minus to e minus pi plus pi minus). B means baryon number violation.

Table listing various lepton and baryon number violating modes with their corresponding LF/B values and branching ratios.

[a] Basis mode for the tau.

[b] See the Particle Listings below for the energy limits used in this measurement.

CONSTRAINED FIT INFORMATION

An overall fit to 66 branching ratios uses 138 measurements and one constraint to determine 31 parameters. The overall fit has a chi-squared = 128.9 for 108 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients <delta x_i delta x_j> / (delta x_i delta x_j), in percent, from the fit to the branching fractions, x_i = Gamma_i / Gamma_Total. The fit constrains the x_i whose labels appear in this array to sum to one.

 τ BRANCHING FRACTIONS

Revised April 2012 by K.G. Hayes (Hillsdale College).

Since the previous edition of this *Review*, there have been 7 published papers that have contributed to the τ Listings: 4 by the BaBar collaboration and 3 by the Belle collaboration. Four of these papers have provided new upper limits on the branching fractions for neutrinoless τ -decay modes. Of the 59 neutrinoless τ -decay modes in the τ Listings, 17 have had improved limits set. The upper limits have been reduced by factors that range between 1.3 and 43 with the median reduction being a factor of 1.5.

There are now 30 measurements and 13 upper limits from Belle and BaBar on branching fractions of conventional τ -decay modes, up from 1 measurement and 3 upper limits in the 2006 edition of this *Review*. Sixteen of these measurements are used in the constrained fit to τ branching fractions, and 20 are for τ -decay modes for which older non- B -factory measurements exist. For those 20 measurements, the new B -factory measurements have on average about sixty times the number of events as the most precise earlier measurements, and the statistical uncertainties on the B -factory measurements are on average about eight times smaller. However, the systematic uncertainties now greatly exceed the statistical uncertainties of all B -factory branching fraction measurements of major τ -decay modes. For example, the average ratio of systematic to statistical uncertainty of the B -factory measurements of τ branching fractions larger than 10^{-3} is 17.6, while the average ratio for branching fractions smaller than 10^{-4} is 0.8. Thus, the total uncertainty on the branching fraction measurements from B -factories is on average only about 3.4 times smaller than the previous most precise non- B -factory measurements.

The constrained fit to τ branching fractions: The Lepton Summary Table and the List of τ -Decay Modes contain branching fractions for 119 conventional τ -decay modes and upper limits on the branching fractions for 31 other conventional τ -decay modes. Of the 119 modes with branching fractions, 82 are derived from a constrained fit to τ branching fraction data. The goal of the constrained fit is to make optimal use of the experimental data to determine τ branching fractions. For example, the branching fractions for the decay mode $\tau^- \rightarrow \pi^- \pi^+ \pi^- \pi^0 \nu_\tau$ is determined mostly from experimental measurements of the branching fraction for $\tau^- \rightarrow h^- h^- h^+ \pi^0 \nu_\tau$ and measurements

of exclusive branching fractions for 3-prong modes containing charged kaons and 1 π^0 .

Branching fractions from the constrained fit are derived from a set of basis modes. The basis modes form an exclusive set whose branching fractions are constrained to sum exactly to one. The set of selected basis modes expands as branching fraction measurements for new τ -decay modes are published. The number of basis modes has expanded from 12 in the year 1994 fit to 31 in the 2002 through 2012 fits. The 31 basis modes selected for the 2012 fit are listed in Table 1. See the 1996 edition of this *Review* [1] for a complete description of our notation for naming τ -decay modes and the selection of the basis modes. For each edition since the 1996 edition, the changes in the selected basis modes from the previous edition are described in the τ Branching Fractions Review. Figure 1 illustrates the basis mode branching fractions from the 2012 fit.

Table 1: Basis modes and fit values(%) for the 2012 fit to τ branching fraction data.

$e^- \bar{\nu}_e \nu_\tau$	17.83 ± 0.04
$\mu^- \bar{\nu}_\mu \nu_\tau$	17.41 ± 0.04
$\pi^- \nu_\tau$	10.83 ± 0.06
$\pi^- \pi^0 \nu_\tau$	25.52 ± 0.09
$\pi^- 2\pi^0 \nu_\tau$ (ex. K^0)	9.30 ± 0.11
$\pi^- 3\pi^0 \nu_\tau$ (ex. K^0)	1.05 ± 0.07

$K^- K^0 \pi^0 \nu_\tau$	0.159 ± 0.020
$\pi^- \pi^+ \pi^- \nu_\tau$ (ex. K^0, ω)	8.99 ± 0.06
$\pi^- \pi^+ \pi^- \pi^0 \nu_\tau$ (ex. K^0, ω)	2.70 ± 0.08
$K^- \pi^+ \pi^- \nu_\tau$ (ex. K^0)	0.294 ± 0.015
$K^- \pi^+ \pi^- \pi^0 \nu_\tau$ (ex. K^0, η)	0.078 ± 0.012
$K^- K^+ \pi^- \nu_\tau$	0.144 ± 0.005
$K^- K^+ \pi^- \pi^0 \nu_\tau$	0.0061 ± 0.0025
$h^- h^- h^+ 2\pi^0 \nu_\tau$ (ex. K^0, ω, η)	0.10 ± 0.04
$h^- h^- h^+ 3\pi^0 \nu_\tau$	0.023 ± 0.006
$3h^- 2h^+ \nu_\tau$ (ex. K^0)	0.0839 ± 0.0035
$3h^- 2h^+ \pi^0 \nu_\tau$ (ex. K^0)	0.0178 ± 0.0027
$h^- \omega \nu_\tau$	2.00 ± 0.08
$h^- \omega \pi^0 \nu_\tau$	0.41 ± 0.04
$\eta \pi^- \pi^0 \nu_\tau$	0.139 ± 0.010
$\eta K^- \nu_\tau$	0.0152 ± 0.0008

Figure 1: Basis mode branching fractions of the τ . Six modes account for 90% of the decays, 25 modes account for the last 10%. The list of excluded intermediate states for each basis mode has been suppressed.

In selecting the basis modes, assumptions and choices must be made. For example, we assume the decays $\tau^- \rightarrow \pi^- K^+ \pi^- \geq 0\pi^0 \nu_\tau$ and $\tau^- \rightarrow \pi^+ K^- K^- \geq 0\pi^0 \nu_\tau$ have negligible branching fractions. This is consistent with standard model predictions for τ decay, although the experimental limits for these branching fractions are not very stringent. The 95% confidence level upper limits for these branching fractions in the current Listings are $B(\tau^- \rightarrow \pi^- K^+ \pi^- \geq 0\pi^0 \nu_\tau) < 0.25\%$ and $B(\tau^- \rightarrow \pi^+ K^- K^- \geq 0\pi^0 \nu_\tau) < 0.09\%$, values not so different from measured branching fractions for allowed 3-prong modes containing charged kaons. Although our usual goal is to impose as few theoretical constraints as possible so that the world averages and fit results can be used to test the theoretical constraints (*i.e.*, we do not make use of the theoretical constraint from lepton universality on the ratio of the τ -leptonic branching fractions $B(\tau^- \rightarrow \mu^- \bar{\nu}_\mu \nu_\tau) / B(\tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau) = 0.9726$), the

experimental challenge to identify charged prongs in 3-prong τ decays is sufficiently difficult that experimenters have been forced to make these assumptions when measuring the branching fractions of the allowed decays. We are constrained by the assumptions made by the experimenters.

There are several τ -decay modes with small but well-measured (> 2.5 sigma from zero) branching fractions [2] which cannot be expressed in terms of the selected basis modes and are therefore left out of the fit:

$$\begin{aligned} B(\tau^- \rightarrow \pi^- K_S^0 K_L^0 \pi^0 \nu_\tau) &= (3.1 \pm 1.2) \times 10^{-4} \\ B(\tau^- \rightarrow 2K^- K^+ \nu_\tau) &= (0.21 \pm 0.08) \times 10^{-4} \\ B(\tau^- \rightarrow \eta K^- \pi^0 \nu_\tau) &= (0.48 \pm 0.12) \times 10^{-4} \\ B(\tau^- \rightarrow \eta \bar{K}^0 \pi^- \nu_\tau) &= (0.93 \pm 0.15) \times 10^{-4}. \end{aligned}$$

Certain components of other small but well-measured τ -decay modes cannot be expressed in terms of the selected basis modes and therefore are also left out of the fit:

$$\begin{aligned} B(\tau^- \rightarrow \eta \pi^- \pi^0 \pi^0 \nu_\tau) \times \\ B(\eta \rightarrow \gamma\gamma \text{ or } \eta \rightarrow \pi^+ \pi^- \gamma \text{ or } \eta \rightarrow 3\pi^0) &= (1.1 \pm 0.4) \times 10^{-4}, \\ B(\tau^- \rightarrow \eta \pi^- \pi^+ \pi^- \nu_\tau) \times \\ B(\eta \rightarrow \gamma\gamma \text{ or } \eta \rightarrow \pi^+ \pi^- \gamma) &= (0.72 \pm 0.05) \times 10^{-4}, \\ B(\tau^- \rightarrow \phi K^- \nu_\tau) \times \\ B(\phi \rightarrow K_S^0 K_L^0 \text{ or } \phi \rightarrow \eta\gamma) &= (0.13 \pm 0.01) \times 10^{-4}, \\ B(\tau^- \rightarrow f_1(1285) \pi^- \nu_\tau) B(f_1(1285) \rightarrow \rho^0 \gamma) &= (0.20 \pm 0.06) \times 10^{-4}, \\ B(\tau^- \rightarrow h^- \omega \pi^0 \pi^0 \nu_\tau) B(\omega \rightarrow \pi^0 \gamma) &= (0.12 \pm 0.04) \times 10^{-4}, \\ B(\tau^- \rightarrow 2h^- h^+ \omega \nu_\tau) B(\omega \rightarrow \pi^0 \gamma) &= (0.10 \pm 0.02) \times 10^{-4}. \end{aligned}$$

The sum of these excluded branching fractions is $(0.07 \pm 0.01)\%$. This is near our goal of 0.1% for the internal consistency of the τ Listings for this edition, and thus for simplicity we do not include these small branching fraction decay modes in the basis set.

Beginning with the 2002 edition, the fit algorithm has been improved to allow for correlations between branching fraction measurements used in the fit. If only a few measurements are correlated, the correlation coefficients are listed in the footnote for each measurement. If a large number of measurements are correlated, then the full correlation matrix is listed in the footnote to the measurement that first appears in the τ Listings. Footnotes to the other measurements refer to the first measurement. For example, the large correlation matrices for the branching fraction measurements contained in Refs. [3,4] are listed in Footnotes to the $\Gamma(e^- \bar{\nu}_e \nu_\tau) / \Gamma_{\text{total}}$ and $\Gamma(h^- \nu_\tau) / \Gamma_{\text{total}}$ measurements respectively. Sometimes experimental papers contain correlation coefficients between measurements using only statistical errors without including systematic errors. We usually cannot make use of these correlation coefficients.

The 2012 constrained fit has a χ^2 of 128.9 for 108 degrees of freedom, up from 102.9 for 103 degrees of freedom in the 2010 fit. Two basis-mode branching fractions changed by more than 1.0σ from their 2010 values, $B(\mu^- \bar{\nu}_\mu \nu_\tau)$ and $B(\pi^- \nu_\tau)$, due to new measurements by the BaBar Collaboration [5] of τ -decay

Lepton Particle Listings

τ

modes containing one charged prong and no neutral particles other than neutrinos.

Inconsistencies in the τ lepton Branching Fraction Data:

Several inconsistencies are known to exist in the branching fraction measurements that are used to determine the τ -lepton branching fractions. The sources of the inconsistencies are unknown. The treatment of discrepant data used for fits and averages is described in the introduction of this *Review*. Of the 82 branching fractions that are derived from the constrained fit, 12 (15%) have scale factors that are 1.5 or larger, and the largest is 2.7. Of the 37 branching fractions that are not derived from the constrained fit, 20 make use of only one measurement. Of the 17 averages that make use of more than one measurement, 3 (18%) have scale factors that are 1.5 or larger, and the largest is 5.4. Ideograms for 8 branching fractions are currently displayed in the τ Listings.

Figure 2: Distribution of the normalized difference between the 20 B -factory measurements of conventional τ -decay branching fractions and non- B -factory measurements. The Belle and BaBar collaborations have published 11 and 9 measurements respectively.

The τ branching fraction measurements by BaBar and Belle tend to be smaller than the non- B -factory measurements. There are 20 B -factory branching fraction measurements of τ -decay modes for which older non- B -factory measurements exist. Comparing the B -factory branching fraction measurements to the earlier non- B -factory measurements reveals a systematic discrepancy between the two sets of measurements. Figure 2 shows a histogram of the normalized difference ($(B$ -factory value minus non- B -factory value)/estimated uncertainty in the difference) for the 20 measurements. The value used for the non- B -factory measurement is the value listed in the latest edition of this *Review* prior to the first B -factory measurement for that decay mode. Eighteen of the 20 B -factory branching

fraction measurements are smaller than the non- B -factory values. The average normalized difference between the two sets of measurements is -1.30 (-1.41 for the 11 Belle measurements and -1.24 for the 9 BaBar measurements). The Heavy Flavor Averaging Group (HFAG) analysis of τ branching fractions includes a similar comparison of the B -factory and non- B -factory measurements [6].

Belle and BaBar have each published branching fraction measurements for the six τ -decay modes listed in Table 2. The normalized difference between the two measured values is calculated by subtracting the Belle value from the BaBar value and dividing this difference by the quadratic sum of the statistical and systematic errors for each measurement. When a measurement has asymmetric errors, the larger of the two values is used in the quadratic sum. It is apparent from the values in Table 2 that the Belle and BaBar values differ significantly for several of the τ -decay modes.

Table 2: Comparison of the Belle and Babar branching fraction measurements for the six τ -decay modes that both experiments have measured. The normalized difference is the difference between the Belle and BaBar branching fraction values divided by the quadratic sum of the statistical and systematic errors for both measurements.

Mode	BaBar – Belle Normalized Difference ($\#\sigma$)
$\pi^- \pi^+ \pi^- \nu_\tau$ (ex. K^0)	+1.4
$K^- \pi^+ \pi^- \nu_\tau$ (ex. K^0)	-2.9
$K^- K^+ \pi^- \nu_\tau$	-2.9
$K^- K^+ K^- \nu_\tau$	-5.4
$\eta K^- \nu_\tau$	-1.0
$\phi K^- \nu_\tau$	-1.3

Overconsistency of Leptonic Branching Fraction Measurements:

To minimize the effects of older experiments which often have larger systematic errors and sometimes make assumptions that have later been shown to be invalid, we exclude old measurements in decay modes which contain at least several newer data of much higher precision. As a rule, we exclude those experiments with large errors which together would contribute no more than 5% of the weight in the average. This procedure leaves five measurements for $B_e \equiv B(\tau^- \rightarrow e^- \bar{\nu}_e \nu_\tau)$ and five measurements for $B_\mu \equiv B(\tau^- \rightarrow \mu^- \bar{\nu}_\mu \nu_\tau)$. For both B_e and B_μ , the selected measurements are considerably more consistent with each other than should be expected from the quoted errors on the individual measurements. The χ^2 from the calculation of the average of the selected measurements is 0.34 for B_e and 0.08 for B_μ . Assuming normal errors, the probability of a smaller χ^2 is 1.3% for B_e and 0.08% for B_μ .

τ^- BRANCHING RATIOS

$$\Gamma(\text{particle}^- \geq 0 \text{ neutrals} \geq 0K^0 \nu_\tau \text{ ("1-prong")})/\Gamma_{\text{total}} \quad \Gamma_1/\Gamma$$

$$\Gamma_1/\Gamma = (\Gamma_3 + \Gamma_5 + \Gamma_9 + \Gamma_{10} + \Gamma_{14} + \Gamma_{16} + \Gamma_{20} + \Gamma_{23} + \Gamma_{27} + \Gamma_{28} + \Gamma_{30} + \Gamma_{35} + \Gamma_{37} + \Gamma_{40} + \Gamma_{42} + 2\Gamma_{47} + \Gamma_{48} + 0.708\Gamma_{125} + 0.715\Gamma_{127} + 0.09\Gamma_{149} + 0.09\Gamma_{151})/\Gamma$$

The charged particle here can be e , μ , or hadron. In many analyses, the sum of the topological branching fractions (1, 3, and 5 prongs) is constrained to be unity. Since the 5-prong fraction is very small, the measured 1-prong and 3-prong fractions are highly correlated and cannot be treated as independent quantities in our overall fit. We arbitrarily choose to use the 3-prong fraction in our fit, and leave the 1-prong fraction out. We do, however, use these 1-prong measurements in our average below. The measurements used only for the average are marked "avg," whereas "f&a" marks a result used for the fit and the average.
