REVIEW OF PARTICLE PHYSICS*

Particle Data Group

Abstract

This biennial *Review* summarizes much of particle physics. Using data from previous editions, plus 2658 new measurements from 644 papers, we list, evaluate, and average measured properties of gauge bosons, leptons, quarks, mesons, and baryons. We summarize searches for hypothetical particles such as Higgs bosons, heavy neutrinos, and supersymmetric particles. All the particle properties and search limits are listed in Summary Tables. We also give numerous tables, figures, formulae, and reviews of topics such as the Standard Model, particle detectors, probability, and statistics. Among the 112 reviews are many that are new or heavily revised including those on Heavy-Quark and Soft-Collinear Effective Theory, Neutrino Cross Section Measurements, Monte Carlo Event Generators, Lattice QCD, Heavy Quarkonium Spectroscopy, Top Quark, Dark Matter, V_{cb} & V_{ub} , Quantum Chromodynamics, High-Energy Collider Parameters, Astrophysical Constants, Cosmological Parameters, and Dark Matter.

A booklet is available containing the Summary Tables and abbreviated versions of some of the other sections of this full *Review*. All tables, listings, and reviews (and errata) are also available on the Particle Data Group website: <http://pdg.lbl.gov>.

DOI: 10.1103/PhysRevD.86.010001

The 2012 edition of *Review of Particle Physics* is published for the Particle Data Group as article 010001 in volume 86 of *Physical Review D*.

This edition should be cited as: J. Beringer et al. (Particle Data Group), Phys. Rev. D **86**, 010001 (2012).

HIGHLIGHTS OF THE 2012 EDITION OF THE REVIEW OF PARTICLE PHYSICS

644 new papers with 2658 new measurements

- Over 100 papers from **LHC** experiments (ATLAS, CMS, and LHCb).
- Major exclusions in **SUSY** results from the LHC.
- Latest from **B-meson** physics: 120 papers with 555 measurements, including first LHCb results. Stringent limits on $B_s \rightarrow \mu^+ \mu^-$ from LHCb and CMS approaching the SM expectation.
- Updated and new results in **neutrino mixing**, including observation of mixing angle θ_{13} from reactor experiments.
- 63 new **top** results since 2010, many from LHC experiments.
- New CDF/D0 value of **W-mass** with very small error, impact on prediction of Higgs mass.
- New $\eta_c(1S)$ branching ratio fit removing circular dependencies.
- First observations of $h_b(1P)$, $h_b(2P)$, and the $\chi_b(3P)$ triplet, as well as two exotic charged states with bottomonium content (unconfirmed).

112 reviews (most are revised or new)

- **New reviews on:**
 - Heavy-Quark and Soft-Collinear Effective Theory
 - Neutrino Cross Section Measurements
 - Neutrino Beam Lines at High-Energy Proton Synchrotrons
 - Monte Carlo Event Generators
 - Lattice QCD
 - Scalar Meson and $\sigma(500)$ Parameters
 - Heavy Quarkonium Spectroscopy
- **Significant update/revision** to reviews on:
 - **Higgs Boson** (with addendum on new **July 2012 results**)
 - **Astrophysical Constants** (extended to include more cosmological parameters from the **7-year WMAP** analysis)
 - **Dark Matter**
 - **Top Quark** with detailed coverage of LHC results
 - V_{cb} and V_{ub} **CKM elements**
 - **Quantum Chromodynamics**
 - **High-Energy Collider Parameters** (includes CLIC and latest LHC parameters)
 - Particle Detectors for Non-Accel. Physics (addition of **Coherent Radio Cherenkov Detectors**)

See pdgLive.lbl.gov for online access to PDG database.

INTRODUCTION

1. Overview

The *Review of Particle Physics* and the abbreviated version, the *Particle Physics Booklet*, are reviews of the field of Particle Physics. This complete *Review* includes a compilation/evaluation of data on particle properties, called the “Particle Listings.” These Listings include 2,658 new measurements from 644 papers, in addition to the 29,495 measurements from 8,300 papers that first appeared in previous editions [1].

Both books include Summary Tables with our best values and limits for particle properties such as masses, widths or lifetimes, and branching fractions, as well as an extensive summary of searches for hypothetical particles. In addition, we give a long section of “Reviews, Tables, and Plots” on a wide variety of theoretical and experimental topics, a quick reference for the practicing particle physicist.

The *Review* and the *Booklet* are published in even-numbered years. This edition is an updating through January 2012 (and, in some areas, well into 2012). As described in the section “Online Particle Physics Information” following this introduction, the content of this *Review* is available on the World-Wide Web, and is updated between printed editions (<http://pdg.lbl.gov/>).

The Summary Tables give our best values of the properties of the particles we consider to be well established, a summary of search limits for hypothetical particles, and a summary of experimental tests of conservation laws.

The Particle Listings contain all the data used to get the values given in the Summary Tables. Other measurements considered recent enough or important enough to mention, but which for one reason or another are not used to get the best values, appear separately just beneath the data we do use for the Summary Tables. The Particle Listings also give information on unconfirmed particles and on particle searches, as well as short “reviews” on subjects of particular interest or controversy.

The Particle Listings were once an archive of all published data on particle properties. This is no longer possible because of the large quantity of data. We refer interested readers to earlier editions for data now considered to be obsolete.

We organize the particles into six categories:

- Gauge and Higgs bosons
- Leptons
- Quarks
- Mesons
- Baryons
- Searches for monopoles, supersymmetry, compositeness, extra dimensions, *etc.*

The last category only includes searches for particles that do not belong to the previous groups; searches for heavy charged leptons and massive neutrinos, by contrast, are with the leptons.

In Sec. 2 of this Introduction, we list the main areas of responsibility of the authors, and also list our large number of consultants, without whom we would not have been able to produce this *Review*. In Sec. 4, we mention briefly the naming scheme for hadrons. In Sec. 5, we discuss our procedures for choosing among measurements of particle properties and for obtaining best values of the properties

from the measurements.

The accuracy and usefulness of this *Review* depend in large part on interaction between its users and the authors. We appreciate comments, criticisms, and suggestions for improvements of any kind. Please send them to the appropriate author, according to the list of responsibilities in Sec. 2 below, or to the LBNL addresses below.

To order a copy of the *Review* or the *Particle Physics Booklet* from North and South America, Australia, and the Far East, send email to PDG@LBL.GOV

3. Consultants

The Particle Data Group benefits greatly from the assistance of some 700 physicists who are asked to verify every piece of data entered into this *Review*. Of special value is the advice of the PDG Advisory Committee which meets biennially and thoroughly reviews all aspects of our operation. The members of the 2012 committee are:

D. Harris (FNAL)
 P. Janot (CERN)
 J. Olson (Princeton)
 G. Perez (Weizmann)
 J. Tanaka (Tokyo)

We have especially relied on the expertise of the following people for advice on particular topics:

- M. Achasov (BINP, Novosibirsk)
- K.S. Agashe (Maryland)
- H. Aihara (Tokyo)
- S.I. Alekhin (COMPAS Group, IHEP, Protvino)
- F. Anulli (INFN, Rome)
- M. Artuso (Syracuse University)
- H. Bachacou (CEA Saclay)
- S. Banerjee (Victoria U, BC)
- R. Barlow (Manchester U.)
- V. B. Bezerra (UFPb)
- M. Beneke (Aachen, Germany)
- A.M. Bernstein (MIT)
- M. Billing (Cornell University)
- P. B. Mackenzie (FNAL)
- C. Bozzi (INFN, Ferrara)
- T. Brooks (SLAC)
- T. Browder (University of Hawaii)
- O. Bruening (CERN)
- A. Buras (Munich Tech. U.)
- V.D. Burkert (Thomas Jefferson Lab)
- J. Butterworth (UCL)
- A. Chao (SLAC)
- C. Davies (U of Glasgow)
- F. Deliot (CEA, Saclay)
- L. Demortier (Rockefeller University)
- D. Denisov (FNAL)
- J. Dingfelder (Bonn, Germany)
- R. Dixon (FNAL)
- A. Donnachie (University of Manchester)
- A.T. Doyle (Glasgow Univ.)
- W. Fischer (BNL)
- M. Furman (LBNL)

- H. Gallagher (Tufts U.)
- P. Gambino (Univ. degli Studi di Torino)
- R. Garisto (PRL)

4. Naming scheme for hadrons

We introduced in the 1986 edition [2] a new naming scheme for the hadrons. Changes from older terminology affected mainly the heavier mesons made of u , d , and s quarks. Otherwise, the only important change to known hadrons was that the F^\pm became the D_s^\pm . None of the lightest pseudoscalar or vector mesons changed names, nor did the $c\bar{c}$ or $b\bar{b}$ mesons (we do, however, now use χ_c for the $c\bar{c}$ χ states), nor did any of the established baryons. The Summary Tables give both the new and old names whenever a change has occurred.

The scheme is described in “Naming Scheme for Hadrons” (p. 118) of this *Review*.

We give here our conventions on type-setting style. Particle symbols are italic (or slanted) characters: e^- , p , Λ , π^0 , K_L , D_s^+ , b . Charge is indicated by a superscript: B^- , Δ^{++} . Charge is not normally indicated for p , n , or the quarks, and is optional for neutral isosinglets: η or η^0 . Antiparticles and particles are distinguished by charge for charged leptons and mesons: τ^+ , K^- . Otherwise, distinct antiparticles are indicated by a bar (overline): $\bar{\nu}_\mu$, \bar{t} , \bar{p} , \bar{K}^0 , and $\bar{\Sigma}^+$ (the antiparticle of the Σ^-).

5. Procedures

5.1. Selection and treatment of data : The Particle Listings contain all relevant data known to us that are published in journals. With very few exceptions, we do not include results from preprints or conference reports. Nor do we include data that are of historical importance only (the Listings are not an archival record). We search every volume of 20 journals through our cutoff date for relevant data. We also include later published papers that are sent to us by the authors (or others).

In the Particle Listings, we clearly separate measurements that are used to calculate or estimate values given in the Summary Tables from measurements that are not used. We give explanatory comments in many such cases. Among the reasons a measurement might be excluded are the following:

- It is superseded by or included in later results.
- No error is given.
- It involves assumptions we question.
- It has a poor signal-to-noise ratio, low statistical significance, or is otherwise of poorer quality than other data available.
- It is clearly inconsistent with other results that appear to be more reliable. Usually we then state the criterion, which sometimes is quite subjective, for selecting “more reliable” data for averaging. See Sec. 5.4.
- It is not independent of other results.
- It is not the best limit (see below).
- It is quoted from a preprint or a conference report.

In some cases, *none* of the measurements is entirely reliable and no average is calculated. For example, the masses of many of the baryon resonances, obtained from partial-wave analyses, are quoted as estimated ranges thought to probably include the true values, rather than as averages with errors. This is discussed in the Baryon Particle Listings.

For upper limits, we normally quote in the Summary Tables the strongest limit. We do not average or combine upper limits except in a very few cases where they may be re-expressed as measured numbers with Gaussian errors.

As is customary, we assume that particle and antiparticle share the same spin, mass, and mean life. The Tests of Conservation Laws table, following the Summary Tables, lists tests of CPT as well as other conservation laws.

We use the following indicators in the Particle Listings to tell how we get values from the tabulated measurements:

- OUR AVERAGE—From a weighted average of selected data.
- OUR FIT—From a constrained or overdetermined multi-parameter fit of selected data.
- OUR EVALUATION—Not from a direct measurement, but evaluated from measurements of related quantities.
- OUR ESTIMATE—Based on the observed range of the data. Not from a formal statistical procedure.
- OUR LIMIT—For special cases where the limit is evaluated by us from measured ratios or other data. Not from a direct measurement.

An experimentalist who sees indications of a particle will of course want to know what has been seen in that region in the past. Hence we include in the Particle Listings all

reported states that, in our opinion, have sufficient statistical merit and that have not been disproved by more reliable data. However, we promote to the Summary Tables only those states that we feel are well established. This judgment is, of course, somewhat subjective and no precise criteria can be given. For more detailed discussions, see the minireviews in the Particle Listings.

5.2. Averages and fits: We divide this discussion on obtaining averages and errors into three sections: (1) treatment of errors; (2) unconstrained averaging; (3) constrained fits.

5.2.1. Treatment of errors: In what follows, the “error” δx means that the range $x \pm \delta x$ is intended to be a 68.3% confidence interval about the central value x . We treat this error as if it were Gaussian. Thus when the error is Gaussian, δx is the usual one standard deviation (1σ). Many experimenters now give statistical and systematic errors separately, in which case we usually quote both errors, with the statistical error first. For averages and fits, we then add the two errors in quadrature and use this combined error for δx .

When experimenters quote asymmetric errors $(\delta x)^+$ and $(\delta x)^-$ for a measurement x , the error that we use for that measurement in making an average or a fit with other measurements is a continuous function of these three quantities. When the resultant average or fit \bar{x} is less than $x - (\delta x)^-$, we use $(\delta x)^-$; when it is greater than $x + (\delta x)^+$, we use $(\delta x)^+$. In between, the error we use is a linear function of x . Since the errors we use are functions of the result, we iterate to get the final result. Asymmetric output errors are determined from the input errors assuming a linear relation between the input and output quantities.

In fitting or averaging, we usually do not include correlations between different measurements, but we try to select data in such a way as to reduce correlations. Correlated errors are, however, treated explicitly when there are a number of results of the form $A_i \pm \sigma_i \pm \Delta$ that have identical systematic errors Δ . In this case, one can first average the $A_i \pm \sigma_i$ and then combine the resulting statistical error with Δ . One obtains, however, the same result by averaging $A_i \pm (\sigma_i^2 + \Delta_i^2)^{1/2}$, where $\Delta_i = \sigma_i \Delta [\sum (1/\sigma_j^2)]^{1/2}$. This procedure has the advantage that, with the modified systematic errors Δ_i , each measurement may be treated as independent and averaged in the usual way with other data. Therefore, when appropriate, we adopt this procedure. We tabulate Δ and invoke an automated procedure that computes Δ_i before averaging and we include a note saying that there are common systematic errors.

Another common case of correlated errors occurs when experimenters measure two quantities and then quote the two and their difference, e.g., m_1 , m_2 , and $\Delta = m_2 - m_1$. We cannot enter all of m_1 , m_2 and Δ into a constrained fit because they are not independent. In some cases, it is a good approximation to ignore the quantity with the largest error and put the other two into the fit. However, in some cases correlations are such that the errors on m_1 , m_2 and Δ are comparable and none of the three values can be ignored. In this case, we put all three values into the fit and invoke an automated procedure to increase the errors prior to fitting such that the three quantities can be treated as independent measurements in the constrained fit. We include a note saying that this has been done.

5.2.2. Unconstrained averaging: To average data, we use a standard weighted least-squares procedure and in some cases, discussed below, increase the errors with a “scale factor.” We begin by assuming that measurements of a given quantity are uncorrelated, and calculate a weighted average and error as

$$\bar{x} \pm \delta\bar{x} = \frac{\sum_i w_i x_i}{\sum_i w_i} \pm (\sum_i w_i)^{-1/2}, \quad (1)$$

where

$$w_i = 1/(\delta x_i)^2.$$

Here x_i and δx_i are the value and error reported by the i th experiment, and the sums run over the N experiments. We then calculate $\chi^2 = \sum w_i (\bar{x} - x_i)^2$ and compare it with $N - 1$, which is the expectation value of χ^2 if the measurements are from a Gaussian distribution.

If $\chi^2/(N - 1)$ is less than or equal to 1, and there are no known problems with the data, we accept the results.

If $\chi^2/(N - 1)$ is very large, we may choose not to use the average at all. Alternatively, we may quote the calculated average, but then make an educated guess of the error, a conservative estimate designed to take into account known problems with the data.

Finally, if $\chi^2/(N - 1)$ is greater than 1, but not greatly so, we still average the data, but then also do the following:

(a) We increase our quoted error, $\delta\bar{x}$ in Eq. (1), by a scale factor S defined as

$$S = [\chi^2/(N - 1)]^{1/2}. \quad (2)$$

Our reasoning is as follows. The large value of the χ^2 is likely to be due to underestimation of errors in at least one of the experiments. Not knowing which of the errors are underestimated, we assume they are all underestimated by the same factor S . If we scale up all the input errors by this factor, the χ^2 becomes $N - 1$, and of course the output error $\delta\bar{x}$ scales up by the same factor. See Ref. 3.

When combining data with widely varying errors, we modify this procedure slightly. We evaluate S using only the experiments with smaller errors. Our cutoff or ceiling on δx_i is arbitrarily chosen to be

$$\delta_0 = 3N^{1/2} \delta\bar{x},$$

where $\delta\bar{x}$ is the unscaled error of the mean of all the experiments. Our reasoning is that although the low-precision experiments have little influence on the values \bar{x} and $\delta\bar{x}$, they can make significant contributions to the χ^2 , and the contribution of the high-precision experiments thus tends to be obscured. Note that if each experiment has the same error δx_i , then $\delta\bar{x}$ is $\delta x_i/N^{1/2}$, so each δx_i is well below the cutoff. (More often, however, we simply exclude measurements with relatively large errors from averages and fits: new, precise data chase out old, imprecise data.)

Our scaling procedure has the property that if there are two values with comparable errors separated by much more than their stated errors (with or without a number of other values of lower accuracy), the scaled-up error $\delta\bar{x}$ is approximately half the interval between the two discrepant values.

We emphasize that our scaling procedure for *errors* in no way affects central values. And if you wish to recover the unscaled error $\delta\bar{x}$, simply divide the quoted error by S .

(b) If the number M of experiments with an error smaller than δ_0 is at least three, and if $\chi^2/(M-1)$ is greater than 1.25, we show in the Particle Listings an ideogram of the data. Figure 1 is an example. Sometimes one or two data points lie apart from the main body; other times the data split into two or more groups. We extract no numbers from these ideograms; they are simply visual aids, which the reader may use as he or she sees fit.

Figure 1: A typical ideogram. The arrow at the top shows the position of the weighted average, while the width of the shaded pattern shows the error in the average after scaling by the factor S . The column on the right gives the χ^2 contribution of each of the experiments. Note that the next-to-last experiment, denoted by the incomplete error flag (\perp), is not used in the calculation of S (see the text).

Each measurement in an ideogram is represented by a Gaussian with a central value x_i , error δx_i , and area proportional to $1/\delta x_i$. The choice of $1/\delta x_i$ for the area is somewhat arbitrary. With this choice, the center of gravity of the ideogram corresponds to an average that uses weights $1/\delta x_i$ rather than the $(1/\delta x_i)^2$ actually used in the averages. This may be appropriate when some of the experiments have seriously underestimated systematic errors. However, since for this choice of area the height of the Gaussian for each measurement is proportional to $(1/\delta x_i)^2$, the peak position of the ideogram will often favor the high-precision measurements at least as much as does the least-squares average. See our 1986 edition [2] for a detailed discussion of the use of ideograms.

5.2.3. Constrained fits: In some cases, such as branching ratios or masses and mass differences, a constrained fit may be needed to obtain the best values of a set of parameters. For example, most branching ratios and rate measurements are analyzed by making a simultaneous least-squares fit to all the data and extracting the partial decay fractions P_i , the partial widths Γ_i , the full width Γ (or mean life), and the associated error matrix.

Assume, for example, that a state has m partial decay fractions P_i , where $\sum P_i = 1$. These have been measured in N_r different ratios R_r , where, e.g., $R_1 = P_1/P_2$, R_2

$= P_1/P_3$, etc. [We can handle any ratio R of the form $\sum \alpha_i P_i / \sum \beta_i P_i$, where α_i and β_i are constants, usually 1 or 0. The forms $R = P_i P_j$ and $R = (P_i P_j)^{1/2}$ are also allowed.] Further assume that each ratio R has been measured by N_k experiments (we designate each experiment with a subscript k , e.g., R_{1k}). We then find the best values of the fractions P_i by minimizing the χ^2 as a function of the $m-1$ independent parameters:

$$\chi^2 = \sum_{r=1}^{N_r} \sum_{k=1}^{N_k} \left(\frac{R_{rk} - R_r}{\delta R_{rk}} \right)^2, \quad (3)$$

where the R_{rk} are the measured values and R_r are the fitted values of the branching ratios.

In addition to the fitted values \bar{P}_i , we calculate an error matrix $\langle \delta \bar{P}_i \delta \bar{P}_j \rangle$. We tabulate the diagonal elements of $\delta \bar{P}_i = \langle \delta \bar{P}_i \delta \bar{P}_i \rangle^{1/2}$ (except that some errors are scaled as discussed below). In the Particle Listings, we give the complete correlation matrix; we also calculate the fitted value of each ratio, for comparison with the input data, and list it above the relevant input, along with a simple unconstrained average of the same input.

Three comments on the example above:

(1) There was no connection assumed between measurements of the full width and the branching ratios. But often we also have information on partial widths Γ_i as well as the total width Γ . In this case we must introduce Γ as a parameter in the fit, along with the P_i , and we give correlation matrices for the widths in the Particle Listings.

(2) We try to pick those ratios and widths that are as independent and as close to the original data as possible. When one experiment measures all the branching fractions and constrains their sum to be one, we leave one of them (usually the least well-determined one) out of the fit to make the set of input data more nearly independent. We now do allow for correlations between input data.

(3) We calculate scale factors for both the R_r and P_i when the measurements for any R give a larger-than-expected contribution to the χ^2 . According to Eq. (3), the double sum for χ^2 is first summed over experiments $k = 1$ to N_k , leaving a single sum over ratios $\chi^2 = \sum \chi_r^2$. One is tempted to define a scale factor for the ratio r as $S_r = \chi_r^2 / \langle \chi_r^2 \rangle$. However, since $\langle \chi_r^2 \rangle$ is not a fixed quantity (it is somewhere between N_k and N_{k-1}), we do not know how to evaluate this expression. Instead we define

$$S_r^2 = \frac{1}{N_k} \sum_{k=1}^{N_k} \frac{(R_{rk} - \bar{R}_r)^2}{\langle (R_{rk} - \bar{R}_r)^2 \rangle}. \quad (4)$$

With this definition the expected value of S_r^2 is one. We can show that

$$\langle (R_{rk} - \bar{R}_r)^2 \rangle = \langle (\delta R_{rk})^2 \rangle - (\delta \bar{R}_r)^2, \quad (5)$$

where $\delta \bar{R}_r$ is the fitted error for ratio r .

The fit is redone using errors for the branching ratios that are scaled by the larger of S_r and unity, from which new and often larger errors $\delta \bar{P}_i'$ are obtained. The scale factors we finally list in such cases are defined by $S_i = \delta \bar{P}_i' / \delta \bar{P}_i$. However, in line with our policy of not letting S affect the central values, we give the values of \bar{P}_i obtained from the original (unscaled) fit.

There is one special case in which the errors that are obtained by the preceding procedure may be changed. When a fitted branching ratio (or rate) \overline{P}_i turns out to be less than three standard deviations ($\delta\overline{P}_i'$) from zero, a new smaller error ($\delta\overline{P}_i''$)⁻ is calculated on the low side by requiring the area under the Gaussian between $\overline{P}_i - (\delta\overline{P}_i'')^-$ and \overline{P}_i to be 68.3% of the area between zero and \overline{P}_i . A similar correction is made for branching fractions that are within three standard deviations of one. This keeps the quoted errors from overlapping the boundary of the physical region.

5.3. Rounding: While the results shown in the Particle Listings are usually exactly those published by the experiments, the numbers that appear in the Summary Tables (means, averages and limits) are subject to a set of rounding rules.

The basic rule states that if the three highest order digits of the error lie between 100 and 354, we round to two significant digits. If they lie between 355 and 949, we round to one significant digit. Finally, if they lie between 950 and 999, we round up to 1000 and keep two significant digits. In all cases, the central value is given with a precision that matches that of the error. So, for example, the result (coming from an average) 0.827 ± 0.119 would appear as 0.83 ± 0.12 , while 0.827 ± 0.367 would turn into 0.8 ± 0.4 .

Rounding is not performed if a result in a Summary Table comes from a single measurement, without any averaging. In that case, the number of digits published in the original paper is kept, unless we feel it inappropriate. Note that, even for a single measurement, when we combine statistical and systematic errors in quadrature, rounding rules apply to the result of the combination. It should be noted also that most of the limits in the Summary Tables come from a single source (the best limit) and, therefore, are not subject to rounding.

Finally, we should point out that in several instances, when a group of results come from a single fit to a set of data, we have chosen to keep two significant digits for all the results. This happens, for instance, for several properties of the W and Z bosons and the τ lepton.

5.4. Discussion: The problem of averaging data containing discrepant values is nicely discussed by Taylor in Ref. 4. He considers a number of algorithms that attempt to incorporate inconsistent data into a meaningful average. However, it is difficult to develop a procedure that handles simultaneously in a reasonable way two basic types of situations: (a) data that lie apart from the main body of the data are incorrect (contain unreported errors); and (b) the opposite—it is the main body of data that is incorrect. Unfortunately, as Taylor shows, case (b) is not infrequent. He concludes that the choice of procedure is less significant than the initial choice of data to include or exclude.

We place much emphasis on this choice of data. Often we solicit the help of outside experts (consultants). Sometimes, however, it is simply impossible to determine which of a set of discrepant measurements are correct. Our scale-factor technique is an attempt to address this ignorance by increasing the error. In effect, we are saying that present experiments do not allow a precise determination of this quantity because of unresolvable discrepancies, and one must await further measurements. The reader is warned of this situation by the size of the scale factor, and if he or she desires can go back to the literature (via the Particle

Listings) and redo the average with a different choice of data.

Our situation is less severe than most of the cases Taylor considers, such as estimates of the fundamental constants like \hbar , *etc.* Most of the errors in his case are dominated by systematic effects. For our data, statistical errors are often at least as large as systematic errors, and statistical errors are usually easier to estimate. A notable exception occurs in partial-wave analyses, where different techniques applied to the same data yield different results. In this case, as stated earlier, we often do not make an average but just quote a range of values.

A brief history of early Particle Data Group averages is given in Ref. 3. Figure 2 shows some histories of our values of a few particle properties. Sometimes large changes occur. These usually reflect the introduction of significant new data or the discarding of older data. Older data are discarded in favor of newer data when it is felt that the newer data have smaller systematic errors, or have more checks on systematic errors, or have made corrections unknown at the time of the older experiments, or simply have much smaller errors. Sometimes, the scale factor becomes large near the time at which a large jump takes place, reflecting the uncertainty introduced by the new and inconsistent data. By and large, however, a full scan of our history plots shows a dull progression toward greater precision at central values quite consistent with the first data points shown.

We conclude that the reliability of the combination of experimental data and our averaging procedures is usually good, but it is important to be aware that fluctuations outside of the quoted errors can and do occur.

ACKNOWLEDGMENTS

The publication of the *Review of Particle Physics* is supported by the Director, Office of Science, Office of High Energy and Nuclear Physics, the Division of High Energy Physics of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231; by the U.S. National Science Foundation under Agreement No. PHY-0652989; by the European Laboratory for Particle Physics (CERN); by an implementing arrangement between the governments of Japan (Monbusho) and the United States (DOE) on cooperative research and development.

We thank all those who have assisted in the many phases of preparing this *Review*. We particularly thank the many who have responded to our requests for verification of data entered in the Listings, and those who have made suggestions or pointed out errors.

1. Introduction

The collection of online information resources in particle physics and related areas presented in this chapter is of necessity incomplete. An expanded and regularly updated online version can be found at

<http://library.web.cern.ch/library/rpp>.

Suggestions for additions and updates are very welcome.

2. Particle Data Group (PDG) resources

- **REVIEW OF PARTICLE PHYSICS (RPP):** A comprehensive report on the fields of particle physics and cosmology, including both review articles and a compilation/evaluation of data on particle properties. The review section includes articles, tables and plots on a wide variety of theoretical and experimental topics of interest to particle physicists and astrophysicists. The particle properties section provides tables of published measurements as well as the Particle Data Group's best values and limits for particle properties such as masses, widths, lifetimes, and branching fractions, and an extensive summary of searches for hypothetical particles. RPP is published as a 1400-page book every two years, with partial updates made available once each year on the web. All the contents of the 1400-page book version of RPP are available online at:

<http://pdg.lbl.gov>

- **PARTICLE PHYSICS BOOKLET:** An abridged version of the Review of Particle Physics available as a pocket-sized 300-page booklet. Although produced in print and available online only as a PDF file, the booklet is included in this guide because it is one of the most useful summaries of physics data. The booklet contains an abbreviated set of reviews and the summary tables from the most recent edition of the Review of Particle Physics.

The PDF file of the booklet can be downloaded:

<http://pdg.lbl.gov/current/booklet.pdf>.

The printed booklet can be ordered:

http://pdg.lbl.gov/current/html/receive_our_products.html.

[†] Please send comments and corrections to Annette.Holtkamp@cern.ch or tullio.basaglia@cern.ch.

- **PDGLive:** A web application for browsing the contents of the PDG database that contains the information published in the Review of Particle Physics. It allows one to navigate to a particle of interest, see a summary of the information available, and then proceed to the detailed information published in the Review of Particle Physics. Data entries are directly linked to the corresponding bibliographic information in INSPIRE. pdgLive can be accessed at:

<http://pdglive.lbl.gov>

- **COMPUTER-READABLE FILES:** Data files that can be downloaded from PDG include tables of particle masses and widths, PDG Monte Carlo particle numbers, and cross-section data. The files are updated with each new edition of the Review of Particle Physics and are available at:

http://pdg.lbl.gov/current/html/computer_read.html

Of historical interest is the complete RPP collection which, apart from the very first version from the year 1957, can be found online at

http://tiny.cc/RPP_historical

3. Particle Physics Information Platforms

- **SPIRES:** This indispensable information tool for high energy physicists worldwide was replaced by INSPIRE in November 2011. SPIRES started as a bibliographic database SPIRES-HEP in 1974 hosted at SLAC in collaboration with DESY and became remotely accessible in the mid 80's. Several databases - CONF, EXP, INST, HEPNames and JOBS - followed and FermiLab joined the team. In December 1991 SPIRES became the first web server outside Europe, from the start closely related to the arXiv repository. For High Energy Physics SPIRES-HEP was the reference for publications, covering not only journal articles and preprints but also conference proceedings, technical reports, theses and other 'gray' literature, the value of the information enhanced by thorough proof-reading, keywords and links to the sister SPIRES databases and other information services. Content and service are now taken over by INSPIRE.

- **INSPIRE:** The time-honored SPIRES database suite has now been replaced by INSPIRE which combines the most successful aspects of SPIRES like comprehensive content and high-quality metadata - with the modern technology of Invenio, the CERN open-source digital-library software, offering major improvements like increased speed and Google-like free-text search syntax. INSPIRE serves as one-stop information platform for the particle physics community, comprising 6 interlinked databases on literature, conferences, institutions, researchers, experiments, jobs. INSPIRE is jointly developed and maintained by the three laboratories that have been running SPIRES (DESY, Fermilab and SLAC) and CERN. Close interaction with the user community and with arXiv, ADS, HepData, PDG and publishers is the backbone of INSPIRE's evolution.

<http://inspirehep.net/>

More information on this project at

<http://www.projecthepinpire.net/>

4. Literature Databases

- **ADS:** The SAO/NASA Astrophysics Data System is a Digital Library portal for researchers in Astronomy and Physics, operated by the Smithsonian Astrophysical Observatory (SAO) under a NASA grant. The ADS maintains three bibliographic databases containing more than 9.3 million records: Astronomy and Astrophysics, Physics, and arXiv e-prints. The main body of data in the ADS consists of bibliographic records, which are searchable through highly customizable query forms, and full-text scans of much of the astronomical literature which can be browsed or searched via a full-text search interface. Integrated in its databases, the ADS provides access and pointers to a wealth of external resources, including electronic articles, data catalogues and archives. In addition, ADS provides the myADS Update Service, a free custom

notification service promoting current awareness of the recent literature in astronomy and physics based on each individual subscriber's queries.

<http://adswww.harvard.edu/>

- arXiv.org: A repository of full text papers in physics, mathematics, computer science, statistics, nonlinear sciences, quantitative finance and quantitative biology interlinked with ADS and INSPIRE. Papers are usually sent by their authors to arXiv in advance of submission to a journal for publication. Primarily covers 1991 to the present but authors are encouraged to post older papers retroactively. Permits searching by author, title, and words in abstract and experimentally also in the fulltext. Allows limiting by subfield archive or by date.
<http://arXiv.org>
- CDS: The CERN Document Server contains records of more than 1,000,000 CERN and non-CERN articles, preprints, theses. It includes records for internal and technical notes, official CERN committee documents, and multimedia objects. CDS is going to focus on its role as institutional repository covering all CERN material from the early 50s and reflecting the holdings of the CERN library. Non-CERN particle and accelerator physics content is in the process of being exported to INSPIRE.
<http://cdsweb.cern.ch>
- INSPIRE HEP: The HEP database serves almost 1 Mio bibliographic records covering particle physics and related topics with a growing number of fulltexts attached and metadata including author affiliations, abstracts, references, keywords as well as links to arXiv, PDG, HepData and publisher platforms. It provides fast metadata and fulltext searches, plots extracted from fulltext, author disambiguation, author profile pages and citation analysis and is expanding its content to e.g. experimental notes.
<http://inspirehep.net>
- JACoW: The Joint Accelerator Conference Website publishes the proceedings of APAC, EPAC, PAC, ABDW, BIW, COOL, CYCLOTRONS, DIPAC, ECR, FEL, ICALEPCS, ICAP, LINAC, North American PAC, PCaPAC, RuPAC, SRF. A custom interface allows searching on keywords, titles, authors, and in the fulltext.
<http://www.JACoW.org/>
- KISS (KEK INFORMATION SERVICE SYSTEM) FOR PREPRINTS: The KEK Library preprint and technical report database contains bibliographic records of preprints and technical reports held in the KEK library with links to the full text images of more than 100,000 papers scanned from their worldwide collection of preprints. Particularly useful for older scanned preprints:
http://www-lib.kek.jp/KISS/kiss_preprint.html
- OSTI: The Office of Scientific and Technical Information databases search collections of research results, including those produced throughout the DOE National Laboratory complex and by Departmental grantees. You can find current and legacy research results, search ongoing research and development project descriptions, browse scientific subject portals of interest, access and search scientific e-prints, sign up for alerts, search science conference papers and proceedings. Among the key resources are the Energy Citations Database, providing free access to over 2,450,000 science research citations and 292,000 electronic documents, primarily from 1943 forward, and Information Bridge, covering DOE R&D reports with searchable full-text and bibliographic citations.
<http://www.osti.gov/>

5. Particle Physics Journals and Conference Proceedings Series

A list of journals and conference series publishing particle physics content can be found at:

<http://library.web.cern.ch/library/journals.html>

For each journal or conference series, information is given on Open Access and copyright policies and terms of use.

6. Conference Databases

- INSPIRE CONFERENCES: The database of more than 18,400 past, present and future conferences, schools, and meetings of interest to high-energy physics and related fields is searchable by title, acronym, series, date, location. Included are information about published proceedings, links to conference contributions in the INSPIRE HEP database, and links to the conference Web site when available. New conferences can be submitted from the entry page.

<http://inspirehep.net/Conferences>

7. Research Institutions

- INSPIRE INSTITUTIONS: The database of over 9,800 institutes, laboratories, and university departments in which research on particle physics and astrophysics is performed covers six continents and over a hundred countries. Included are address, e-mail address, and Web links where available as well as links to the papers from each institution in the HEP database. Searches can be performed by name, acronym, location, etc. The site offers an alphabetical list by country as well as a list of the top 500 HEP and astrophysics institutions sorted by country.

<http://inspirehep.net/Institutions>

8. People

- INSPIRE HEPNames: Searchable worldwide database of over 97,000 people associated with particle physics and related fields. The affiliation history of these researchers, their e-mail addresses, web pages, experiments they participated in, PhD advisor, information on their graduate students and links to their papers in the INSPIRE HEP, arXiv and ADS databases are provided as well as a user interface to update these information.

<http://inspirehep.net/HepNames>

9. Experiments

- SPIRES/INSPIRE EXPERIMENTS: Contains more than 2,400 past, present, and future experiments in particle physics. Lists both accelerator and non-accelerator experiments. Includes official experiment name and number, location, and collaboration lists. Simple searches by participant, title, experiment number, institution, date approved, accelerator, or detector, return a description of the experiment, including a complete list of authors, title, overview of the experiment's goals and methods, and a link to the experiment's Web page if available. Publication lists distinguish articles in refereed journals, theses, technical or instrumentation papers and those which rank among Topcite at 50 or more citations.

<http://www.slac.stanford.edu/spires/experiments/>

soon to be replaced by

<http://inspirehep.net/Experiments>

- COSMIC RAY/GAMMA RAY/NEUTRINO AND SIMILAR EXPERIMENTS: This extensive collection of experimental Web sites is organized by focus of study and also by location. Additional sections link to educational materials, organizations, related Web sites, etc. The site is maintained at the Max Planck Institute for Nuclear Physics, Heidelberg:

<http://www.mpi-hd.mpg.de/hfm/CosmicRay/CosmicRaySites.html>

10. Jobs

- APS Careers: gateway for physicists, students, and physics enthusiasts to information about physics jobs and careers. Physics job listings, career advice, upcoming workshops and meetings, and career and job related resources provided by the American Physical Society:
<http://www.aps.org/jobs/>
- BRIGHTRECRUITS.COM: A recruitment service run by IOP Publishing that connects employers from different industry sectors with jobseekers who have a background in physics and engineering
<http://brightrecruits.com/>
- IOP CAREERS: careers information and resources primarily aimed at university students provided by the UK Institute of Physics:
<http://www.iop.org/careers/>
- INSPIRE HEPJobs: lists academic and research jobs in high energy physics, nuclear physics, accelerator physics and astrophysics with the option to post a job or to receive email notices of new job listings. About 1300 jobs are currently listed.
<http://inspirehep.net/Jobs>
- PHYSICSTODAY JOBS: online recruitment advertising website for Physics Today magazine, published by the American Institute of Physics. Physics TodayJobs is the managing partner of the AIP Career Network, an online job board network for the physical science, engineering, and computing disciplines. Over 8,500 resumes are currently available, and almost 3,000 jobs were posted in 2011.
<http://www.physicstoday.org/jobs>

11. Software Repositories

Particle Physics

- BSM Generators: a repository of codes relevant to Beyond-the-Standard-Model (BSM) physics
<http://www.ippm.dur.ac.uk/montecarlo/BSM>
- CERNLIB: The CERN PROGRAM LIBRARY contains a large collection of general purpose libraries and modules offered in both source code and object code forms. It provides programs applicable to a wide range of physics research problems such as general mathematics, data analysis, detectors simulation, data-handling, etc. It also includes links to commercial, free, and other software. Development of this site has been discontinued.
<http://wwwasd.web.cern.ch/wwwasd/index.html>
- FERMITOOLS: Fermilab's software tools program provides a repository of Fermilab-developed software packages of value to the HEP community. Permits searching for packages by title or subject category:
<http://www.fnal.gov/fermitools/>
- FREEHEP: A collection of software and information about software useful in high-energy physics and adjacent disciplines, focusing on open-source software for data analysis and visualization. Searching can be done by title, subject, date acquired, date updated, or by browsing an alphabetical list of all packages. The site does not seem to be updated any longer but still provides useful information.
<http://www.freehep.org/>
- GEANT4: Toolkit for the simulation of the passage of particles through matter, maintained by a world-wide collaboration of scientists and software engineers. Its areas of application include high energy, nuclear and accelerator physics, as well as studies in medical and space science.
<http://geant4.cern.ch/>
- GENSER: The Generator Services project collaborates with Monte Carlo (MC) generators authors and with LHC experiments in order to prepare validated LCG compliant code for both the theoretical and experimental communities at the LHC, sharing the user support duties, providing assistance for the development of the

new object-oriented generators and guaranteeing the maintenance of the older packages on the LCG supported platforms. The project consists of the generators repository, validation, HepMC record and MCDB event databases.

<http://sftweb.cern.ch/generators/>

- HEPFORGE: A development environment for high-energy physics software development projects, in particular housing many event-generator related projects, that offers a ready-made, easy-to-use set of Web based tools, including shell account with up to date development tools, web page hosting, subversion and CVS code management systems, mailing lists, bug tracker and wiki system.
<http://www.hepforge.org/>
 - PYTHIA: A program for the generation of high-energy physics events, i.e. for the description of collisions at high energies between elementary particles such as e^+ , e^- , p and p -bar in various combinations. It contains theory and models for a number of physics aspects, including hard and soft interactions, parton distributions, initial- and final-state parton showers, multiple interactions, fragmentation and decay.
<http://home.thep.lu.se/torbjorn/Pythia.html>
 - QUDA: library for performing calculations in lattice QCD on GPUs using NVIDIA's "C for CUDA" API. The current release includes optimized solvers for Wilson, Clover-improved Wilson, Twisted mass, Improved staggered (asqtad or HISQ) and Domain wall fermion actions
<http://lattice.github.com/quda/>
 - ROOT: This framework for data processing in high-energy physics, born at CERN, offers applications to store, access, process, analyze and represent data or perform simulations.
<http://root.cern.ch/drupal>
 - tmLQCD: This freely available software suite provides a set of tools to be used in lattice QCD simulations, mainly a (P)HMC implementation for Wilson and Wilson twisted mass fermions and inverter for different versions of the Dirac operator.
<https://github.com/etmc/tmLQCD>
 - USQCD: The software suite enables lattice QCD computations to be performed with high performance across a variety of architectures. The page contains links to the project web pages of the individual software modules, as well as to complete lattice QCD application packages which use them.
<http://usqcd.jlab.org/usqcd-software/>
- A list of Monte Carlo generators may be found at
<http://cmsdoc.cern.ch/cms/PRS/gentools/www/geners/collection/collection.html>
- The homepage of the SUSY Les Houches Accord contains links to codes relevant for supersymmetry calculations and phenomenology
<http://home.fnal.gov/skands/slha/>
- A variety of codes and algorithmic tools for analysing supersymmetric phenomenology is described in [arXiv:0805.2088](https://arxiv.org/abs/0805.2088)
<http://arxiv.org/abs/0805.2088>
- ### Astrophysics
- IRAF: The Image Reduction and Analysis Facility is a general purpose software system for the reduction and analysis of astronomical data. IRAF is written and supported by the IRAF programming group at the National Optical Astronomy Observatories (NOAO) in Tucson, Arizona.
<http://iraf.noao.edu/>
 - STARLINK: Starlink was a UK Project supporting astronomical data processing. It was shut down in 2005 but its open-source software continues to be developed at the Joint Astronomy Centre. The software products are a collection of applications and libraries, usually focused on a specific aspect of data reduction or analysis.
<http://starlink.jach.hawaii.edu/starlink>

Links to a large number of astronomy software archives are listed at

<http://heasarc.nasa.gov/docs/heasarc/astro-update/>

12. Data repositories

Particle Physics

- HEPDATA: The HepData Project, funded by the STFC(UK) and based at the IPPP at Durham University, has for more than 30 years compiled a Reaction Data database, comprising total and differential cross sections, structure functions, fragmentation functions, distributions of jet measures, polarisations, etc from a wide range of particle physics scattering experiments worldwide. It is regularly updated to cover the latest data including those from the LHC. In addition, it provides a series of on-line data reviews on a wide variety of topics with links to the data in the Reaction Database. It also hosts a Parton Distribution Function server with an on-line PDF calculator and plotter.

<http://durpdg.dur.ac.uk/>

- ILDG: The International Lattice Data Grid is an international organization which provides standards, services, methods and tools that facilitates the sharing and interchange of lattice QCD gauge configurations among scientific collaborations, by uniting their regional data grids. It offers semantic access with local tools to worldwide distributed data. See e.g.

<http://www.usqcd.org/ildg/>

- MCPLOTS: mcplots is a repository of Monte Carlo plots comparing High Energy Physics event generators to a wide variety of available experimental data. The site is supported by the LHC Physics Centre at CERN.

<http://mcplots.cern.ch/>

Astrophysics

- SIMBAD: archives data in the form of object catalogues from many heterogeneous sources

<http://simbad.u-strasbg.fr/simbad/>

- NED: NASA/IPAC extragalactic database, operated by the Jet Propulsion Laboratory, California Institute of Technology

<http://ned.ipac.caltech.edu/>

- The NASA archives provide access to raw and processed datasets from numerous NASA missions.

Hubble telescope, other missions (UV, optical):

<http://archive.stsci.edu/>

Spitzer telescope, other missions (Infrared):

<http://irsa.ipac.caltech.edu/>

Chandra, Fermi telescopes, other missions:

<http://heasarc.gsfc.nasa.gov/>

- The Virtual Observatory provides a suite of resources to query for original data from a large number of archives. Two main tools are provided. One runs queries across multiple databases (such as the SDSS database) and combines the results. The other queries hundreds of archives for all datasets that fall on a particular piece of sky.

<http://www.us-vo.org/>

General Physics

- NIST PHYSICAL MEASUREMENT LABORATORY: The National Institute of Standards and Technology provides access to physical reference data (physical constants, atomic spectroscopy data, x-ray and gamma-ray data, radiation dosimetry data, nuclear physics data and more) and measurements and calibrations data (dimensional measurements, electromagnetic measurements). The site points to a general interest page, linking to exhibits of the Physical Measurement Laboratory in the NIST Virtual Museum.

<http://physics.nist.gov/>

- SPRINGER MATERIALS - THE LANDOLT-BÖRNSTEIN DATABASE: Landolt-Börnstein is a high-quality data collection in all areas of physical sciences and engineering, among others particle physics, electronic structure and transport, magnetism, superconductivity. International experts scan the primary literature in more than 8,000 peer-reviewed journals and evaluate and select the most valid information to be included in the database. It includes more than 100,000 online documents, 1.2 million references, and covers 250,000 chemical substances. The search functionality is freely accessible and the search results are displayed in their context, whereas the full text is secured to subscribers:

<http://www.springermaterials.com/>

13. Data preservation

Particle Physics

- DPHEP: The efforts to define and coordinate Data Preservation and Long Term Analysis in HEP are coordinated by a study group formed to investigate the issues associated with these activities. The group, DPHEP, was initiated during 2008-2009 and includes all HEP major experiments and laboratories. It is endorsed by the International Committee for Future Accelerators (ICFA). Details of the organizational structure, the objectives, workshops and publications can be found at

<http://dphep.org>

The experiments at colliders: BaBar, Belle, BES-III, Cleo, CDF, D0, H1 and ZEUS and the associated computing centres at SLAC (USA), KEK (Japan), IHEP (China), Jlab (USA), BNL (USA), Fermilab (USA), DESY (Germany), and CERN are all represented in the group. The LHC collaborations have also joined the initiative in 2011. The participating experiments are in various stages of studying, preparing, or operating long-term data preservation and analysis systems. Technological methods, such as virtualization, and information management tools such as INSPIRE are also helpful in this area of research. Data access policies and outreach in HEP using real data are among the investigative areas of the DPHEP Study Group.

Astrophysics

More formal and advanced data preservation activity is ongoing in the field of Experimental Astrophysics, including

- SDSS

<http://sdss.org>

- Fermi

<http://fermi.gsfc.nasa.gov/ssc/data>

- IVOA

<http://www.ivoa.net/>

14. Particle Physics Education and Outreach Sites

Science Educators' Networks:

- IPPOG: The International Particle Physics Outreach Group is a network of particle physicists, researchers, informal science educators and science explainers aiming to raise awareness, understanding and standards of global outreach efforts in particle physics and general science by providing discussion forums and regular information exchange for science institutions, proposing and implementing strategies to share lessons learned and best practices and promoting current outreach efforts of network members:

<http://ippog.web.cern.ch/ippog/>

- Interactions.org: designed to serve as a central resource for communicators of particle physics. The daily updated site provides links to current particle physics news from the world's press, high-resolution photos and graphics from the particle physics laboratories of the world; links to education and outreach programs; information about science policy and funding; links to universities; a glossary; a conference calendar; and links to many educational sites

<http://www.interactions.org>

Physics Courses

- MIT OPENCOURSEWARE - PHYSICS: These MIT course materials reflect almost all the undergraduate and graduate subjects taught at MIT. In addition to physics courses, supplementary educational resources are also available.

<http://ocw.mit.edu/courses/physics/>

Master Classes

- INTERNATIONAL MASTERCLASSES: Each year about 6000 high school students in 28 countries come to one of about 130 nearby universities or research centres for one day in order to unravel the mysteries of particle physics. Lectures from active scientists give insight in topics and methods of basic research at the fundamentals of matter and forces, enabling the students to perform measurements on real data from particle physics experiments themselves. At the end of each day, like in an international research collaboration, the participants join in a video conference for discussion and combination of their results.

<http://physicsmasterclasses.org/>

General Sites

- CONTEMPORARY PHYSICS EDUCATION PROJECT (CPEP): Provides charts, brochures, Web links, and classroom activities. Online interactive courses include: Fundamental Particles and Interactions; Plasma Physics and Fusion; History and Fate of the Universe; and Nuclear Science.

<http://www.cpepweb.org/>

- PHYSICSCENTRAL: This site maintained by the American Physical Society provides information about current research and people in physics, experiments that can be performed at home or at school and the possibility to get physics questions answered by physicists.

<http://www.physicscentral.com>

General Physics Lessons & Activities

- HYPERPHYSICS: An exploration environment for concepts in physics employing concept maps and other linking strategies and providing opportunities for numerical exploration.
- PHYSICS2000: An interactive journey through modern physics. Have fun learning visually and conceptually about 20th century science and high-tech devices. Supported by the Colorado Commission on Higher Education and the National Science Foundation

<http://www.colorado.edu/physics/2000>

Particle Physics Lessons & Activities

- Angels and Demons: With the aim of looking at the myth versus the reality of science at CERN this site offers teacher resources, slide shows and videos of talks given to teachers visiting CERN
- ANTIMATTER: MIRROR OF THE UNIVERSE: Find out what antimatter is, where it is made, the history behind its discovery, and how it is a part of our lives. Features colorful photos, illustrations, webcasts, a Kids Corner, and CERN physicists answering your questions on antimatter:

<http://livefromcern.web.cern.ch/livefromcern/antimatter/>

- BIG BANG: An exhibition of the UK Science Museum with an interactive game about the hunt for the Higgs

<http://www.sciencemuseum.org.uk/antenna/bigbang/>

- BIG BANG SCIENCE: EXPLORING THE ORIGINS OF MATTER: This Web site, produced by the Particle Physics and Astronomy Research Council of the UK (PPARC), explains what physicists are looking for with their giant instruments. Big Bang Science focuses on CERN particle detectors and on United Kingdom scientists' contribution to the search for the fundamental building blocks of matter.

<http://hepwww.rl.ac.uk/pub/bigbang/part1.html>

- CERNland: With a range of games, multimedia applications and films CERNland is the virtual theme park developed to bring the excitement of CERN's research to a young audience aged between 7 and 12. CERNland is designed to show children what is being done at CERN and inspire them with some physics at the same time.

<http://www.cernland.net/>

- Collidingparticles: a series of films following a team of physicists involved in research at the LHC

<http://www.collidingparticles.com/>

- Lancaster Particle Physics: This site, suitable for 16+ students, offers a number of simulations and explanations of particle physics, including a section on the LHC.

<http://www.lppp.lancs.ac.uk/>

- PARTICLE ADVENTURE: One of the most popular Web sites for learning the fundamentals of matter and force. An award-winning interactive tour of quarks, neutrinos, antimatter, extra dimensions, dark matter, accelerators and particle detectors from the Particle Data Group of Lawrence Berkeley National Laboratory. Simple elegant graphics and translations into 15 languages:

<http://ParticleAdventure.org>

- PARTICLE DETECTIVES: This website, maintained by the Science and Technology Facilities Council (STFC), is for inquisitive 14-19 year olds, their teachers and for researchers who want to find out and talk about the world's biggest scientific adventure, the Large Hadron Collider, featuring e.g. An LHC experiment simulator.

<http://www.lhc.ac.uk/The+Particle+Detectives/15273.aspx>

- Quarked! - Adventures in the Subatomic Universe: This project, targeted to kids aged 7-12 (and their families), brings subatomic physics to life through a multimedia project including an interactive website, a facilitated program for museums and schools, and an educational outreach program

<http://www.quarked.org/>

- QUARKNET: QuarkNet brings the excitement of particle physics research to high school teachers and their students. Teachers join research groups at about 50 universities and labs across the country. These research groups are part of particle physics experiments at CERN or Fermilab. About 100,000 students from 500+ US high schools learn fundamental physics as they participate in inquiry-oriented investigations and analyze real data online. QuarkNet is supported in part by the National Science Foundation and the U.S. Department of Energy:

<http://QuarkNet.fnal.gov>

- Rewarding Learning videos about CERN: The three videos based on interviews with scientists and engineers at CERN introduce pupils to CERN and the type of research and work undertaken there and are accompanied by teachers' notes.

<http://www.rewardinglearning.org.uk/STEM/cern/>

Lab Education Offices

- Brookhaven National Laboratory (BNL) Educational Programs: The Office of Educational Programs mission is to design, develop, implement, and facilitate workforce development and education initiatives that support the scientific mission at Brookhaven National Laboratory and the Department of Energy.

<http://www.bnl.gov/education/>

- CERN: The CERN education website offers information about teacher programmes and educational resources for schools

<http://education.web.cern.ch/education/>

- DESY: offers courses for pupils and teachers as well as information for the general public, mostly in German.

http://www.desy.de/information_services/education/

- FERMILAB EDUCATION OFFICE: provides education resources and information about activities for educators, physicists, students

and visitors to the Lab. In addition to information on 25 programs, the site provides online data-based investigations for high school students, online versions of exhibits in the Lederman Science Center, links to particle physics discovery resources, web-based instructional resources, what works for education and outreach, and links to the Lederman Science Center and the Teacher Resource Center.

<http://ed.fnal.gov/>

- LBL: Berkeley Lab's Center for Science & Engineering Education (CSEE) carries out the Department of Energy's education mission to train the next generation of scientists, as well as helping them to gain an understanding of the relationships among frontier science, technology, and society.
<http://www.lbl.gov/Education/>
- EXPLORING SLAC SCIENCE: This Stanford Linear Accelerator Center Web site explains physics concepts related to experiments conducted at SLAC.
<http://www6.slac.stanford.edu/ExploringSLACScience.aspx>
- Symmetry: This magazine about particle physics and its connections to other aspects of life and science, from interdisciplinary collaborations to policy to culture is published 6 times per year by Fermilab and SLAC.
<http://www.symmetrymagazine.org>

Educational Programs of Experiments

- ATLAS DISCOVERY QUEST: One of several access points to ATLAS education and outreach pages. This page gives access to explanations of physical concepts, blogs, ATLAS facts, news, and information for students and teachers.
<http://www.atlas.ch/physics.html>
- ATLAS eTours: give a description of the Large Hadron Collider, explain how the ATLAS detector at the LHC works and give an overview over the experiments and their physics goals.
<http://www.atlas.ch/etours.html>
- CMS EDUCATION: Provides access to educational resources (Story of the Universe, The Size of Things, What is a Particle), and to multimedia material, such as interviews, movies and photos.
<http://cms.web.cern.ch/content/cms-education>
- EDUCATION AND OUTREACH @ ICECUBE: Educational pages of the IceCube (South Pole Neutrino Detector)
<http://icecube.wisc.edu/outreach>
- LIGO SCIENCE EDUCATION CENTER: The LIGO (Laser Interferometer Gravitational-wave Observatory) Science Education Center has over 40 interactive, hands-on exhibits that relate to the science of LIGO. The site hosts field trips for students, teacher training programs, and tours for the general public. Visitors can explore science concepts such as light, gravity, waves, and interference; learn about LIGO's search for gravitational waves; and interact with scientists and engineers.
<http://www.ligo-la.caltech.edu/SEC.html>
- PIERRE AUGER OBSERVATORY'S EDUCATIONAL PAGES: The site offers information about cosmic rays and their detection, and provides material for students and teachers.
http://www.auger.org/cosmic_rays/

Art in Physics

- Arts@CERN: a 3-year artist's residency programme in Digital Arts and Dance/Performance
<http://arts.web.cern.ch/collide/>
- Art of Physics Competition: The Canadian Association of Physicists organizes this competition, the first was launched in 1992, with the aim of stimulating interest, especially among non-scientists, in some of the captivating imagery associated with physics. The challenge is to capture photographically a beautiful or unusual physics phenomenon and explain it in less than 200 words in terms that everyone can understand.
<http://www.cap.ca/aop/art.html>
- Photowalk: More than 200 amateur photographers from around the world had the opportunity to experience state-of-the-art accelerators and detectors. Five of the world's leading particle physics laboratories in Asia, Europe and North America offered special behind-the-scenes access to their scientific facilities. The winning photos can be viewed.
<http://www.interactions.org/cms/?pid=1029664>

Blogs

This is a very incomplete collection of particle physics related blogs:

- ATLAS blog
<http://www.atlas.ch/blog>
- U.S. LHC blog: The blog give a vivid account of the daily activity of US LHC researchers.
<http://www.quantumdiaries.org/lab-81/>
- Physics arXiv blog: Technology Review blog on new ideas at arXiv.org
<http://www.technologyreview.com/blog/arxiv/>
- CERN Love:
<http://www.cernlove.org/blog/>
- Not Even Wrong: Peter Woit's blog on topics in physics and mathematics
<http://www.math.columbia.edu/woit/wordpress/>
- Quantum diaries: Thoughts on work and life from particle physicists from around the world.
<http://www.quantumdiaries.org/>
- Science blogs: Launched in January 2006, ScienceBlogs features bloggers from a wide array of scientific disciplines, including physics:
<http://scienceblogs.com/channel/physical-science/>
- Life and Physics: Jon Butterworth's blog in the Guardian
<http://www.guardian.co.uk/science/life-and-physics>

Higgs Bosons — H^0 and H^\pm , Searches for

The July 2012 news about Higgs searches is described in the addendum to the Higgs review in the data listings, but is not reflected here.

The limits for H_1^0 and A^0 refer to the m_h^{max} benchmark scenario for the supersymmetric parameters.

H^0 Mass $m > 115.5$ and none 127–600 GeV, CL = 95%

H_1^0 in Supersymmetric Models ($m_{H_1^0} < m_{H_2^0}$)

Mass $m > 92.8$ GeV, CL = 95%

A^0 Pseudoscalar Higgs Boson in Supersymmetric Models [1]

Mass $m > 93.4$ GeV, CL = 95% $\tan\beta > 0.4$

H^\pm Mass $m > 79.3$ GeV, CL = 95%

See the Particle Listings for a Note giving details of Higgs Bosons.

Heavy Bosons Other Than Higgs Bosons, Searches for

Additional W Bosons

W' with standard couplings

Mass $m > 2.150 \times 10^3$ GeV, CL = 95%

Additional Z Bosons

Z'_{SM} with standard couplings

Mass $m > 1.830 \times 10^3$ GeV, CL = 95% ($p\bar{p}$ direct search)

Mass $m > 1.500 \times 10^3$ GeV, CL = 95% (electroweak fit)

Z_{LR} of $SU(2)_L \times SU(2)_R \times U(1)$ (with $g_L = g_R$)

Mass $m > 630$ GeV, CL = 95% ($p\bar{p}$ direct search)

Mass $m > 1162$ GeV, CL = 95% (electroweak fit)

Z_χ of $SO(10) \rightarrow SU(5) \times U(1)_\chi$ (with $g_\chi = e/\cos\theta_W$)

Mass $m > 1.640 \times 10^3$ GeV, CL = 95% ($p\bar{p}$ direct search)

Mass $m > 1.141 \times 10^3$ GeV, CL = 95% (electroweak fit)

Z_ψ of $E_6 \rightarrow SO(10) \times U(1)_\psi$ (with $g_\psi = e/\cos\theta_W$)

Mass $m > 1.490 \times 10^3$ GeV, CL = 95% ($p\bar{p}$ direct search)

Mass $m > 476$ GeV, CL = 95% (electroweak fit)

Z_η of $E_6 \rightarrow SU(3) \times SU(2) \times U(1) \times U(1)_\eta$ (with $g_\eta = e/\cos\theta_W$)

Mass $m > 1.540 \times 10^3$ GeV, CL = 95% ($p\bar{p}$ direct search)

Mass $m > 619$ GeV, CL = 95% (electroweak fit)

Scalar Leptoquarks

Mass $m > 660$ GeV, CL = 95% (1st generation, pair prod.)

Mass $m > 298$ GeV, CL = 95% (1st gener., single prod.)

Mass $m > 422$ GeV, CL = 95% (2nd gener., pair prod.)

Mass $m > 73$ GeV, CL = 95% (2nd gener., single prod.)

Mass $m > 247$ GeV, CL = 95% (3rd gener., pair prod.)

(See the Particle Listings for assumptions on leptoquark quantum numbers and branching fractions.)

Axions (A^0) and Other Very Light Bosons, Searches for

The standard Peccei-Quinn axion is ruled out. Variants with reduced couplings or much smaller masses are constrained by various data.

The Particle Listings in the full Review contain a Note discussing axion searches.

The best limit for the half-life of neutrinoless double beta decay with Majoron emission is $> 7.2 \times 10^{24}$ years (CL = 90%).

Gauge & Higgs Boson Summary Table

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S , defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S , see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

- [a] Theoretical value. A mass as large as a few MeV may not be precluded.
- [b] ℓ indicates each type of lepton (e , μ , and τ), not sum over them.
- [c] This represents the width for the decay of the W boson into a charged particle with momentum below detectability, $p < 200$ MeV.

- [d] The Z -boson mass listed here corresponds to a Breit-Wigner resonance parameter. It lies approximately 34 MeV above the real part of the position of the pole (in the energy-squared plane) in the Z -boson propagator.
- [e] This partial width takes into account Z decays into $\nu\bar{\nu}$ and any other possible undetected modes.
- [f] This ratio has not been corrected for the τ mass.
- [g] Here $A \equiv 2g_V g_A / (g_V^2 + g_A^2)$.
- [h] The value is for the sum of the charge states or particle/antiparticle states indicated.
- [i] This value is updated using the product of (i) the $Z \rightarrow b\bar{b}$ fraction from this listing and (ii) the b -hadron fraction in an unbiased sample of weakly decaying b -hadrons produced in Z -decays provided by the Heavy Flavor Averaging Group (HFAG, http://www.slac.stanford.edu/xorg/hfag/osc/PDG_2009/#FRACZ).
- [j] See the Z Particle Listings for the γ energy range used in this measurement.
- [k] For $m_{\gamma\gamma} = (60 \pm 5)$ GeV.
- [l] The limits assume no invisible decays.

Heavy Charged Lepton Searches

 L^\pm – charged lepton

Mass $m > 100.8$ GeV, CL = 95% ^[h] Decay to νW .

 L^\pm – stable charged heavy lepton

Mass $m > 102.6$ GeV, CL = 95%

Neutrino Properties

See the note on “Neutrino properties listings” in the Particle Listings.

Mass $m < 2$ eV (tritium decay)

Mean life/mass, $\tau/m > 300$ s/eV, CL = 90% (reactor)

Mean life/mass, $\tau/m > 7 \times 10^9$ s/eV (solar)

Mean life/mass, $\tau/m > 15.4$ s/eV, CL = 90% (accelerator)

Magnetic moment $\mu < 0.32 \times 10^{-10} \mu_B$, CL = 90% (solar)

Number of Neutrino Types

Number $N = 2.984 \pm 0.008$ (Standard Model fits to LEP data)

Number $N = 2.92 \pm 0.05$ ($S = 1.2$) (Direct measurement of invisible Z width)

Neutrino Mixing

The following values are obtained through data analyses based on the 3-neutrino mixing scheme described in the review “Neutrino Mass, Mixing, and Oscillations” by K. Nakamura and S.T. Petcov in this Review.

$$\sin^2(2\theta_{12}) = 0.857 \pm 0.024$$

$$\Delta m_{21}^2 = (7.50 \pm 0.20) \times 10^{-5} \text{ eV}^2$$

$$\sin^2(2\theta_{23}) > 0.95 \text{ [i]}$$

$$\Delta m_{32}^2 = (2.32^{+0.12}_{-0.08}) \times 10^{-3} \text{ eV}^2 \text{ [j]}$$

$$\sin^2(2\theta_{13}) = 0.098 \pm 0.013$$

Heavy Neutral Leptons, Searches for

For excited leptons, see Compositeness Limits below.

Stable Neutral Heavy Lepton Mass Limits

Mass $m > 45.0$ GeV, CL = 95% (Dirac)

Mass $m > 39.5$ GeV, CL = 95% (Majorana)

Neutral Heavy Lepton Mass Limits

Mass $m > 90.3$ GeV, CL = 95%

(Dirac ν_L coupling to e, μ, τ ; conservative case(τ))

Mass $m > 80.5$ GeV, CL = 95%

(Majorana ν_L coupling to e, μ, τ ; conservative case(τ))

NOTES

In this Summary Table:

When a quantity has “(S = ...)” to its right, the error on the quantity has been enlarged by the “scale factor” S, defined as $S = \sqrt{N^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] This is the best limit for the mode $e^- \rightarrow \nu \gamma$. The best limit for “electron disappearance” is 6.4×10^{24} yr.

[b] See the “Note on Muon Decay Parameters” in the μ Particle Listings for definitions and details.

[c] P_μ is the longitudinal polarization of the muon from pion decay. In standard $V-A$ theory, $P_\mu = 1$ and $\rho = \delta = 3/4$.

[d] This only includes events with the γ energy > 10 MeV. Since the $e^- \bar{\nu}_e \nu_\mu$ and $e^- \bar{\nu}_e \nu_\mu \gamma$ modes cannot be clearly separated, we regard the latter mode as a subset of the former.

[e] See the relevant Particle Listings for the energy limits used in this measurement.

[f] A test of additive vs. multiplicative lepton family number conservation.

[g] Basis mode for the τ .

[h] L^\pm mass limit depends on decay assumptions; see the Full Listings.

[i] The limit quoted corresponds to the projection onto the $\sin^2(2\theta_{23})$ axis of the 90% CL contour in the $\sin^2(2\theta_{23}) - \Delta m_{32}^2$ plane.

[j] The sign of Δm_{32}^2 is not known at this time. The range quoted is for the absolute value.

Quark Summary Table

QUARKS

The u -, d -, and s -quark masses are estimates of so-called “current-quark masses,” in a mass-independent subtraction scheme such as \overline{MS} at a scale $\mu \approx 2$ GeV. The c - and b -quark masses are the “running” masses in the \overline{MS} scheme. For the b -quark we also quote the 1S mass. These can be different from the heavy quark masses obtained in potential models.

u $I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$
 $m_u = 2.3^{+0.7}_{-0.5}$ MeV Charge = $\frac{2}{3} e$ $I_z = +\frac{1}{2}$
 $m_u/m_d = 0.38\text{--}0.58$

d $I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$
 $m_d = 4.8^{+0.7}_{-0.3}$ MeV Charge = $-\frac{1}{3} e$ $I_z = -\frac{1}{2}$
 $m_s/m_d = 17\text{--}22$
 $\overline{m} = (m_u + m_d)/2 = 3.2\text{--}4.4$ MeV

s $I(J^P) = 0(\frac{1}{2}^+)$
 $m_s = 95 \pm 5$ MeV Charge = $-\frac{1}{3} e$ Strangeness = -1
 $m_s / ((m_u + m_d)/2) = 27 \pm 1$

c $I(J^P) = 0(\frac{1}{2}^+)$
 $m_c = 1.275 \pm 0.025$ GeV Charge = $\frac{2}{3} e$ Charm = $+1$

b $I(J^P) = 0(\frac{1}{2}^+)$
 Charge = $-\frac{1}{3} e$ Bottom = -1
 $m_b(\overline{MS}) = 4.18 \pm 0.03$ GeV
 $m_b(1S) = 4.65 \pm 0.03$ GeV

t $I(J^P) = 0(\frac{1}{2}^+)$
 Charge = $\frac{2}{3} e$ Top = $+1$

Mass (direct measurements) $m = 173.5 \pm 0.6 \pm 0.8$ GeV ^[a,b]

All searches since 1977 have had negative results.

NOTES

- [a] A discussion of the definition of the top quark mass in these measurements can be found in the review “The Top Quark.”
 [b] Based on published top mass measurements using data from Tevatron Run-I and Run-II and LHC at $\sqrt{s} = 7$ TeV. Including the most recent unpublished results from Tevatron Run-II, the Tevatron Electroweak Working Group reports a top mass of 173.2 ± 0.9 GeV. See the note “The Top Quark” in the Quark Particle Listings of this Review.
 [c] ℓ means e or μ decay mode, not the sum over them.
 [d] Assumes lepton universality and W -decay acceptance.
 [e] This limit is for $\Gamma(t \rightarrow \gamma q)/\Gamma(t \rightarrow Wb)$.
 [f] This limit is for $\Gamma(t \rightarrow Zq)/\Gamma(t \rightarrow Wb)$.

Meson Summary Table

LIGHT UNFLAVORED MESONS ($S = C = B = 0$)

For $I = 1$ (π, b, ρ, a): $u\bar{d}, (u\bar{u}-d\bar{d})/\sqrt{2}, d\bar{u}$;
for $I = 0$ ($\eta, \eta', h, h', \omega, \phi, f, f'$): $c_1(u\bar{u} + d\bar{d}) + c_2(s\bar{s})$

 π^\pm

$$I^G(J^{PC}) = 1^-(0^-)$$

Mass $m = 139.57018 \pm 0.00035$ MeV ($S = 1.2$)
Mean life $\tau = (2.6033 \pm 0.0005) \times 10^{-8}$ s ($S = 1.2$)
 $c\tau = 7.8045$ m

$\pi^\pm \rightarrow \ell^\pm \nu \gamma$ form factors [a]

$F_V = 0.0254 \pm 0.0017$
 $F_A = 0.0119 \pm 0.0001$
 F_V slope parameter $a = 0.10 \pm 0.06$
 $R = 0.059^{+0.009}_{-0.008}$

π^- modes are charge conjugates of the modes below.

For decay limits to particles which are not established, see the section on Searches for Axions and Other Very Light Bosons.

π^\pm DECAY MODES	Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)
$\mu^+ \nu_\mu$	[b] (99.98770 \pm 0.00004) %		30
$\mu^+ \nu_\mu \gamma$	[c] (2.00 \pm 0.25) $\times 10^{-4}$		30
$e^+ \nu_e$	[b] (1.230 \pm 0.004) $\times 10^{-4}$		70
$e^+ \nu_e \gamma$	[c] (7.39 \pm 0.05) $\times 10^{-7}$		70
$e^+ \nu_e \pi^0$	(1.036 \pm 0.006) $\times 10^{-8}$		4
$e^+ \nu_e e^+ e^-$	(3.2 \pm 0.5) $\times 10^{-9}$		70
$e^+ \nu_e \nu \bar{\nu}$	< 5 $\times 10^{-6}$	90%	70

Lepton Family number (LF) or Lepton number (L) violating modes

$\mu^+ \bar{\nu}_e$	L [d] < 1.5	$\times 10^{-3}$	90%	30
$\mu^+ \nu_e$	LF [d] < 8.0	$\times 10^{-3}$	90%	30
$\mu^- e^+ e^+ \nu$	LF < 1.6	$\times 10^{-6}$	90%	30

 π^0

$$I^G(J^{PC}) = 1^-(0^{++})$$

Mass $m = 134.9766 \pm 0.0006$ MeV ($S = 1.1$)
 $m_{\pi^\pm} - m_{\pi^0} = 4.5936 \pm 0.0005$ MeV
Mean life $\tau = (8.52 \pm 0.18) \times 10^{-17}$ s ($S = 1.2$)
 $c\tau = 25.5$ nm

For decay limits to particles which are not established, see the appropriate Search sections (A^0 (axion) and Other Light Boson (X^0) Searches, etc.).

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K_S^0 modes, not as \bar{K}^0 modes. Nearly always it is a K_S^0 that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\Gamma(K_S^0) = \Gamma(\bar{K}^0)$.

$$r_2 \equiv a_1/a_0 \text{ in } D^0 \rightarrow \pi^-\ell^+\nu_\ell = 6 \pm 3.0$$

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K_S^0 modes, not as \overline{K}^0 modes. Nearly always it is a K_S^0 that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\Gamma(K_S^0) = \Gamma(\overline{K}^0)$.

BOTTOM MESONS

$$(B = \pm 1)$$

$B^+ = u\bar{b}, B^0 = d\bar{b}, \bar{B}^0 = \bar{d}b, B^- = \bar{u}b$, similarly for B^{*+} s

B-particle organization

Many measurements of B decays involve admixtures of B hadrons. Previously we arbitrarily included such admixtures in the B^\pm section, but because of their importance we have created two new sections: " B^\pm/B^0 Admixture" for $\Upsilon(4S)$ results and " $B^\pm/B^0/B_s^0/b$ -baryon Admixture" for results at higher energies. Most inclusive decay branching fractions and χ_b at high energy are found in the Admixture sections. $B^0-\bar{B}^0$ mixing data are found in the B^0 section, while $B_s^0-\bar{B}_s^0$ mixing data and $B-\bar{B}$ mixing data for a B^0/B_s^0 admixture are found in the B_s^0 section. CP -violation data are found in the B^\pm, B^0 , and B^\pm/B^0 Admixture sections. b -baryons are found near the end of the Baryon section.

The organization of the B sections is now as follows, where bullets indicate particle sections and brackets indicate reviews.

- B^\pm
mass, mean life, CP violation, branching fractions
- B^0
mass, mean life, $B^0-\bar{B}^0$ mixing, CP violation, branching fractions
- B^\pm/B^0 Admixtures
 CP violation, branching fractions
- $B^\pm/B^0/B_s^0/b$ -baryon Admixtures
mean life, production fractions, branching fractions
- B^*
mass
- $B_1(5721)^0$
mass
- $B_2^*(5747)^0$
mass
- B_s^0

mass, mean life, $B_s^0-\bar{B}_s^0$ mixing, CP violation, branching fractions

- B_s^*
mass
- $B_{s1}(5830)^0$
mass
- $B_{s2}^*(5840)^0$
mass
- B_c^\pm
mass, mean life, branching fractions

At the end of Baryon Listings:

- Λ_b
mass, mean life, branching fractions
- Σ_b
mass
- Σ_b^*
mass
- Ξ_b^0, Ξ_b^-
mass, mean life, branching fractions
- Ω_b^-
mass, branching fractions
- b -baryon Admixture
mean life, branching fractions

B^\pm

$$I(J^P) = \frac{1}{2}(0^-)$$

I, J, P need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m_{B^\pm} = 5279.25 \pm 0.17$ MeV
Mean life $\tau_{B^\pm} = (1.641 \pm 0.008) \times 10^{-12}$ s
 $c\tau = 492.0$ μm

\end{aligned}$$

B^- modes are charge conjugates of the modes below. Modes which do not identify the charge state of the B are listed in the B^\pm/B^0 ADMIXTURE section.

The branching fractions listed below assume 50% $B^0 \bar{B}^0$ and 50% $B^+ B^-$ production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^* , and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, e.g., $B \rightarrow D^\pm$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

Meson Summary Table

\bar{B}^0 modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing. Modes which do not identify the charge state of the B are listed in the B^\pm/B^0 ADMIXTURE section.

The branching fractions listed below assume 50% $B^0\bar{B}^0$ and 50% B^+B^- production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^* , and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, e.g., $B \rightarrow D^\pm$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

B^0 DECAY MODES	Fraction (Γ_i/Γ)	Scale factor / Confidence level	p (MeV/c)

\end{aligned}$$

Meson Summary Table

The branching fraction measurements are for an admixture of B mesons at the $\Upsilon(4S)$. The values quoted assume that $B(\Upsilon(4S) \rightarrow B\bar{B}) = 100\%$.

For inclusive branching fractions, e.g., $B \rightarrow D^\pm$ anything, the treatment of multiple D 's in the final state must be defined. One possibility would be to count the number of events with one-or-more D 's and divide by the total number of B 's. Another possibility would be to count the total number of D 's and divide by the total number of B 's, which is the definition of average multiplicity. The two definitions are identical if only one D is allowed in the final state. Even though the "one-or-more" definition seems sensible, for practical reasons inclusive branching fractions are almost always measured using the multiplicity definition. For heavy final state particles, authors call their results inclusive branching fractions while for light particles some authors call their results multiplicities. In the B sections, we list all results as inclusive branching fractions, adopting a multiplicity definition. This means that inclusive branching fractions can exceed 100% and that inclusive partial widths can exceed total widths, just as inclusive cross sections can exceed total cross section.

\bar{B} modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing.

B DECAY MODES	Fraction (Γ_j/Γ)	Scale factor/ Confidence level (MeV/c)	p

 $B^\pm/B^0/B_s^0/b$ -baryon ADMIXTURE

These measurements are for an admixture of bottom particles at high energy (LHC, LEP, Tevatron, $Sp\bar{p}S$).

$$\text{Mean life } \tau = (1.568 \pm 0.009) \times 10^{-12} \text{ s}$$

$$\text{Mean life } \tau = (1.72 \pm 0.10) \times 10^{-12} \text{ s} \quad \text{Charged } b\text{-hadron admixture}$$

$$\text{Mean life } \tau = (1.58 \pm 0.14) \times 10^{-12} \text{ s} \quad \text{Neutral } b\text{-hadron admixture}$$

$$\tau_{\text{charged } b\text{-hadron}}/\tau_{\text{neutral } b\text{-hadron}} = 1.09 \pm 0.13$$

$$|\Delta\tau_b|/\tau_{b,\bar{b}} = -0.001 \pm 0.014$$

$$\text{Re}(\epsilon_b) / (1 + |\epsilon_b|^2) = (-2.0 \pm 0.5) \times 10^{-3}$$

The branching fraction measurements are for an admixture of B mesons and baryons at energies above the $\Upsilon(4S)$. Only the highest energy results (LHC, LEP, Tevatron, $Sp\bar{p}S$) are used in the branching fraction averages. In the following, we assume that the production fractions are the same at the LHC, LEP, and at the Tevatron.

For inclusive branching fractions, e.g., $B \rightarrow D^\pm$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

The modes below are listed for a \bar{b} initial state. b modes are their charge conjugates. Reactions indicate the weak decay vertex and do not include mixing.

\bar{b} DECAY MODES	Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)
-----------------------	--------------------------------	-----------------------------------	----------------

PRODUCTION FRACTIONS

The production fractions for weakly decaying b -hadrons at high energy have been calculated from the best values of mean lives, mixing parameters, and branching fractions in this edition by the Heavy Flavor Averaging Group (HFAG) as described in the note “ B^0 - \bar{B}^0 Mixing” in the B^0 Particle Listings. The production fractions in b -hadronic Z decay or $p\bar{p}$ collisions at the Tevatron are also listed at the end of the section. Values assume

$$\text{B}(\bar{b} \rightarrow B^+) = \text{B}(\bar{b} \rightarrow B^0)$$

$$\text{B}(\bar{b} \rightarrow B^+) + \text{B}(\bar{b} \rightarrow B^0) + \text{B}(\bar{b} \rightarrow B_s^0) + \text{B}(b \rightarrow b\text{-baryon}) = 100 \text{ \%}$$

The correlation coefficients between production fractions are also reported:

$$\text{cor}(B_s^0, b\text{-baryon}) = -0.277$$

$$\text{cor}(B_s^0, B^\pm=B^0) = -0.119$$

$$\text{cor}(b\text{-baryon}, B^\pm=B^0) = -0.921.$$

The notation for production fractions varies in the literature ($f_d, d_{B^0}, f(b \rightarrow \bar{B}^0), \text{B}_f(b \rightarrow \bar{B}^0)$). We use our own branching fraction notation here, $\text{B}(\bar{b} \rightarrow B^0)$.

Note these production fractions are b -hadronization fractions, not the conventional branching fractions of b -quark to a B -hadron, which may have considerable dependence on the initial and final state kinematic and production environment.

$$B_s^0 = s\bar{b}, \bar{B}_s^0 = \bar{s}b, \text{ similarly for } B_s^{*+}s$$

 B_s^0

$$I(J^P) = 0(0^-)$$

I, J, P need confirmation. Quantum numbers shown are quark-model predictions.

$$\text{Mass } m_{B_s^0} = 5366.77 \pm 0.24 \text{ MeV}$$

$$m_{B_s^0} - m_B = 87.35 \pm 0.23 \text{ MeV}$$

$$\text{Mean life } \tau = (1.497 \pm 0.015) \times 10^{-12} \text{ s}$$

$$c\tau = 449 \mu\text{m}$$

$$\Delta\Gamma_{B_s^0} = \Gamma_{B_{sL}^0} - \Gamma_{B_{sH}^0} = (0.100 \pm 0.013) \times 10^{12} \text{ s}^{-1}$$

 B_s^0 - \bar{B}_s^0 mixing parameters

$$\Delta m_{B_s^0} = m_{B_{sH}^0} - m_{B_{sL}^0} = (17.69 \pm 0.08) \times 10^{12} \text{ h s}^{-1}$$

$$= (116.4 \pm 0.5) \times 10^{-10} \text{ MeV}$$

$$x_s = \Delta m_{B_s^0}/\Gamma_{B_s^0} = 26.49 \pm 0.29$$

$$\chi_s = 0.499292 \pm 0.000016$$

CP violation parameters in B_s^0

$$\text{Re}(\epsilon_{B_s^0}) / (1 + |\epsilon_{B_s^0}|^2) = (-2.6 \pm 1.6) \times 10^{-3}$$

$$\text{CP Violation phase } \beta_s = 0.08^{+0.05}_{-0.07}$$

$$A_{CP}(B_s \rightarrow \pi^+ K^-) = 0.39 \pm 0.17$$

These branching fractions all scale with $B(\bar{b} \rightarrow B_s^0)$.

The branching fraction $B(B_s^0 \rightarrow D_s^- \ell^+ \nu_\ell \text{ anything})$ is not a pure measurement since the measured product branching fraction $B(\bar{b} \rightarrow B_s^0) \times B(B_s^0 \rightarrow D_s^- \ell^+ \nu_\ell \text{ anything})$ was used to determine $B(\bar{b} \rightarrow B_s^0)$, as described in the note on " B^0 - \bar{B}^0 Mixing"

For inclusive branching fractions, e.g., $B \rightarrow D^\pm \text{ anything}$, the values usually are multiplicities, not branching fractions. They can be greater than one.

 $\psi(3770)$

$$I^G(J^{PC}) = 0^-(1^{--})$$

Mass $m = 3773.15 \pm 0.33$ MeV

Full width $\Gamma = 27.2 \pm 1.0$ MeV

$\Gamma_{ee} = 0.262 \pm 0.018$ keV (S = 1.4)

In addition to the dominant decay mode to $D\bar{D}$, $\psi(3770)$ was found to decay into the final states containing the J/ψ (BAI 05, ADAM 06). ADAMS 06 and HUANG 06A searched for various decay modes with light hadrons and found a statistically significant signal for the decay to $\phi\eta$ only (ADAMS 06).

NOTES

In this Summary Table:

When a quantity has “(S = . . .)” to its right, the error on the quantity has been enlarged by the “scale factor” S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] See the “Note on $\pi^\pm \rightarrow \ell^\pm \nu \gamma$ and $K^\pm \rightarrow \ell^\pm \nu \gamma$ Form Factors” in the π^\pm Particle Listings for definitions and details.

[b] Measurements of $\Gamma(e^+ \nu_e)/\Gamma(\mu^+ \nu_\mu)$ always include decays with γ 's, and measurements of $\Gamma(e^+ \nu_e \gamma)$ and $\Gamma(\mu^+ \nu_\mu \gamma)$ never include low-energy γ 's. Therefore, since no clean separation is possible, we consider the modes with γ 's to be subreactions of the modes without them, and let $[\Gamma(e^+ \nu_e) + \Gamma(\mu^+ \nu_\mu)]/\Gamma_{\text{total}} = 100\%$.

[c] See the π^\pm Particle Listings for the energy limits used in this measurement; low-energy γ 's are not included.

[d] Derived from an analysis of neutrino-oscillation experiments.

[e] Astrophysical and cosmological arguments give limits of order 10^{-13} ; see the π^0 Particle Listings.

[f] C parity forbids this to occur as a single-photon process.

[g] See the “Note on scalar mesons” in the $f_0(500)$ Particle Listings. The interpretation of this entry as a particle is controversial.

[h] See the “Note on $\rho(770)$ ” in the $\rho(770)$ Particle Listings.

[i] The $\omega\rho$ interference is then due to $\omega\rho$ mixing only, and is expected to be small. If $e\mu$ universality holds, $\Gamma(\rho^0 \rightarrow \mu^+\mu^-) = \Gamma(\rho^0 \rightarrow e^+e^-) \times 0.99785$.

[j] See the “Note on scalar mesons” in the $f_0(500)$ Particle Listings.

[k] See the “Note on $a_1(1260)$ ” in the $a_1(1260)$ Particle Listings in PDG 06, Journal of Physics, G **33** 1 (2006).

[l] This is only an educated guess; the error given is larger than the error on the average of the published values. See the Particle Listings for details.

[m] See the “Note on non- $q\bar{q}$ mesons” in the Particle Listings in PDG 06, Journal of Physics, G **33** 1 (2006).

[n] See the “Note on the $\eta(1405)$ ” in the $\eta(1405)$ Particle Listings.

[o] See the “Note on the $f_1(1420)$ ” in the $\eta(1405)$ Particle Listings.

[p] See also the $\omega(1650)$ Particle Listings.

[q] See the “Note on the $\rho(1450)$ and the $\rho(1700)$ ” in the $\rho(1700)$ Particle Listings.

[r] See also the $\omega(1420)$ Particle Listings.

[s] See the “Note on $f_0(1710)$ ” in the $f_0(1710)$ Particle Listings in 2004 edition of *Review of Particle Physics*.

[t] See the note in the K^\pm Particle Listings.

[u] The definition of the slope parameter g of the $K \rightarrow 3\pi$ Dalitz plot is as follows (see also “Note on Dalitz Plot Parameters for $K \rightarrow 3\pi$ Decays” in the K^\pm Particle Listings):

$$|M|^2 = 1 + g(s_3 - s_0)/m_{\pi^+}^2 + \dots$$

[v] For more details and definitions of parameters see the Particle Listings.

[w] See the K^\pm Particle Listings for the energy limits used in this measurement.

[x] Most of this radiative mode, the low-momentum γ part, is also included in the parent mode listed without γ 's.

[y] Structure-dependent part.

[z] Direct-emission branching fraction.

[aa] Violates angular-momentum conservation.

[bb] Derived from measured values of ϕ_{+-} , ϕ_{00} , $|\eta|$, $|m_{K_L^0} - m_{K_S^0}|$, and $\tau_{K_S^0}$, as described in the introduction to “Tests of Conservation Laws.”

[cc] The CP -violation parameters are defined as follows (see also “Note on CP Violation in $K_S \rightarrow 3\pi$ ” and “Note on CP Violation in K_L^0 Decay” in the Particle Listings):

$$\eta_{+-} = |\eta_{+-}|e^{i\phi_{+-}} = \frac{A(K_L^0 \rightarrow \pi^+\pi^-)}{A(K_S^0 \rightarrow \pi^+\pi^-)} = \epsilon + \epsilon'$$

$$\eta_{00} = |\eta_{00}| e^{i\phi_{00}} = \frac{A(K_L^0 \rightarrow \pi^0 \pi^0)}{A(K_S^0 \rightarrow \pi^0 \pi^0)} = \epsilon - 2\epsilon'$$

$$\delta = \frac{\Gamma(K_L^0 \rightarrow \pi^- \ell^+ \nu) - \Gamma(K_L^0 \rightarrow \pi^+ \ell^- \nu)}{\Gamma(K_L^0 \rightarrow \pi^- \ell^+ \nu) + \Gamma(K_L^0 \rightarrow \pi^+ \ell^- \nu)},$$

$$\text{Im}(\eta_{+-0})^2 = \frac{\Gamma(K_S^0 \rightarrow \pi^+ \pi^- \pi^0)_{CP \text{ viol.}}}{\Gamma(K_L^0 \rightarrow \pi^+ \pi^- \pi^0)},$$

$$\text{Im}(\eta_{000})^2 = \frac{\Gamma(K_S^0 \rightarrow \pi^0 \pi^0 \pi^0)}{\Gamma(K_L^0 \rightarrow \pi^0 \pi^0 \pi^0)}.$$

where for the last two relations CPT is assumed valid, *i.e.*, $\text{Re}(\eta_{+-0}) \simeq 0$ and $\text{Re}(\eta_{000}) \simeq 0$.

- [*dd*] See the K_S^0 Particle Listings for the energy limits used in this measurement.
- [*ee*] The value is for the sum of the charge states or particle/antiparticle states indicated.
- [*ff*] $\text{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.
- [*gg*] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K_L^0 \rightarrow \pi^+ \pi^- \gamma$ (DE).
- [*hh*] See the K_L^0 Particle Listings for the energy limits used in this measurement.
- [*ij*] Allowed by higher-order electroweak interactions.
- [*jj*] Violates CP in leading order. Test of direct CP violation since the indirect CP -violating and CP -conserving contributions are expected to be suppressed.
- [*kk*] See the "Note on $f_0(1370)$ " in the $f_0(1370)$ Particle Listings and in the 1994 edition.
- [*ll*] See the note in the $L(1770)$ Particle Listings in Reviews of Modern Physics **56** S1 (1984), p. S200. See also the "Note on $K_2(1770)$ and the $K_2(1820)$ " in the $K_2(1770)$ Particle Listings.
- [*mm*] See the "Note on $K_2(1770)$ and the $K_2(1820)$ " in the $K_2(1770)$ Particle Listings.
- [*nn*] This result applies to $Z^0 \rightarrow c\bar{c}$ decays only. Here ℓ^+ is an average (not a sum) of e^+ and μ^+ decays.
- [*oo*] See the Particle Listings for the (complicated) definition of this quantity.
- [*pp*] The branching fraction for this mode may differ from the sum of the submodes that contribute to it, due to interference effects. See the relevant papers in the Particle Listings.
- [*qq*] These subfractions of the $K^- 2\pi^+$ mode are uncertain: see the Particle Listings.
- [*rr*] Submodes of the $D^+ \rightarrow K^- 2\pi^+ \pi^0$ and $K_S^0 2\pi^+ \pi^-$ modes were studied by ANJOS 92C and COFFMAN 92B, but with at most 142 events for the first mode and 229 for the second – not enough for precise results. With nothing new for 18 years, we refer to our 2008 edition, Physics Letters **B667** 1 (2008), for those results.
- [*ss*] The natural decay modes of the resonances are included.
- [*tt*] This is *not* a test for the $\Delta C=1$ weak neutral current, but leads to the $\pi^+ \ell^+ \ell^-$ final state.
- [*uu*] This mode is not a useful test for a $\Delta C=1$ weak neutral current because both quarks must change flavor in this decay.
- [*vv*] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.
- [*ww*] This value is obtained by subtracting the branching fractions for 2-, 4- and 6-prongs from unity.
- [*xx*] This is the sum of our $K^- 2\pi^+ \pi^-$, $K^- 2\pi^+ \pi^- \pi^0$, $K^0 2\pi^+ 2\pi^-$, $K^+ 2K^- \pi^+$, $2\pi^+ 2\pi^-$, $2\pi^+ 2\pi^- \pi^0$, $K^+ K^- \pi^+ \pi^-$, and $K^+ K^- \pi^+ \pi^- \pi^0$, branching fractions.
- [*yy*] This is the sum of our $K^- 3\pi^+ 2\pi^-$ and $3\pi^+ 3\pi^-$ branching fractions.
- [*zz*] The branching fractions for the $K^- e^+ \nu_e$, $K^*(892)^- e^+ \nu_e$, $\pi^- e^+ \nu_e$, and $\rho^- e^+ \nu_e$ modes add up to $6.19 \pm 0.17\%$.
- [*aaa*] This is a doubly Cabibbo-suppressed mode.
- [*bbb*] The two experiments measuring this fraction are in serious disagreement. See the Particle Listings.
- [*ccc*] Submodes of the $D^0 \rightarrow K_S^0 \pi^+ \pi^- \pi^0$ mode with a K^* and/or ρ were studied by COFFMAN 92B, but with only 140 events. With nothing new for 18 years, we refer to our 2008 edition, Physics Letters **B667** 1 (2008), for those results.
- [*ddd*] This branching fraction includes all the decay modes of the resonance in the final state.
- [*eee*] The experiments on the division of this charge mode amongst its submodes disagree, and the submode branching fractions here add up to considerably more than the charged-mode fraction.
- [*fff*] However, these upper limits are in serious disagreement with values obtained in another experiment.
- [*ggg*] This limit is for either D^0 or \bar{D}^0 to $p e^-$.
- [*hhh*] This limit is for either D^0 or \bar{D}^0 to $\bar{p} e^+$.
- [*iii*] This is the purely e^+ semileptonic branching fraction: the e^+ fraction from τ^+ decays has been subtracted off. The sum of our (non- τ) e^+ exclusive fractions — an $e^+ \nu_e$ with an η , η' , ϕ , K^0 , K^* , or $f_0(980)$ — is $7.0 \pm 0.4\%$.
- [*jjj*] This fraction includes η from η' decays.
- [*kkk*] Two times (to include μ decays) the $\eta' e^+ \nu_e$ branching fraction, plus the $\eta' \pi^+$, $\eta' \rho^+$, and $\eta' K^+$ fractions, is $(18.6 \pm 2.3)\%$, which considerably exceeds the inclusive η' fraction of $(11.7 \pm 1.8)\%$. Our best guess is that the $\eta' \rho^+$ fraction, $(12.5 \pm 2.2)\%$, is too large.
- [*lll*] This branching fraction includes all the decay modes of the final-state resonance.
- [*mmm*] A test for $u\bar{u}$ or $d\bar{d}$ content in the D_s^+ . Neither Cabibbo-favored nor Cabibbo-suppressed decays can contribute, and $\omega - \phi$ mixing is an unlikely explanation for any fraction above about 2×10^{-4} .
- [*nnn*] We decouple the $D_s^+ \rightarrow \phi \pi^+$ branching fraction obtained from mass projections (and used to get some of the other branching fractions) from the $D_s^+ \rightarrow \phi \pi^+$, $\phi \rightarrow K^+ K^-$ branching fraction obtained from the Dalitz-plot analysis of $D_s^+ \rightarrow K^+ K^- \pi^+$. That is, the ratio of these two branching fractions is not exactly the $\phi \rightarrow K^+ K^-$ branching fraction 0.491.
- [*ooo*] This is the average of a model-independent and a K -matrix parametrization of the $\pi^+ \pi^-$ S -wave and is a sum over several f_0 mesons.
- [*ppp*] An ℓ indicates an e or a μ mode, not a sum over these modes.
- [*qqq*] An $CP(\pm 1)$ indicates the $CP=+1$ and $CP=-1$ eigenstates of the D^0 - \bar{D}^0 system.
- [*rrr*] D denotes D^0 or \bar{D}^0 .
- [*sss*] $D_{CP\pm}^0$ decays into $D^0 \pi^0$ with the D^0 reconstructed in CP -even eigenstates $K^+ K^-$ and $\pi^+ \pi^-$.
- [*ttt*] \bar{D}^{*} represents an excited state with mass $2.2 < M < 2.8$ GeV/ c^2 .
- [*uuu*] $X(3872)^+$ is a hypothetical charged partner of the $X(3872)$.
- [*vvv*] $\Theta(1710)^{++}$ is a possible narrow pentaquark state and $G(2220)$ is a possible glueball resonance.
- [*www*] $(\bar{A}_c^- \rho)_s$ denotes a low-mass enhancement near 3.35 GeV/ c^2 .
- [*xxx*] Stands for the possible candidates of $K^*(1410)$, $K_0^*(1430)$ and $K_2^*(1430)$.
- [*yyy*] B^0 and B_s^0 contributions not separated. Limit is on weighted average of the two decay rates.
- [*zzz*] This decay refers to the coherent sum of resonant and nonresonant $J^P = 0^+ K \pi$ components with $1.60 < m_{K\pi} < 2.15$ GeV/ c^2 .
- [*aaaa*] $X(214)$ is a hypothetical particle of mass 214 MeV/ c^2 reported by the HyperCP experiment, Physical Review Letters **94** 021801 (2005)
- [*bbbb*] $\Theta(1540)^+$ denotes a possible narrow pentaquark state.
- [*cccc*] These values are model dependent.
- [*dddd*] Here "anything" means at least one particle observed.
- [*eeee*] D^{**} stands for the sum of the $D(1^1 P_1)$, $D(1^3 P_0)$, $D(1^3 P_1)$, $D(1^3 P_2)$, $D(2^1 S_0)$, and $D(2^1 S_1)$ resonances.
- [*ffff*] $D^{(*)} \bar{D}^{(*)}$ stands for the sum of $D^* \bar{D}^*$, $D^* \bar{D}$, $D \bar{D}^*$, and $D \bar{D}$.
- [*gggg*] $X(3915)$ denotes a near-threshold enhancement in the $\omega J/\psi$ mass spectrum.
- [*hhhh*] Inclusive branching fractions have a multiplicity definition and can be greater than 100%.
- [*iii*] D_j represents an unresolved mixture of pseudoscalar and tensor D^{**} (P -wave) states.
- [*jjjj*] Not a pure measurement. See note at head of B_S^0 Decay Modes.
- [*kkkk*] For $E_\gamma > 100$ MeV.
- [*llll*] Includes $p\bar{p} \pi^+ \pi^- \gamma$ and excludes $p\bar{p} \eta$, $p\bar{p} \omega$, $p\bar{p} \eta'$.
- [*mmmm*] For a narrow state A with mass less than 960 MeV.
- [*nnnn*] For a narrow resonance in the range $2.2 < M(X) < 2.8$ GeV.

Meson Summary Table

[oooo] BHARDWAJ 11 does not observe this decay and presents a stronger 90% CL limit than this value. See measurements listings for details.

[pppp] J^{PC} known by production in e^+e^- via single photon annihilation. I^G is not known; interpretation of this state as a single resonance is unclear because of the expectation of substantial threshold effects in this energy region.

[qqqq] $2m_\tau < M(\tau^+\tau^-) < 7500$ MeV

[rrrr] $2 < m_{K^+K^-} < 3$ GeV

[ssss] $X = \text{scalar with } m < 8.0$ GeV

[tttt] $X\bar{X} = \text{vectors with } m < 3.1$ GeV

[uuuu] X and $\bar{X} = \text{zero spin with } m < 4.5$ GeV

[vvvv] $1.5 \text{ GeV} < m_X < 5.0$ GeV

[wwww] $201 < M(\mu^+\mu^-) < 3565$ MeV

[xxxx] Spectroscopic labeling for these states is theoretical, pending experimental information.

[yyyy] $1.5 \text{ GeV} < m_X < 5.0$ GeV

[zzzz] $1.5 \text{ GeV} < m_X < 5.0$ GeV

[aaaa] For $m_{\tau^+\tau^-}$ in the ranges 4.03–9.52 and 9.61–10.10 GeV.

Meson Summary Table

See also the table of suggested $q\bar{q}$ quark-model assignments in the Quark Model section.

• Indicates particles that appear in the preceding Meson Summary Table. We do not regard the other entries as being established.

Baryon Summary Table

This short table gives the name, the quantum numbers (where known), and the status of baryons in the Review. Only the baryons with 3- or 4-star status are included in the Baryon Summary Table. Due to insufficient data or uncertain interpretation, the other entries in the table are not established baryons. The names with masses are of baryons that decay strongly. The spin-parity J^P (when known) is given with each particle. For the strongly decaying particles, the J^P values are considered to be part of the names.

 Mean life $\tau > 2.1 \times 10^{29}$ years, CL = 90% [d] ($p \rightarrow$ invisible mode)
 Mean life $\tau > 10^{31}$ to 10^{33} years [d] (mode dependent)

See the "Note on Nucleon Decay" in our 1994 edition (Phys. Rev. **D50**, 1173) for a short review.

The "partial mean life" limits tabulated here are the limits on τ/B_j , where τ is the total mean life and B_j is the branching fraction for the mode in question. For N decays, p and n indicate proton and neutron partial lifetimes.

p DECAY MODES	Partial mean life (10^{30} years)	Confidence level	p (MeV/c)
Antilepton + meson			
$N \rightarrow e^+ \pi$	> 158 (n), > 8200 (p)	90%	459
$N \rightarrow \mu^+ \pi$	> 100 (n), > 6600 (p)	90%	453
$N \rightarrow \nu \pi$	> 112 (n), > 25 (p)	90%	459
$p \rightarrow e^+ \eta$	> 313	90%	309
$p \rightarrow \mu^+ \eta$	> 126	90%	297
$n \rightarrow \nu \eta$	> 158	90%	310
$N \rightarrow e^+ \rho$	> 217 (n), > 75 (p)	90%	149
$N \rightarrow \mu^+ \rho$	> 228 (n), > 110 (p)	90%	113
$N \rightarrow \nu \rho$	> 19 (n), > 162 (p)	90%	149
$p \rightarrow e^+ \omega$	> 107	90%	143
$p \rightarrow \mu^+ \omega$	> 117	90%	105

$p \rightarrow \mu^+ K_L^0$	> 83	90%	326
$N \rightarrow \nu K$	> 86 (n), > 670 (p)	90%	339
$n \rightarrow \nu K_S^0$	> 51	90%	338
$p \rightarrow e^+ K^*(892)^0$	> 84	90%	45
$N \rightarrow \nu K^*(892)$	> 78 (n), > 51 (p)	90%	45
Antilepton + mesons			
$p \rightarrow e^+ \pi^+ \pi^-$	> 82	90%	448
$p \rightarrow e^+ \pi^0 \pi^0$	> 147	90%	449
$n \rightarrow e^+ \pi^- \pi^0$	> 52	90%	449
$p \rightarrow \mu^+ \pi^+ \pi^-$	> 133	90%	425
$p \rightarrow \mu^+ \pi^0 \pi^0$	> 101	90%	427
$n \rightarrow \mu^+ \pi^- \pi^0$	> 74	90%	427
$n \rightarrow e^+ K^0 \pi^-$	> 18	90%	319
Lepton + meson			
$n \rightarrow e^- \pi^+$	> 65	90%	459
$n \rightarrow \mu^- \pi^+$	> 49	90%	453
$n \rightarrow e^- \rho^+$	> 62	90%	150
$n \rightarrow \mu^- \rho^+$	> 7	90%	114
$n \rightarrow e^- K^+$	> 32	90%	340
$n \rightarrow \mu^- K^+$	> 57	90%	330

Lepton + mesons

$p \rightarrow e^- \pi^+ \pi^+$	> 30	90%	448
$n \rightarrow e^- \pi^+ \pi^0$	> 29	90%	449
$p \rightarrow \mu^- \pi^+ \pi^+$	> 17	90%	425
$n \rightarrow \mu^- \pi^+ \pi^0$	> 34	90%	427
$p \rightarrow e^- \pi^+ K^+$	> 75	90%	320
$p \rightarrow \mu^- \pi^+ K^+$	> 245	90%	279

Antilepton + photon(s)

$p \rightarrow e^+ \gamma$	> 670	90%	469
$p \rightarrow \mu^+ \gamma$	> 478	90%	463
$n \rightarrow \nu \gamma$	> 28	90%	470
$p \rightarrow e^+ \gamma \gamma$	> 100	90%	469
$n \rightarrow \nu \gamma \gamma$	> 219	90%	470

Three (or more) leptons

$p \rightarrow e^+ e^+ e^-$	> 793	90%	469
$p \rightarrow e^+ \mu^+ \mu^-$	> 359	90%	457
$p \rightarrow e^+ \nu \nu$	> 17	90%	469
$n \rightarrow e^+ e^- \nu$	> 257	90%	470
$n \rightarrow \mu^+ e^- \nu$	> 83	90%	464
$n \rightarrow \mu^+ \mu^- \nu$	> 79	90%	458
$p \rightarrow \mu^+ e^+ e^-$	> 529	90%	463
$p \rightarrow \mu^+ \mu^+ \mu^-$	> 675	90%	439
$p \rightarrow \mu^+ \nu \nu$	> 21	90%	463
$p \rightarrow e^- \mu^+ \mu^+$	> 6	90%	457
$n \rightarrow 3\nu$	> 0.0005	90%	470

Inclusive modes

$N \rightarrow e^+$ anything	> 0.6 (n, p)	90%	—
$N \rightarrow \mu^+$ anything	> 12 (n, p)	90%	—
$N \rightarrow e^+ \pi^0$ anything	> 0.6 (n, p)	90%	—

 $\Delta B = 2$ dinucleon modes

The following are lifetime limits per iron nucleus.

$pp \rightarrow \pi^+ \pi^+$	> 0.7	90%	—
$pn \rightarrow \pi^+ \pi^0$	> 2	90%	—
$nn \rightarrow \pi^+ \pi^-$	> 0.7	90%	—
$nn \rightarrow \pi^0 \pi^0$	> 3.4	90%	—
$pp \rightarrow e^+ e^+$	> 5.8	90%	—
$pp \rightarrow e^+ \mu^+$	> 3.6	90%	—
$pp \rightarrow \mu^+ \mu^+$	> 1.7	90%	—
$pn \rightarrow e^+ \bar{\nu}$	> 2.8	90%	—
$pn \rightarrow \mu^+ \bar{\nu}$	> 1.6	90%	—
$nn \rightarrow \nu_e \bar{\nu}_e$	> 0.000049	90%	—
$pn \rightarrow$ invisible	> 2.10×10^{25}	90%	—
$pp \rightarrow$ invisible	> 0.00005	90%	—

 Ω BARYONS
($S = -3, I = 0$)

$$\Omega^- = sss$$

 Ω^-

$$I(J^P) = 0(\frac{3}{2}^+)$$

$J^P = \frac{3}{2}^+$ is the quark-model prediction; and $J = 3/2$ is fairly well established.

Mass $m = 1672.45 \pm 0.29$ MeV
 $(m_{\Omega^-} - m_{\bar{\Omega}^+}) / m_{\Omega^-} = (-1 \pm 8) \times 10^{-5}$
 Mean life $\tau = (0.821 \pm 0.011) \times 10^{-10}$ s
 $c\tau = 2.461$ cm
 $(\tau_{\Omega^-} - \tau_{\bar{\Omega}^+}) / \tau_{\Omega^-} = 0.00 \pm 0.05$
 Magnetic moment $\mu = -2.02 \pm 0.05 \mu_N$

Decay parameters

ΛK^- $\alpha = 0.0180 \pm 0.0024$
 $\Lambda K^-, \bar{\Lambda} K^+$ $(\alpha + \bar{\alpha}) / (\alpha - \bar{\alpha}) = -0.02 \pm 0.13$
 $\Xi^0 \pi^-$ $\alpha = 0.09 \pm 0.14$
 $\Xi^- \pi^0$ $\alpha = 0.05 \pm 0.21$

$$\Xi_c^+ = usc, \quad \Xi_c^0 = dsc, \quad \Omega_c^0 = ssc$$

 Λ_c^+

$$I(J^P) = 0(\frac{1}{2}^+)$$

J is not well measured; $\frac{1}{2}$ is the quark-model prediction.

Mass $m = 2286.46 \pm 0.14$ MeV
 Mean life $\tau = (200 \pm 6) \times 10^{-15}$ s ($S = 1.6$)
 $c\tau = 59.9 \mu\text{m}$

Baryon Summary Table

Decay asymmetry parameters

$$\begin{aligned} \Lambda\pi^+ & \alpha = -0.91 \pm 0.15 \\ \Sigma^+\pi^0 & \alpha = -0.45 \pm 0.32 \\ \Lambda\ell^+\nu_\ell & \alpha = -0.86 \pm 0.04 \\ (\alpha + \bar{\alpha})/(\alpha - \bar{\alpha}) \text{ in } \Lambda_C^+ \rightarrow \Lambda\pi^+, \bar{\Lambda}_C^- \rightarrow \bar{\Lambda}\pi^- & = -0.07 \pm 0.31 \\ (\alpha + \bar{\alpha})/(\alpha - \bar{\alpha}) \text{ in } \Lambda_C^+ \rightarrow \Lambda e^+\nu_e, \bar{\Lambda}_C^- \rightarrow \bar{\Lambda}e^-\bar{\nu}_e & = 0.00 \pm 0.04 \end{aligned}$$

Nearly all branching fractions of the Λ_C^+ are measured relative to the $pK^-\pi^+$ mode, but there are no model-independent measurements of this branching fraction. We explain how we arrive at our value of $B(\Lambda_C^+ \rightarrow pK^-\pi^+)$ in a Note at the beginning of the branching-ratio measurements in the Listings. When this branching fraction is eventually well determined, all the other branching fractions will slide up or down proportionally as the true value differs from the value we use here.

 $\Lambda_C(2595)^+$

$$J^P = 0(\frac{1}{2}^-)$$

The spin-parity follows from the fact that $\Sigma_C(2455)\pi$ decays, with little available phase space, are dominant. This assumes that $J^P = 1/2^+$ for the $\Sigma_C(2455)$.

$$\text{Mass } m = 2592.25 \pm 0.28 \text{ MeV}$$

$$m - m_{\Lambda_C^+} = 305.79 \pm 0.24 \text{ MeV}$$

$$\text{Full width } \Gamma = 2.6 \pm 0.6 \text{ MeV}$$

$\Lambda_C^+\pi\pi$ and its submode $\Sigma_C(2455)\pi$ — the latter just barely — are the only strong decays allowed to an excited Λ_C^+ having this mass; and the submode seems to dominate.

 $\Lambda_C(2595)^+$ DECAY MODES

NOTES

This Summary Table only includes established baryons. The Particle Listings include evidence for other baryons. The masses, widths, and branching fractions for the resonances in this Table are Breit-Wigner parameters, but pole positions are also given for most of the N and Δ resonances.

For most of the resonances, the parameters come from various partial-wave analyses of more or less the same sets of data, and it is not appropriate to treat the results of the analyses as independent or to average them together. Furthermore, the systematic errors on the results are not well understood. Thus, we usually only give ranges for the parameters. We then also give a best guess for the mass (as part of the name of the resonance) and for the width. The *Note on N and Δ Resonances* and the *Note on Λ and Σ Resonances* in the Particle Listings review the partial-wave analyses.

When a quantity has “(S = ...)” to its right, the error on the quantity has been enlarged by the “scale factor” S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame. For any resonance, the *nominal* mass is used in calculating p . A dagger (“†”) in this column indicates that the mode is forbidden when the nominal masses of resonances are used, but is in fact allowed due to the nonzero widths of the resonances.

- [a] The masses of the p and n are most precisely known in u (unified atomic mass units). The conversion factor to MeV, $1 u = 931.494028(23)$ MeV, is less well known than are the masses in u .
- [b] The $|m_p - m_{\bar{p}}|/m_p$ and $|q_p + q_{\bar{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\bar{p}}/m_{\bar{p}}|/(q_p/m_p)$.
- [c] The limit is from neutrality-of-matter experiments; it assumes $q_n = q_p + q_e$. See also the charge of the neutron.

[d] The first limit is for $p \rightarrow$ anything or “disappearance” modes of a bound proton. The second entry, a rough range of limits, assumes the dominant decay modes are among those investigated. For antiprotons the best limit, inferred from the observation of cosmic ray \bar{p} 's is $\tau_{\bar{p}} > 10^7$ yr, the cosmic-ray storage time, but this limit depends on a number of assumptions. The best direct observation of stored antiprotons gives $\tau_{\bar{p}}/B(\bar{p} \rightarrow e^- \gamma) > 7 \times 10^9$ yr.

[e] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the best limit comes). The first limit here is from reactor experiments with free neutrons.

[f] Lee and Yang in 1956 proposed the existence of a mirror world in an attempt to restore global parity symmetry—thus a search for oscillations between the two worlds. Oscillations between the worlds would be maximal when the magnetic fields B and B' were equal. The limit for any B' in the range 0 to $12.5 \mu\text{T}$ is > 12 s (95% CL).

[g] The parameters g_A , g_V , and g_{WM} for semileptonic modes are defined by $\bar{B}_f[\gamma_\lambda(g_V + g_A\gamma_5) + i(g_{WM}/m_{B_i})\sigma_{\lambda\nu}q^\nu]B_i$, and ϕ_{AV} is defined by $g_A/g_V = |g_A/g_V|e^{i\phi_{AV}}$. See the “Note on Baryon Decay Parameters” in the neutron Particle Listings.

[h] Time-reversal invariance requires this to be 0° or 180° .

[i] This coefficient is zero if time invariance is not violated.

[j] This limit is for γ energies between 15 and 340 keV.

[k] The decay parameters γ and Δ are calculated from α and ϕ using

$$\gamma = \sqrt{1-\alpha^2} \cos\phi, \quad \tan\Delta = -\frac{1}{\alpha} \sqrt{1-\alpha^2} \sin\phi.$$

See the “Note on Baryon Decay Parameters” in the neutron Particle Listings.

[l] See the Listings for the pion momentum range used in this measurement.

[m] The error given here is only an educated guess. It is larger than the error on the weighted average of the published values.

[n] A theoretical value using QED.

[o] See the note on “ Λ_c^+ Branching Fractions” in the Λ_c^+ Particle Listings.

[p] This branching fraction includes all the decay modes of the final-state resonance.

[q] An ℓ indicates an e or a μ mode, not a sum over these modes.

[r] The value is for the sum of the charge states or particle/antiparticle states indicated.

[s] Assuming isospin conservation, so that the other third is $\Lambda_c^+ \pi^0 \pi^0$.

[t] A test that the isospin is indeed 0, so that the particle is indeed a Λ_c^+ .

[u] No absolute branching fractions have been measured. The value here is the branching *ratio* relative to $\Xi^- 2\pi^+$.

[v] Not a pure measurement. See note at head of Λ_b^0 Decay Modes.

[w] Here h^- means π^- or K^- .

SEARCHES FOR MONOPOLES, SUPERSYMMETRY, TECHNICOLOR, COMPOSITENESS, EXTRA DIMENSIONS, etc.

Magnetic Monopole Searches

Isolated supermassive monopole candidate events have not been confirmed. The most sensitive experiments obtain negative results.

Best cosmic-ray supermassive monopole flux limit:

$$< 1.0 \times 10^{-15} \text{ cm}^{-2}\text{sr}^{-1}\text{s}^{-1} \quad \text{for } 1.1 \times 10^{-4} < \beta < 0.1$$

Supersymmetric Particle Searches

Limits are based on the Minimal Supersymmetric Standard Model. Assumptions include: 1) $\tilde{\chi}_1^0$ (or $\tilde{\gamma}$) is lightest supersymmetric particle; 2) R -parity is conserved; 3) With the exception of \tilde{t} and \tilde{b} , all scalar quarks are assumed to be degenerate in mass and $m_{\tilde{q}_R} = m_{\tilde{q}_L}$. 4) Limits for sleptons refer to the $\tilde{\ell}_R$ states. 5) Gaugino mass unification at the GUT scale.

See the Particle Listings for a Note giving details of supersymmetry.

$\tilde{\chi}_i^0$ — neutralinos (mixtures of $\tilde{\gamma}$, \tilde{Z}^0 , and \tilde{H}_i^0)

[all $\tan\beta$, all m_0 , all $m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^0}$]

Mass $m_{\tilde{\chi}_2^0} > 62.4 \text{ GeV}$, CL = 95%

[$1 < \tan\beta < 40$, all m_0 , all $m_{\tilde{\chi}_3^0} - m_{\tilde{\chi}_1^0}$]

Mass $m_{\tilde{\chi}_3^0} > 99.9 \text{ GeV}$, CL = 95%

[$1 < \tan\beta < 40$, all m_0 , all $m_{\tilde{\chi}_4^0} - m_{\tilde{\chi}_1^0}$]

Mass $m_{\tilde{\chi}_4^0} > 116 \text{ GeV}$, CL = 95%

[$1 < \tan\beta < 40$, all m_0 , all $m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^0}$]

$\tilde{\chi}_i^\pm$ — charginos (mixtures of \tilde{W}^\pm and \tilde{H}_i^\pm)

Mass $m_{\tilde{\chi}_1^\pm} > 94 \text{ GeV}$, CL = 95%

[$\tan\beta < 40$, $m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_1^0} > 3 \text{ GeV}$, all m_0]

\tilde{e} — scalar electron (selectron)

Mass $m > 107 \text{ GeV}$, CL = 95% [all $m_{\tilde{e}_R} - m_{\tilde{\chi}_1^0}$]

$\tilde{\mu}$ — scalar muon (smuon)

Mass $m > 94 \text{ GeV}$, CL = 95%

[$1 \leq \tan\beta \leq 40$, $m_{\tilde{\mu}_R} - m_{\tilde{\chi}_1^0} > 10 \text{ GeV}$]

$\tilde{\tau}$ — scalar tau (stau)

Mass $m > 81.9 \text{ GeV}$, CL = 95%

[$m_{\tilde{\tau}_R} - m_{\tilde{\chi}_1^0} > 15 \text{ GeV}$, all θ_τ]

\tilde{q} — scalar quark (squark)

These limits include the effects of cascade decays, evaluated assuming a fixed value of the parameters μ and $\tan\beta$. The limits are weakly sensitive to these parameters over much of parameter space. Limits assume GUT relations between gaugino masses and the gauge coupling.

Mass $m > 1.100 \times 10^3 \text{ GeV}$, CL = 95% [$\tan\beta=10$, $\mu > 0$, $A_0=0$]

\tilde{b} — scalar bottom (sbottom)

Mass $m > 89 \text{ GeV}$, CL = 95% [$m_{\tilde{b}_1} - m_{\tilde{\chi}_1^0} > 8 \text{ GeV}$, all θ_b]

\tilde{t} — scalar top (stop)

Mass $m > 95.7 \text{ GeV}$, CL = 95%

[$\tilde{t} \rightarrow c\tilde{\chi}_1^0$, all θ_t , $m_{\tilde{t}} - m_{\tilde{\chi}_1^0} > 10 \text{ GeV}$]

\tilde{g} — gluino

The limits summarised here refer to the high-mass region ($m_{\tilde{g}} \gtrsim 5 \text{ GeV}$), and include the effects of cascade decays, evaluated assuming a fixed value of the parameters μ and $\tan\beta$.

The limits are weakly sensitive to these parameters over much of parameter space. Limits assume GUT relations between gaugino masses and the gauge coupling,

Mass $m > 500 \text{ GeV}$, CL = 95% [any $m_{\tilde{q}}$]

Technicolor

Searches for a color-octet techni- ρ constrain its mass to be greater than 260 to 480 GeV, depending on allowed decay channels. Similar bounds exist on the color-octet techni- ω .

Quark and Lepton Compositeness, Searches for

Scale Limits Λ for Contact Interactions (the lowest dimensional interactions with four fermions)

If the Lagrangian has the form

$$\pm \frac{g^2}{2\Lambda^2} \bar{\psi}_L \gamma_\mu \psi_L \bar{\psi}_L \gamma^\mu \psi_L$$

(with $g^2/4\pi$ set equal to 1), then we define $\Lambda \equiv \Lambda_{LL}^\pm$. For the full definitions and for other forms, see the Note in the Listings on Searches for Quark and Lepton Compositeness in the full Review and the original literature.

Mass $m > 86$ GeV, CL = 95% (Stable ℓ_8)

Color Octet Neutrinos (ν_8)

Mass $m > 110$ GeV, CL = 90% ($\nu_8 \rightarrow \nu g$)

Extra Dimensions

Please refer to the Extra Dimensions section of the full *Review* for a discussion of the model-dependence of these bounds, and further constraints.

Constraints on the fundamental gravity scale

$M_{TT} > 1.74$ TeV, CL = 95% (dim-8 ops; $\Lambda = +1$; $pp \rightarrow \gamma\gamma$)

$M_C > 1.59$ TeV, CL = 95% (compactification scale with TeV extra dimensions; $p\bar{p} \rightarrow$ dijet, angular distrib.)

$M_D > 1.63$ TeV, CL = 95% ($pp \rightarrow G \rightarrow \ell\bar{\ell}$)

Constraints on the radius of the extra dimensions, for the case of two-flat dimensions of equal radii

$R < 30 \mu\text{m}$, CL = 95% (direct tests of Newton's law)

$R < 72 \mu\text{m}$, CL = 95% ($pp \rightarrow jG$)

$R < 0.16\text{--}916$ nm (astrophysics; limits depend on technique and assumptions)

TESTS OF CONSERVATION LAWS

Updated May 2012 by L. Wolfenstein (Carnegie-Mellon University) and C.-J. Lin (LBNL) .

In keeping with the current interest in tests of conservation laws, we collect together a Table of experimental limits on all weak and electromagnetic decays, mass differences, and moments, and on a few reactions, whose observation would violate conservation laws. The Table is given only in the full *Review of Particle Physics*, not in the Particle Physics Booklet. For the benefit of Booklet readers, we include the best limits from the Table in the following text. Limits in this text are for CL=90% unless otherwise specified. The Table is in two parts: “Discrete Space-Time Symmetries,” *i.e.*, C , P , T , CP , and CPT ; and “Number Conservation Laws,” *i.e.*, lepton, baryon, hadronic flavor, and charge conservation. The references for these data can be found in the the Particle Listings in the *Review*. A discussion of these tests follows.

CPT INVARIANCE

General principles of relativistic field theory require invariance under the combined transformation CPT . The simplest tests of CPT invariance are the equality of the masses and lifetimes of a particle and its antiparticle. The best test comes from the limit on the mass difference between K^0 and \bar{K}^0 . Any such difference contributes to the CP -violating parameter ϵ . Assuming CPT invariance, ϕ_ϵ , the phase of ϵ should be very close to 44° . (See the review “ CP Violation in K_L decay” in this edition.) In contrast, if the entire source of CP violation in K^0 decays were a $K^0 - \bar{K}^0$ mass difference, ϕ_ϵ would be $44^\circ + 90^\circ$.

Assuming that there is no other source of CPT violation than this mass difference, it is possible to deduce that[1]

$$m_{\bar{K}^0} - m_{K^0} \approx \frac{2(m_{K_L^0} - m_{K_S^0}) |\eta| (\frac{2}{3}\phi_{+-} + \frac{1}{3}\phi_{00} - \phi_{SW})}{\sin \phi_{SW}},$$

where $\phi_{SW} = (43.51 \pm 0.05)^\circ$, the superweak angle. Using our best values of the CP -violation parameters, we get $|(m_{\bar{K}^0} - m_{K^0})/m_{K^0}| \leq 0.6 \times 10^{-18}$ at CL=90%. Limits can also be placed on specific CPT -violating decay amplitudes. Given the small value of $(1 - |\eta_{00}/\eta_{+-}|)$, the value of $\phi_{00} - \phi_{+-}$ provides a measure of CPT violation in $K_L^0 \rightarrow 2\pi$ decay. Results from CERN [1] and Fermilab [2] indicate no CPT -violating effect.

CP AND T INVARIANCE

Given CPT invariance, CP violation and T violation are equivalent. The original evidence for CP violation came from the measurement of $|\eta_{+-}| = |A(K_L^0 \rightarrow \pi^+\pi^-)/A(K_S^0 \rightarrow \pi^+\pi^-)| = (2.232 \pm 0.011) \times 10^{-3}$. This could be explained in terms of $K^0 - \bar{K}^0$ mixing, which also leads to the asymmetry $[\Gamma(K_L^0 \rightarrow \pi^- e^+ \nu) - \Gamma(K_L^0 \rightarrow \pi^+ e^- \bar{\nu})]/[\text{sum}] = (0.334 \pm 0.007)\%$. Evidence for CP violation in the kaon decay amplitude comes from the measurement of $(1 - |\eta_{00}/\eta_{+-}|)/3 = \text{Re}(\epsilon'/\epsilon) = (1.66 \pm 0.23) \times 10^{-3}$. In the Standard Model much larger CP -violating effects are expected. The first of these, which is associated with $B - \bar{B}$ mixing, is the parameter $\sin(2\beta)$ now measured

quite accurately to be 0.679 ± 0.020 . A number of other CP -violating observables are being measured in B decays; direct evidence for CP violation in the B decay amplitude comes from the asymmetry $[\Gamma(\bar{B}^0 \rightarrow K^- \pi^+) - \Gamma(B^0 \rightarrow K^+ \pi^-)]/[\text{sum}] = -0.097 \pm 0.012$. Direct tests of T violation are much more difficult; a measurement by CPLEAR of the difference between the oscillation probabilities of K^0 to \bar{K}^0 and \bar{K}^0 to K^0 is related to T violation [3]. Other searches for CP or T violation involve effects that are expected to be unobservable in the Standard Model. The most sensitive are probably the searches for an electric dipole moment of the neutron, measured to be $< 2.9 \times 10^{-26}$ e cm, and the electron $(10.5 \pm 0.07) \times 10^{-28}$ e cm. A nonzero value requires both P and T violation.

CONSERVATION OF LEPTON NUMBERS

Present experimental evidence and the standard electroweak theory are consistent with the absolute conservation of three separate lepton numbers: electron number L_e , muon number L_μ , and tau number L_τ , except for the effect of neutrino mixing associated with neutrino masses. Searches for violations are of the following types:

a) $\Delta L = 2$ for one type of charged lepton. The best limit comes from the search for neutrinoless double beta decay $(Z, A) \rightarrow (Z + 2, A) + e^- + e^-$. The best laboratory limit is $t_{1/2} > 1.9 \times 10^{25}$ yr (CL=90%) for ^{76}Ge .

b) Conversion of one charged-lepton type to another. For purely leptonic processes, the best limits are on $\mu \rightarrow e\gamma$ and $\mu \rightarrow 3e$, measured as $\Gamma(\mu \rightarrow e\gamma)/\Gamma(\mu \rightarrow \text{all}) < 2.4 \times 10^{-12}$ and $\Gamma(\mu \rightarrow 3e)/\Gamma(\mu \rightarrow \text{all}) < 1.0 \times 10^{-12}$. For semileptonic processes, the best limit comes from the coherent conversion process in a muonic atom, $\mu^- + (Z, A) \rightarrow e^- + (Z, A)$, measured as $\Gamma(\mu^- \text{Ti} \rightarrow e^- \text{Ti})/\Gamma(\mu^- \text{Ti} \rightarrow \text{all}) < 4.3 \times 10^{-12}$. Of special interest is the case in which the hadronic flavor also changes, as in $K_L \rightarrow e\mu$ and $K^+ \rightarrow \pi^+ e^- \mu^+$, measured as $\Gamma(K_L \rightarrow e\mu)/\Gamma(K_L \rightarrow \text{all}) < 4.7 \times 10^{-12}$ and $\Gamma(K^+ \rightarrow \pi^+ e^- \mu^+)/\Gamma(K^+ \rightarrow \text{all}) < 1.3 \times 10^{-11}$. Limits on the conversion of τ into e or μ are found in τ decay and are much less stringent than those for $\mu \rightarrow e$ conversion, *e.g.*, $\Gamma(\tau \rightarrow \mu\gamma)/\Gamma(\tau \rightarrow \text{all}) < 4.4 \times 10^{-8}$ and $\Gamma(\tau \rightarrow e\gamma)/\Gamma(\tau \rightarrow \text{all}) < 3.3 \times 10^{-8}$.

c) Conversion of one type of charged lepton into another type of charged antilepton. The case most studied is $\mu^- + (Z, A) \rightarrow e^+ + (Z - 2, A)$, the strongest limit being $\Gamma(\mu^- \text{Ti} \rightarrow e^+ \text{Ca})/\Gamma(\mu^- \text{Ti} \rightarrow \text{all}) < 3.6 \times 10^{-11}$.

d) Neutrino oscillations. It is expected even in the standard electroweak theory that the lepton numbers are not separately conserved, as a consequence of lepton mixing analogous to Cabibbo-Kobayashi-Maskawa quark mixing. However, if the only source of lepton-number violation is the mixing of low-mass neutrinos then processes such as $\mu \rightarrow e\gamma$ are expected to have extremely small unobservable probabilities. For small neutrino masses, the lepton-number violation would be observed first in neutrino oscillations, which have been the subject of extensive experimental studies. Compelling evidence for neutrino mixing has come from atmospheric, solar, accelerator, and

Tests of Conservation Laws

reactor neutrinos. Recently, the reactor neutrino experiments have measured the last neutrino mixing angle θ_{13} and found it to be relatively large. For a comprehensive review on neutrino mixing, including the latest results on θ_{13} , see the review “*Neutrino Mass, Mixing, and Oscillations*” by K. Nakamura and S.T. Petcov in this edition of RPP.

CONSERVATION OF HADRONIC FLAVORS

In strong and electromagnetic interactions, hadronic flavor is conserved, *i.e.* the conversion of a quark of one flavor (d, u, s, c, b, t) into a quark of another flavor is forbidden. In the Standard Model, the weak interactions violate these conservation laws in a manner described by the Cabibbo-Kobayashi-Maskawa mixing (see the section “Cabibbo-Kobayashi-Maskawa Mixing Matrix”). The way in which these conservation laws are violated is tested as follows:

(a) $\Delta S = \Delta Q$ rule. In the strangeness-changing semileptonic decay of strange particles, the strangeness change equals the change in charge of the hadrons. Tests come from limits on decay rates such as $\Gamma(\Sigma^+ \rightarrow ne^+\nu)/\Gamma(\Sigma^+ \rightarrow \text{all}) < 5 \times 10^{-6}$, and from a detailed analysis of $K_L \rightarrow \pi e \nu$, which yields the parameter x , measured to be $(\text{Re } x, \text{Im } x) = (-0.002 \pm 0.006, 0.0012 \pm 0.0021)$. Corresponding rules are $\Delta C = \Delta Q$ and $\Delta B = \Delta Q$.

(b) **Change of flavor by two units.** In the Standard Model this occurs only in second-order weak interactions. The classic example is $\Delta S = 2$ via $K^0 - \bar{K}^0$ mixing, which is directly measured by $m(K_L) - m(K_S) = (0.5293 \pm 0.0009) \times 10^{10} \hbar s^{-1}$. The $\Delta B = 2$ transitions in the B^0 and B_s^0 systems via mixing are also well established. The measured mass differences between the eigenstates are $(m_{B_H^0} - m_{B_L^0}) = (0.507 \pm 0.004) \times 10^{12} \hbar s^{-1}$ and $(m_{B_{sH}^0} - m_{B_{sL}^0}) = (17.69 \pm 0.08) \times 10^{12} \hbar s^{-1}$. There is now strong evidence of $\Delta C = 2$ transition in the charm sector with the mass difference $m_{D_H^0} - m_{D_L^0} = (1.44^{+0.48}_{-0.50}) \times 10^{10} \hbar s^{-1}$. All results are consistent with the second-order calculations in the Standard Model.

(c) **Flavor-changing neutral currents.** In the Standard Model the neutral-current interactions do not change flavor. The low rate $\Gamma(K_L \rightarrow \mu^+\mu^-)/\Gamma(K_L \rightarrow \text{all}) = (6.84 \pm 0.11) \times 10^{-9}$ puts limits on such interactions; the nonzero value for this rate is attributed to a combination of the weak and electromagnetic interactions. The best test should come from $K^+ \rightarrow \pi^+\nu\bar{\nu}$, which occurs in the Standard Model only as a second-order weak process with a branching fraction of $(0.4 \text{ to } 1.2) \times 10^{-10}$. Combining results from BNL-E787 and BNL-E949 experiments yield $\Gamma(K^+ \rightarrow \pi^+\nu\bar{\nu})/\Gamma(K^+ \rightarrow \text{all}) = (1.7 \pm 1.1) \times 10^{-10}$ [4]. Limits for charm-changing or bottom-changing neutral currents are less stringent: $\Gamma(D^0 \rightarrow \mu^+\mu^-)/\Gamma(D^0 \rightarrow \text{all}) < 1.4 \times 10^{-7}$ and $\Gamma(B^0 \rightarrow \mu^+\mu^-)/\Gamma(B^0 \rightarrow \text{all}) < 1.4 \times 10^{-9}$. One cannot isolate flavor-changing neutral current (FCNC) effects in non leptonic

decays. For example, the FCNC transition $s \rightarrow d + (\bar{u} + u)$ is equivalent to the charged-current transition $s \rightarrow u + (\bar{u} + d)$. Tests for FCNC are therefore limited to hadron decays into lepton pairs. Such decays are expected only in second-order in the electroweak coupling in the Standard Model.

--	--------------------------------------

In this Summary Table:

When a quantity has “(S = ...)” to its right, the error on the quantity has been enlarged by the “scale factor” S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

- [a] C parity forbids this to occur as a single-photon process.
- [b] See the Particle Listings for the (complicated) definition of this quantity.
- [c] Time-reversal invariance requires this to be 0° or 180° .
- [d] This coefficient is zero if time invariance is not violated.
- [e] Allowed by higher-order electroweak interactions.
- [f] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.
- [g] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.
- [h] $\text{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.
- [i] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K_L^0 \rightarrow \pi^+ \pi^- \gamma$ (DE).
- [j] Neglecting photon channels. See, e.g., A. Pais and S.B. Treiman, *Phys. Rev. D* **12**, 2744 (1975).
- [k] Derived from measured values of ϕ_{+-} , ϕ_{00} , $|\eta|$, $|m_{K_L^0} - m_{K_S^0}|$, and $\tau_{K_S^0}$, as described in the introduction to “Tests of Conservation Laws.”
- [l] The $|m_p - m_{\bar{p}}|/m_p$ and $|q_p + q_{\bar{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\bar{p}}/m_{\bar{p}}|/(q_p/m_p)$.
- [m] The value is for the sum of the charge states or particle/antiparticle states indicated.
- [n] A test of additive vs. multiplicative lepton family number conservation.
- [o] The limit quoted corresponds to the projection onto the $\sin^2(2\theta_{23})$ axis of the 90% CL contour in the $\sin^2(2\theta_{23}) - \Delta m_{32}^2$ plane.
- [p] The sign of Δm_{32}^2 is not known at this time. The range quoted is for the absolute value.
- [q] Derived from an analysis of neutrino-oscillation experiments.
- [r] This limit is for either D^0 or \bar{D}^0 to $p e^-$.
- [s] This limit is for either D^0 or \bar{D}^0 to $\bar{p} e^+$.
- [t] The first limit is for $p \rightarrow$ anything or “disappearance” modes of a bound proton. The second entry, a rough range of limits, assumes the dominant decay modes are among those investigated. For antiprotons the best limit, inferred from the observation of cosmic ray \bar{p} 's is $\tau_{\bar{p}} > 10^7$ yr, the cosmic-ray storage time, but this limit depends on a number of assumptions. The best direct observation of stored antiprotons gives $\tau_{\bar{p}}/B(\bar{p} \rightarrow e^- \gamma) > 7 \times 10^5$ yr.
- [u] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the best limit comes). The first limit here is from reactor experiments with free neutrons.
- [v] This is the best limit for the mode $e^- \rightarrow \nu \gamma$. The best limit for “electron disappearance” is 6.4×10^{24} yr.
- [w] See the K_S^0 Particle Listings for the energy limits used in this measurement.
- [x] See the K_L^0 Particle Listings for the energy limits used in this measurement.
- [y] An ℓ indicates an e or a μ mode, not a sum over these modes.
- [z] This limit is for $\Gamma(t \rightarrow Z q)/\Gamma(t \rightarrow W b)$.

1. PHYSICAL CONSTANTS

Table 1.1. Reviewed 2011 by P.J. Mohr (NIST). Mainly from the “CODATA Recommended Values of the Fundamental Physical Constants: 2010” by P.J. Mohr, B.N. Taylor, and D.B. Newell in [arXiv:1203.5425](https://arxiv.org/abs/1203.5425) and Rev. Mod. Phys. (to be published). The last group of constants (beginning with the Fermi coupling constant) comes from the Particle Data Group. The figures in parentheses after the values give the 1-standard-deviation uncertainties in the last digits; the corresponding fractional uncertainties in parts per 10⁹ (ppb) are given in the last column. This set of constants (aside from the last group) is recommended for international use by CODATA (the Committee on Data for Science and Technology). The full 2010 CODATA set of constants may be found at <http://physics.nist.gov/constants>. See also P.J. Mohr and D.B. Newell, “Resource Letter FC-1: The Physics of Fundamental Constants,” Am. J. Phys., **78** (2010) 338.

Quantity	Symbol, equation	Value	Uncertainty (ppb)
speed of light in vacuum	c	299 792 458 m s ⁻¹	exact*
Planck constant	h	6.626 069 57(29)×10 ⁻³⁴ J s	44
Planck constant, reduced	$\hbar \equiv h/2\pi$	1.054 571 726(47)×10 ⁻³⁴ J s = 6.582 119 28(15)×10 ⁻²² MeV s	44 22
electron charge magnitude	e	1.602 176 565(35)×10 ⁻¹⁹ C = 4.803 204 50(11)×10 ⁻¹⁰ esu	22, 22
conversion constant	$\hbar c$	197.326 9718(44) MeV fm	22
conversion constant	$(\hbar c)^2$	0.389 379 338(17) GeV ² mbarn	44
electron mass	m_e	0.510 998 928(11) MeV/c ² = 9.109 382 91(40)×10 ⁻³¹ kg	22, 44

1 in ≡ 0.0254 m	1 G ≡ 10 ⁻⁴ T	1 eV = 1.602 176 565(35) × 10 ⁻¹⁹ J	kT at 300 K = [38.681 731(35)] ⁻¹ eV
1 Å ≡ 0.1 nm	1 dyne ≡ 10 ⁻⁵ N	1 eV/c ² = 1.782 661 845(39) × 10 ⁻³⁶ kg	0 °C ≡ 273.15 K
1 barn ≡ 10 ⁻²⁸ m ²	1 erg ≡ 10 ⁻⁷ J	2.997 924 58 × 10 ⁹ esu = 1 C	1 atmosphere ≡ 760 Torr ≡ 101 325 Pa

* The meter is the length of the path traveled by light in vacuum during a time interval of 1/299 792 458 of a second.

† At $Q^2 = 0$. At $Q^2 \approx m_W^2$ the value is $\sim 1/128$.

‡ Absolute lab measurements of G_N have been made only on scales of about 1 cm to 1 m.

** See the discussion in Sec. 10, “Electroweak model and constraints on new physics.”

†† The corresponding $\sin^2 \theta$ for the effective angle is 0.23146(12).

2. ASTROPHYSICAL CONSTANTS AND PARAMETERS

Table 2.1. Revised February 2012 by E. Bergren and D.E. Groom (LBNL). The figures in parentheses after some values give the 1- σ uncertainties in the last digit(s). Physical constants are from Ref. 1. While every effort has been made to obtain the most accurate current values of the listed quantities, the table does not represent a critical review or adjustment of the constants, and is not intended as a primary reference.

The values and uncertainties for the cosmological parameters depend on the exact data sets, priors, and basis parameters used in the fit. Many of the derived parameters reported in this table have non-Gaussian likelihoods. Parameters may be highly correlated, so care must be taken in propagating errors. Unless otherwise specified, cosmological parameters are from six-parameter fits to a flat Λ CDM cosmology using 7-year WMAP data alone [2]. For more information see Ref. 3 and the original papers.

Quantity	Symbol, equation	Value	Reference, footnote
speed of light	c	299 792 458 m s ⁻¹	exact[4]
Newtonian gravitational constant	G_N	6.673 8(8) $\times 10^{-11}$ m ³ kg ⁻¹ s ⁻²	[1]

- While A is approximately equal to the semi-major axis of the Earth’s orbit, it is not exactly so. Nor is it exactly the mean Earth-Sun distance. There are a number of reasons: a) the Earth’s orbit is not exactly Keplerian due to relativity and to perturbations from other planets; b) the adopted value for the Gaussian gravitational constant k is not exactly equal to the Earth’s mean motion; and c) the mean distance in a Keplerian orbit is not equal to the semi-major axis a : $\langle r \rangle = a(1 + e^2/2)$, where e is the eccentricity. (Discussion courtesy of Myles Standish, JPL).
- The distance at which 1 A subtends 1 arc sec: 1 A divided by $\pi/648000$.
- Product of $2/c^2$ and the heliocentric gravitational constant $G_N M_\odot = A^3 k^2 / 86400^2$, where k is the Gaussian gravitational constant, 0.017 202 098 95 (exact) [5]. The value and error for A given in this table are used.

- Average of WMAP7 [2] and independent Cepheid-based measurement by A.G. Reiss *et al.*, *Astrophys. J.* **730**, 119 (2011). Other high-quality measurements could have been included.
- R. Amanullah *et al.*, *Astrophys. J.* **716**, 712 (2010). Fit with curvature unconstrained. For a flat Universe, $w = -1.00 \pm 0.08$.
- $\Omega_\nu h^2 = \sum m_{\nu_j} / 93 \text{ eV}$, where the sum is over all neutrino mass eigenstates. The lower limit follows from neutrino mixing results reported in this *Review* combined with the assumptions that there are three light neutrinos ($m_\nu < 45 \text{ GeV}/c^2$) and that the lightest neutrino is substantially less massive than the others: $\Delta m_{32}^2 = (2.43 \pm 0.13) \times 10^{-3} \text{ eV}^2$, so $\sum m_{\nu_j} \geq m_{\nu_3} \approx \sqrt{\Delta m_{32}^2} = 0.05 \text{ eV}$. (This becomes 0.10 eV if the mass hierarchy is inverted, with $m_{\nu_1} \approx m_{\nu_2} \gg m_{\nu_3}$.) Astrophysical determinations of $\sum m_{\nu_j}$, reported in the Full Listings of this *Review* under “Sum of the neutrino masses,” range from $< 0.17 \text{ eV}$ to $< 2.3 \text{ eV}$ in papers published since 2003. Alternatively, if the limit obtained from tritium decay experiments ($m_\nu < 2 \text{ eV}$) is used for the upper limit, then $\Omega_\nu < 0.04$.
- If the Universe were reionized instantaneously at z_{reion} .
- G. Kopp & J.L. Lean, *Geophys. Res. Lett.* **38**, L01706 (2011). Kopp & Lean give $1360.8 \pm 0.6 \text{ W m}^{-2}$, but given the scatter in the data we use the rounded value without quoting an error.

3. INTERNATIONAL SYSTEM OF UNITS (SI)

See “The International System of Units (SI),” NIST Special Publication **330**, B.N. Taylor, ed. (USGPO, Washington, DC, 1991); and “Guide for the Use of the International System of Units (SI),” NIST Special Publication **811**, 1995 edition, B.N. Taylor (USGPO, Washington, DC, 1995).

Physical quantity	Name of unit	Symbol
<i>Base units</i>		
length	meter	m
mass	kilogram	kg
time	second	s
electric current	ampere	A
thermodynamic temperature	kelvin	K
amount of substance	mole	mol
luminous intensity	candela	cd
<i>Derived units with special names</i>		
plane angle	radian	rad
solid angle	steradian	sr
frequency	hertz	Hz
energy	joule	J
force	newton	N
pressure	pascal	Pa
power	watt	W
electric charge	coulomb	C
electric potential	volt	V
electric resistance	ohm	Ω
electric conductance	siemens	S
electric capacitance	farad	F
magnetic flux	weber	Wb
inductance	henry	H
magnetic flux density	tesla	T
luminous flux	lumen	lm
illuminance	lux	lx
celsius temperature	degree celsius	$^{\circ}\text{C}$
activity (of a radioactive source)*	becquerel	Bq
absorbed dose (of ionizing radiation)*	gray	Gy
dose equivalent*	sievert	Sv

SI prefixes

10^{24}	yotta	(Y)
10^{21}	zetta	(Z)
10^{18}	exa	(E)
10^{15}	peta	(P)
10^{12}	tera	(T)
10^9	giga	(G)
10^6	mega	(M)

*See our section 33, on “Radioactivity and radiation protection,” p. 381.

Table 4.1. Revised 2011 by D.E. Groom (LBNL), and E. Bergren. Atomic weights of stable elements are adapted from the Commission on Isotopic Abundances and Atomic Weights, "Atomic Weights of the Elements 2007," <http://www.chem.qmul.ac.uk/iupac/AtWt/>. The atomic number (top left) is the number of protons in the nucleus. The atomic mass (bottom) of a stable elements is weighted by isotopic abundances in the Earth's surface. If the element has no stable isotope, the atomic mass (in parentheses) of the most stable isotope currently known is given. In this case the mass is from <http://www.nndc.bnl.gov/amdc/masstable/Ame2003/mass.mas03> and the longest-lived isotope is from www.nndc.bnl.gov/ensdf/za.form.jsp. The exceptions are Th, Pa, and U, which do have characteristic terrestrial compositions. Atomic masses are relative to the mass of ^{12}C , defined to be exactly 12 unified atomic mass units (u) (approx. g/mole). Relative isotopic abundances often vary considerably, both in natural and commercial samples; this is reflected in the number of significant figures given for the atomic mass. IUPAC does not accept the claims for elements 113, 115, 117, and 118 as conclusive at this time.

5. ELECTRONIC STRUCTURE OF THE ELEMENTS

Table 5.1. Reviewed 2011 by J.E. Sansonetti (NIST). The electronic configurations and the ionization energies are from the NIST database, “Ground Levels and Ionization Energies for the Neutral Atoms,” W.C. Martin, A. Musgrove, S. Kotochigova, and J.E. Sansonetti, http://www.nist.gov/pml/data/ion_energy.cfm. The electron configuration for, say, iron indicates an argon electronic core (see argon) plus six $3d$ electrons and two $4s$ electrons.

	Element	Electron configuration ($3d^5 =$ five $3d$ electrons, <i>etc.</i>)	Ground state $2S+1L_J$	Ionization energy (eV)
1	H Hydrogen	$1s$	$^2S_{1/2}$	13.5984

6. ATOMIC AND NUCLEAR PROPERTIES OF MATERIALS

Table 6.1 Abridged from pdg.lbl.gov/AtomicNuclearProperties by D. E. Groom (2007). See web pages for more detail about entries in this table including chemical formulae, and for several hundred other entries. Quantities in parentheses are for NTP (20° C and 1 atm), and square brackets indicate quantities evaluated at STP. Boiling points are at 1 atm. Refractive indices n are evaluated at the sodium D line blend (589.2 nm); values $\gg 1$ in brackets are for $(n - 1) \times 10^6$ (gases).

Material	Z	A	$\langle Z/A \rangle$	Nucl.coll. length λ_T {g cm ⁻² }	Nucl.inter. length λ_I {g cm ⁻² }	Rad.len. X_0 {g cm ⁻² }	$dE/dx _{\min}$ { MeV g ⁻¹ cm ² }	Density {g cm ⁻³ } {(gℓ ⁻¹)}	Melting point (K)	Boiling point (K)	Refract. index (@ Na D)

7.1. Impedances (SI units)

ρ = resistivity at room temperature in $10^{-8} \Omega \text{ m}$:
 ~ 1.7 for Cu ~ 5.5 for W
 ~ 2.4 for Au ~ 73 for SS 304
 ~ 2.8 for Al ~ 100 for Nichrome
 (Al alloys may have double the Al value.)

For alternating currents, instantaneous current I , voltage V , angular frequency ω :

$$V = V_0 e^{j\omega t} = ZI. \quad (7.1)$$

Impedance of self-inductance L : $Z = j\omega L$.

Impedance of capacitance C : $Z = 1/j\omega C$.

Impedance of free space: $Z = \sqrt{\mu_0/\epsilon_0} = 376.7 \Omega$.

High-frequency surface impedance of a good conductor:

$$Z = \frac{(1+j)\rho}{\delta}, \quad \text{where } \delta = \text{skin depth}; \quad (7.2)$$

$$\delta = \sqrt{\frac{\rho}{\pi\nu\mu}} \approx \frac{6.6 \text{ cm}}{\sqrt{\nu \text{ (Hz)}}} \quad \text{for Cu}. \quad (7.3)$$

7.2. Capacitors, inductors, and transmission Lines

The capacitance between two parallel plates of area A spaced by the distance d and enclosing a medium with the dielectric constant ϵ is

$$C = K\epsilon A/d, \quad (7.4)$$

where the correction factor K depends on the extent of the fringing field. If the dielectric fills the capacitor volume without extending beyond the electrodes, the correction factor $K \approx 0.8$ for capacitors of typical geometry.

The inductance at high frequencies of a straight wire whose length ℓ is much greater than the wire diameter d is

$$L \approx 2.0 \left[\frac{\text{nH}}{\text{cm}} \right] \cdot \ell \left(\ln \left(\frac{4\ell}{d} \right) - 1 \right). \quad (7.5)$$

For very short wires, representative of vias in a printed circuit board, the inductance is

$$L(\text{in nH}) \approx \ell/d. \quad (7.6)$$

A transmission line is a pair of conductors with inductance L and capacitance C . The characteristic impedance $Z = \sqrt{L/C}$ and the phase velocity $v_p = 1/\sqrt{LC} = 1/\sqrt{\mu\epsilon}$, which decreases with the inverse square root of the dielectric constant of the medium. Typical coaxial and ribbon cables have a propagation delay of about 5 ns/cm. The impedance of a coaxial cable with outer diameter D and inner diameter d is

$$Z = 60 \Omega \cdot \frac{1}{\sqrt{\epsilon_r}} \ln \frac{D}{d}, \quad (7.7)$$

where the relative dielectric constant $\epsilon_r = \epsilon/\epsilon_0$. A pair of parallel wires of diameter d and spacing $a > 2.5d$ has the impedance

$$Z = 120 \Omega \cdot \frac{1}{\sqrt{\epsilon_r}} \ln \frac{2a}{d}. \quad (7.8)$$

This yields the impedance of a wire at a spacing h above a ground plane,

$$Z = 60 \Omega \cdot \frac{1}{\sqrt{\epsilon_r}} \ln \frac{4h}{d}. \quad (7.9)$$

A common configuration utilizes a thin rectangular conductor above a ground plane with an intermediate dielectric (microstrip). Detailed calculations for this and other transmission line configurations are given by Gunston.*

7.3. Synchrotron radiation (CGS units)

For a particle of charge e , velocity $v = \beta c$, and energy $E = \gamma mc^2$, traveling in a circular orbit of radius R , the classical energy loss per revolution δE is

$$\delta E = \frac{4\pi}{3} \frac{e^2}{R} \beta^3 \gamma^4. \quad (7.10)$$

For high-energy electrons or positrons ($\beta \approx 1$), this becomes

$$\delta E \text{ (in MeV)} \approx 0.0885 [E(\text{in GeV})]^4 / R(\text{in m}). \quad (7.11)$$

For $\gamma \gg 1$, the energy radiated per revolution into the photon energy interval $d(\hbar\omega)$ is

$$dI = \frac{8\pi}{9} \alpha \gamma F(\omega/\omega_c) d(\hbar\omega), \quad (7.12)$$

where $\alpha = e^2/\hbar c$ is the fine-structure constant and

$$\omega_c = \frac{3\gamma^3 c}{2R} \quad (7.13)$$

is the critical frequency. The normalized function $F(y)$ is

$$F(y) = \frac{9}{8\pi} \sqrt{3} y \int_y^\infty K_{5/3}(x) dx, \quad (7.14)$$

where $K_{5/3}(x)$ is a modified Bessel function of the third kind. For electrons or positrons,

$$\hbar\omega_c \text{ (in keV)} \approx 2.22 [E(\text{in GeV})]^3 / R(\text{in m}). \quad (7.15)$$

Fig. 7.1 shows $F(y)$ over the important range of y .

Figure 7.1: The normalized synchrotron radiation spectrum $F(y)$.

For $\gamma \gg 1$ and $\omega \ll \omega_c$,

$$\frac{dI}{d(\hbar\omega)} \approx 3.3\alpha (\omega R/c)^{1/3}, \quad (7.16)$$

whereas for

$$\gamma \gg 1 \text{ and } \omega \gtrsim 3\omega_c,$$

$$\frac{dI}{d(\hbar\omega)} \approx \sqrt{\frac{3\pi}{2}} \alpha \gamma \left(\frac{\omega}{\omega_c} \right)^{1/2} e^{-\omega/\omega_c} \left[1 + \frac{55}{72} \frac{\omega_c}{\omega} + \dots \right]. \quad (7.17)$$

The radiation is confined to angles $\lesssim 1/\gamma$ relative to the instantaneous direction of motion. For $\gamma \gg 1$, where Eq. (7.12) applies, the mean number of photons emitted per revolution is

$$N_\gamma = \frac{5\pi}{\sqrt{3}} \alpha \gamma, \quad (7.18)$$

and the mean energy per photon is

$$\langle \hbar\omega \rangle = \frac{8}{15\sqrt{3}} \hbar\omega_c. \quad (7.19)$$

When $\langle \hbar\omega \rangle \gtrsim O(E)$, quantum corrections are important.

* M.A.R. Gunston. Microwave Transmission Line Data, Noble Publishing Corp., Atlanta (1997) ISBN 1-884932-57-6, TK6565.T73G85.

See J.D. Jackson, *Classical Electrodynamics*, 3rd edition (John Wiley & Sons, New York, 1998) for more formulae and details. (Note that earlier editions had ω_c twice as large as Eq. (7.13).

8. NAMING SCHEME FOR HADRONS

Revised 2008 by M. Roos (University of Finland) and C.G. Wohl (LBNL).

8.1. Introduction

We introduced in the 1986 edition [1] a new naming scheme for the hadrons. Changes from older terminology affected mainly the heavier mesons made of the light (u , d , and s) quarks. Old and new names were listed alongside until 1994. Names also change from edition to edition because some characteristic like mass or spin changes. The Summary Tables give both the new and old names whenever a change occurred.

8.2. “Neutral-flavor” mesons ($S=C=B=T=0$)

Table 8.1 shows the names for mesons having the strangeness and all heavy-flavor quantum numbers equal to zero. The scheme is designed for all ordinary non-exotic mesons, but it will work for many exotic types too, if needed.

Table 8.1: Symbols for mesons with the strangeness and all heavy-flavor quantum numbers equal to zero.

J^{PC}	$\begin{cases} 0^{-+} \\ 2^{-+} \\ \vdots \end{cases}$	$\begin{cases} 1^{+-} \\ 3^{+-} \\ \vdots \end{cases}$	$\begin{cases} 1^{--} \\ 2^{--} \\ \vdots \end{cases}$	$\begin{cases} 0^{++} \\ 1^{++} \\ \vdots \end{cases}$	
$q\bar{q}$ content	$2^{S+1}L_J$	${}^1(L\text{ even})_J$	${}^1(L\text{ odd})_J$	${}^3(L\text{ even})_J$	${}^3(L\text{ odd})_J$
$u\bar{d}, u\bar{u} - d\bar{d}, d\bar{u}$ ($I=1$)	π	b	ρ	a	
$d\bar{d} + u\bar{u}$ and/or $s\bar{s}$ } ($I=0$)	η, η'	h, h'	ω, ϕ	f, f'	
$c\bar{c}$	η_c	h_c	ψ^\dagger	χ_c	
$b\bar{b}$	η_b	h_b	Υ	χ_b	
$t\bar{t}$	η_t	h_t	θ	χ_t	

[†]The J/ψ remains the J/ψ .

First, we assign names to those states with quantum numbers compatible with being $q\bar{q}$ states. The rows of the Table give the possible $q\bar{q}$ content. The columns give the possible parity/charge-conjugation states,

$$PC = -+, ++, --, \text{ and } ++;$$

these combinations correspond one-to-one with the angular-momentum state ${}^{2S+1}L_J$ of the $q\bar{q}$ system being

$${}^1(L\text{ even})_J, {}^1(L\text{ odd})_J, {}^3(L\text{ even})_J, \text{ or } {}^3(L\text{ odd})_J.$$

Here S , L , and J are the spin, orbital, and total angular momenta of the $q\bar{q}$ system. The quantum numbers are related by $P = (-1)^{L+1}$, $C = (-1)^{L+S}$, and G parity $= (-1)^{L+S+I}$, where of course the C quantum number is only relevant to neutral mesons.

The entries in the Table give the meson names. The spin J is added as a subscript except for pseudoscalar and vector mesons, and the mass is added in parentheses for mesons that decay strongly. However, for the lightest meson resonances, we omit the mass.

Measurements of the mass, quark content (where relevant), and quantum numbers I , J , P , and C (or G) of a meson thus fix its symbol. Conversely, these properties may be inferred unambiguously from the symbol.

If the main symbol cannot be assigned because the quantum numbers are unknown, X is used. Sometimes it is not known whether a meson is mainly the isospin-0 mix of $u\bar{u}$ and $d\bar{d}$ or is mainly $s\bar{s}$. A prime (or pair ω , ϕ) may be used to distinguish two such mixing states.

We follow custom and use spectroscopic names such as $\Upsilon(1S)$ as the primary name for most of those ψ , Υ , and χ states whose spectroscopic identity is known. We use the form $\Upsilon(9460)$ as an alternative, and as the primary name when the spectroscopic identity is not known.

Names are assigned for $t\bar{t}$ mesons, although the top quark is evidently so heavy that it is expected to decay too rapidly for bound states to form.

Gluonium states or other mesons that are not $q\bar{q}$ states are, if the quantum numbers are *not* exotic, to be named just as are the $q\bar{q}$ mesons. Such states will probably be difficult to distinguish from $q\bar{q}$ states and will likely mix with them, and we make no attempt to distinguish those “mostly gluonium” from those “mostly $q\bar{q}$.”

An “exotic” meson with J^{PC} quantum numbers that a $q\bar{q}$ system cannot have, namely $J^{PC} = 0^{--}, 0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, \dots$, would use the same symbol as does an ordinary meson with all the same quantum numbers as the exotic meson except for the C parity. But then the J subscript may still distinguish it; for example, an isospin-0 1^{-+} meson could be denoted ω_1 .

8.3. Mesons with nonzero S , C , B , and/or T

Since the strangeness or a heavy flavor of these mesons is nonzero, none of them are eigenstates of charge conjugation, and in each of them one of the quarks is heavier than the other. The rules are:

1. The main symbol is an upper-case italic letter indicating the heavier quark as follows:

$$s \rightarrow \bar{K} \quad c \rightarrow D \quad b \rightarrow \bar{B} \quad t \rightarrow T.$$

We use the convention that *the flavor and the charge of a quark have the same sign*. Thus the strangeness of the s quark is negative, the charm of the c quark is positive, and the bottom of the b quark is negative. In addition, I_3 of the u and d quarks are positive and negative, respectively. The effect of this convention is as follows: *Any flavor carried by a charged meson has the same sign as its charge*. Thus the K^+ , D^+ , and B^+ have positive strangeness, charm, and bottom, respectively, and all have positive I_3 . The D_s^+ has positive charm *and* strangeness. Furthermore, the $\Delta(\text{flavor}) = \Delta Q$ rule, best known for the kaons, applies to every flavor.

2. If the lighter quark is not a u or a d quark, its identity is given by a subscript. The D_s^+ is an example.
3. If the spin-parity is in the “normal” series, $J^P = 0^+, 1^-, 2^+, \dots$, a superscript “*” is added.
4. The spin is added as a subscript except for pseudoscalar or vector mesons.

8.4. Ordinary (3-quark) baryons

The symbols N , Δ , Λ , Σ , Ξ , and Ω used for more than 30 years for the baryons made of light quarks (u , d , and s quarks) tell the isospin and quark content, and the same information is conveyed by the symbols used for the baryons containing one or more heavy quarks (c and b quarks). The rules are:

1. Baryons with *three* u and/or d quarks are N 's (isospin 1/2) or Δ 's (isospin 3/2).
2. Baryons with *two* u and/or d quarks are Λ 's (isospin 0) or Σ 's (isospin 1). If the third quark is a c , b , or t quark, its identity is given by a subscript.
3. Baryons with *one* u or d quark are Ξ 's (isospin 1/2). One or two subscripts are used if one or both of the remaining quarks are heavy: thus Ξ_c , Ξ_{cc} , Ξ_b , *etc.**
4. Baryons with *no* u or d quarks are Ω 's (isospin 0), and subscripts indicate any heavy-quark content.
5. A baryon that decays strongly has its mass as part of its name. Thus p , $\Sigma^-, \Omega^-, \Lambda_c^+$, *etc.*, but $\Delta(1232)^0$, $\Sigma(1385)^-$, $\Xi_c(2645)^+$, *etc.*

In short, the number of u plus d quarks together with the isospin determine the main symbol, and subscripts indicate any content of heavy quarks. A Σ always has isospin 1, an Ω always has isospin 0, *etc.*

8.5. Exotic baryons

In 2003, several experiments reported finding a strangeness $S = +1$, charge $Q = +1$ baryon, and one experiment reported finding an $S = -2$, $Q = -2$ baryon. Baryons with such quantum numbers cannot be made from three quarks, and thus they are exotic. The $S = +1$ baryon, which once would have been called a Z , was quickly dubbed the $\Theta(1540)^+$, and we proposed to name the $S = -2$ baryon the $\Phi(1860)$. However, these “discoveries” were then completely ruled out by many experiments with far larger statistics: See our 2008 *Review* [2].

Footnote and Reference:

- * Sometimes a prime is necessary to distinguish two Ξ_c 's in the same $SU(n)$ multiplet. See the “Note on Charmed Baryons” in the Charmed Baryon Listings.

9. QUANTUM CHROMODYNAMICS

Revised April 2012 by S. Bethke (MPP, Munich), G. Dissertori (ETH, Zurich) and G.P. Salam (CERN, Princeton University and LPTHE, Paris).

9.1. Basics

Quantum Chromodynamics (QCD), the gauge field theory that describes the strong interactions of colored quarks and gluons, is the SU(3) component of the SU(3)×SU(2)×U(1) Standard Model of Particle Physics.

The Lagrangian of QCD is given by

$$\mathcal{L} = \sum_q \bar{\psi}_{q,a} (i\gamma^\mu \partial_\mu \delta_{ab} - g_s \gamma^\mu t_{ab}^C A_\mu^C - m_q \delta_{ab}) \psi_{q,b} - \frac{1}{4} F_{\mu\nu}^A F^{A\mu\nu}, \quad (9.1)$$

where repeated indices are summed over. The γ^μ are the Dirac γ -matrices. The $\psi_{q,a}$ are quark-field spinors for a quark of flavor q and mass m_q , with a color-index a that runs from $a = 1$ to $N_c = 3$, *i.e.* quarks come in three “colors.” Quarks are said to be in the fundamental representation of the SU(3) color group.

The A_μ^C correspond to the gluon fields, with C running from 1 to $N_c^2 - 1 = 8$, *i.e.* there are eight kinds of gluon. Gluons are said to be in the adjoint representation of the SU(3) color group. The t_{ab}^C correspond to eight 3×3 matrices and are the generators of the SU(3) group (cf. the section on “SU(3) isoscalar factors and representation matrices” in this *Review* with $t_{ab}^C \equiv \lambda_{ab}^C/2$). They encode the fact that a gluon’s interaction with a quark rotates the quark’s color in SU(3) space. The quantity g_s is the QCD coupling constant. Finally, the field tensor $F_{\mu\nu}^A$ is given by

$$F_{\mu\nu}^A = \partial_\mu A_\nu^A - \partial_\nu A_\mu^A - g_s f_{ABC} A_\mu^B A_\nu^C \quad [t^A, t^B] = i f_{ABC} t^C, \quad (9.2)$$

where the f_{ABC} are the structure constants of the SU(3) group.

Neither quarks nor gluons are observed as free particles. Hadrons are color-singlet (*i.e.* color-neutral) combinations of quarks, anti-quarks, and gluons.

Ab-initio predictive methods for QCD include lattice gauge theory and perturbative expansions in the coupling. The Feynman rules of QCD involve a quark-antiquark-gluon ($q\bar{q}g$) vertex, a 3-gluon vertex (both proportional to g_s), and a 4-gluon vertex (proportional to g_s^2). A full set of Feynman rules is to be found for example in Ref. 3.

Useful color-algebra relations include: $t_{ab}^A t_{bc}^A = C_F \delta_{ac}$, where $C_F \equiv (N_c^2 - 1)/(2N_c) = 4/3$ is the color-factor (“Casimir”) associated with gluon emission from a quark; $f^{ACD} f^{BCD} = C_A \delta_{AB}$ where $C_A \equiv N_c = 3$ is the color-factor associated with gluon emission from a gluon; $t_{ab}^A t_{ab}^B = T_R \delta_{AB}$, where $T_R = 1/2$ is the color-factor for a gluon to split to a $q\bar{q}$ pair.

The fundamental parameters of QCD are the coupling g_s (or $\alpha_s = \frac{g_s^2}{4\pi}$) and the quark masses m_q .

There is freedom for an additional CP-violating term to be present in the QCD Lagrangian, $\frac{\theta}{8\pi} F_{\mu\nu}^A \tilde{F}^{A\mu\nu}$, where $F_{\mu\nu}^A \tilde{F}^{A\mu\nu}$ is the dual of the gluon field tensor, $\frac{1}{2} \epsilon_{\mu\nu\rho\sigma} F^{A\sigma\rho}$. Experimental limits on the neutron electric dipole moment [1] constrain the coefficient of this contribution to satisfy $|\theta| \lesssim 10^{-10}$. Further discussion is to be found in Ref. 2 and Axions section in the Listings of this *Review*.

This section will concentrate mainly on perturbative aspects of QCD as they relate to collider physics. Related textbooks and reviews include Refs. 3–6. Aspects specific to Monte Carlo event generators are reviewed in a dedicated section Chap. 38. Lattice QCD is also reviewed in a section of its own Chap. 17, with additional discussion of non-perturbative aspects to be found in the sections on “Quark Masses”, “The CKM quark-mixing matrix”, “Structure Functions” and event generators in this *Review*. For an overview of some of the QCD issues and recent results in heavy-ion physics, see for example Refs. 7, 8.

9.1.1. Running coupling :

In the framework of perturbative QCD (pQCD), predictions for observables are expressed in terms of the renormalized coupling $\alpha_s(\mu_R^2)$, a function of an (unphysical) renormalization scale μ_R . When one takes μ_R close to the scale of the momentum transfer Q in a given process, then $\alpha_s(\mu_R^2 \simeq Q^2)$ is indicative of the effective strength of the strong interaction in that process.

The coupling satisfies the following renormalization group equation (RGE):

$$\mu_R^2 \frac{d\alpha_s}{d\mu_R^2} = \beta(\alpha_s) = -(b_0 \alpha_s^2 + b_1 \alpha_s^3 + b_2 \alpha_s^4 + \dots) \quad (9.3)$$

where $b_0 = (11C_A - 4n_f T_R)/(12\pi) = (33 - 2n_f)/(12\pi)$ is referred to as the 1-loop beta-function coefficient, the 2-loop coefficient is $b_1 = (17C_A^2 - n_f T_R(10C_A + 6C_F))/(24\pi^2) = (153 - 19n_f)/(24\pi^2)$, and the 3-loop coefficient is $b_2 = (2857 - \frac{5033}{9}n_f + \frac{325}{27}n_f^2)/(128\pi^3)$. The 4-loop coefficient, b_3 , is to be found in Refs. 9, 10[†]. The minus sign in Eq. (9.3) is the origin of Asymptotic Freedom, *i.e.* the fact that the strong coupling becomes weak for processes involving large momentum transfers (“hard processes”), $\alpha_s \sim 0.1$ for momentum transfers in the 100 GeV – TeV range.

The β -function coefficients, the b_i , are given for the coupling of an *effective theory* in which n_f of the quark flavors are considered light ($m_q \ll \mu_R$), and in which the remaining heavier quark flavors decouple from the theory. One may relate the coupling for the theory with $n_f + 1$ light flavors to that with n_f flavors through an equation of the form

$$\alpha_s^{(n_f+1)}(\mu_R^2) = \alpha_s^{(n_f)}(\mu_R^2) \left(1 + \sum_{n=1}^{\infty} \sum_{\ell=0}^n c_{n\ell} [\alpha_s^{(n_f)}(\mu_R^2)]^n \ln^\ell \frac{\mu_R^2}{m_h^2} \right), \quad (9.4)$$

where m_h is the mass of the $(n_f + 1)$ th flavor, and the first few $c_{n\ell}$ coefficients are $c_{11} = \frac{1}{6\pi}$, $c_{10} = 0$, $c_{22} = c_{11}^2$, $c_{21} = \frac{19}{24\pi^2}$, and $c_{20} = -\frac{11}{72\pi^2}$ when m_h is the $\overline{\text{MS}}$ mass at scale m_h ($c_{20} = \frac{7}{24\pi^2}$ when m_h is the pole mass — mass definitions are discussed below and in the review on “Quark Masses”). Terms up to $c_{4\ell}$ are to be found in Refs. 11, 12. Numerically, when one chooses $\mu_R = m_h$, the matching is a modest effect, owing to the zero value for the c_{10} coefficient. Relations between n_f and $(n_f + 2)$ flavors where the two heavy flavors are close in mass are given to three loops in Ref. 13.

Working in an energy range where the number of flavors is taken constant, a simple exact analytic solution exists for Eq. (9.3) only if one neglects all but the b_0 term, giving $\alpha_s(\mu_R^2) = (b_0 \ln(\mu_R^2/\Lambda^2))^{-1}$. Here Λ is a constant of integration, which corresponds to the scale where the perturbatively-defined coupling would diverge, *i.e.* it is the non-perturbative scale of QCD. A convenient approximate analytic solution to the RGE that includes also the b_1 , b_2 , and b_3 terms is given by (see for example Ref. 14),

$$\alpha_s(\mu_R^2) \simeq \frac{1}{b_0 t} \left(1 - \frac{b_1 \ln t}{b_0^2 t} + \frac{b_1^2 (\ln^2 t - \ln t - 1) + b_0 b_2}{b_0^4 t^2} - \frac{b_1^3 (\ln^3 t - \frac{5}{2} \ln^2 t - 2 \ln t + \frac{1}{2}) + 3b_0 b_1 b_2 \ln t - \frac{1}{2} b_0^2 b_3}{b_0^6 t^3} \right), \quad t \equiv \ln \frac{\mu_R^2}{\Lambda^2}, \quad (9.5)$$

again parametrized in terms of a constant Λ . Note that Eq. (9.5) is one of several possible approximate 4-loop solutions for $\alpha_s(\mu_R^2)$, and that a value for Λ only defines $\alpha_s(\mu_R^2)$ once one knows which particular approximation is being used. An alternative to the use of formulas such as Eq. (9.5) is to solve the RGE exactly, numerically (including the discontinuities, Eq. (9.4), at flavor thresholds). In such cases the quantity Λ is not defined at all. For these reasons, in determinations

[†] One should be aware that the b_2 and b_3 coefficients are renormalization-scheme-dependent, and given here in the $\overline{\text{MS}}$ scheme, as discussed below.

of the coupling, it has become standard practice to quote the value of α_s at a given scale (typically M_Z) rather than to quote a value for Λ .

The value of the coupling, as well as the exact forms of the b_2, c_{10} (and higher order) coefficients, depend on the renormalization scheme in which the coupling is defined, *i.e.* the convention used to subtract infinities in the context of renormalization. The coefficients given above hold for a coupling defined in the modified minimal subtraction ($\overline{\text{MS}}$) scheme [15], by far the most widely used scheme.

A discussion of determinations of the coupling and a graph illustrating its scale dependence (“running”) are to be found in Section 9.3.4.

9.1.2. Quark masses :

Free quarks are never observed, *i.e.* a quark never exists on its own for a time longer than $\sim 1/\Lambda$: up, down, strange, charm, and bottom quarks all *hadronize*, *i.e.* become part of a meson or baryon, on a timescale $\sim 1/\Lambda$; the top quark instead decays before it has time to hadronize. This means that the question of what one means by the quark mass is a complex one, which requires that one adopts a specific prescription. A perturbatively defined prescription is the pole mass, m_q , which corresponds to the position of the divergence of the propagator. This is close to one’s physical picture of mass. However, when relating it to observable quantities, it suffers from substantial non-perturbative ambiguities (see *e.g.* Ref. 16). An alternative is the $\overline{\text{MS}}$ mass, $\overline{m}_q(\mu_R^2)$, which depends on the renormalization scale μ_R .

Results for the masses of heavier quarks are often quoted either as the pole mass or as the $\overline{\text{MS}}$ mass evaluated at a scale equal to the mass, $\overline{m}_q(\overline{m}_q^2)$; light quark masses are generally quoted in the $\overline{\text{MS}}$ scheme at a scale $\mu_R \sim 2 \text{ GeV}$. The pole and $\overline{\text{MS}}$ masses are related by a slowly converging series that starts $m_q = \overline{m}_q(\overline{m}_q^2)(1 + \frac{4\alpha_s(\overline{m}_q^2)}{3\pi} + \mathcal{O}(\alpha_s^2))$, while the scale-dependence of $\overline{\text{MS}}$ masses is given by

$$\mu_R^2 \frac{d\overline{m}_q(\mu_R^2)}{d\mu_R^2} = \left[-\frac{\alpha_s(\mu_R^2)}{\pi} + \mathcal{O}(\alpha_s^2) \right] \overline{m}_q(\mu_R^2). \quad (9.6)$$

More detailed discussion is to be found in a dedicated section of the *Review*, “Quark Masses.”

9.2. Structure of QCD predictions

9.2.1. Fully inclusive cross sections :

The simplest observables in QCD are those that do not involve initial-state hadrons and that are fully inclusive with respect to details of the final state. One example is the total cross section for $e^+e^- \rightarrow \text{hadrons}$ at center-of-mass energy Q , for which one can write

$$\frac{\sigma(e^+e^- \rightarrow \text{hadrons}, Q)}{\sigma(e^+e^- \rightarrow \mu^+\mu^-, Q)} \equiv R(Q) = R_{\text{EW}}(Q)(1 + \delta_{\text{QCD}}(Q)), \quad (9.7)$$

where $R_{\text{EW}}(Q)$ is the purely electroweak prediction for the ratio and $\delta_{\text{QCD}}(Q)$ is the correction due to QCD effects. To keep the discussion simple, we can restrict our attention to energies $Q \ll M_Z$, where the process is dominated by photon exchange ($R_{\text{EW}} = 3 \sum_q e_q^2$, neglecting finite-quark-mass corrections),

$$\delta_{\text{QCD}}(Q) = \sum_{n=1}^{\infty} c_n \cdot \left(\frac{\alpha_s(Q^2)}{\pi} \right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right). \quad (9.8)$$

The first four terms in the α_s series expansion are then to be found in Refs. 17, 18

$$c_1 = 1, \quad c_2 = 1.9857 - 0.1152n_f, \quad (9.9a)$$

$$c_3 = -6.63694 - 1.20013n_f - 0.00518n_f^2 - 1.240\eta \quad (9.9b)$$

$$c_4 = -156.61 + 18.77n_f - 0.7974n_f^2 + 0.0215n_f^3 + C\eta, \quad (9.9c)$$

with $\eta = (\sum e_q^2)/(3 \sum e_q^2)$ and where the coefficient C of the η -dependent piece in the α_s^4 term has yet to be determined. For

corresponding expressions including also Z exchange and finite-quark-mass effects, see Refs. 19, 20.

A related series holds also for the QCD corrections to the hadronic decay width of the τ lepton, which essentially involves an integral of $R(Q)$ over the allowed range of invariant masses of the hadronic part of the τ decay (see *e.g.* Ref. 17). The series expansions for QCD corrections to Higgs-boson (partial) decay widths are summarized in Refs. 21, 22.

One characteristic feature of Eqs. (9.8) and (9.9) is that the coefficients of α_s^n increase rapidly order by order: calculations in perturbative QCD tend to converge more slowly than would be expected based just on the size of $\alpha_s^{\dagger\dagger}$. Another feature is the existence of an extra “power-correction” term $\mathcal{O}(\Lambda^4/Q^4)$ in Eq. (9.8), which accounts for contributions that are fundamentally non-perturbative. All high-energy QCD predictions involve such corrections, though the exact power of Λ/Q depends on the observable.

Scale dependence. In Eq. (9.8) the renormalization scale for α_s has been chosen equal to Q . The result can also be expressed in terms of the coupling at an arbitrary renormalization scale μ_R ,

$$\delta_{\text{QCD}}(Q) = \sum_{n=1}^{\infty} \overline{c}_n \left(\frac{\mu_R^2}{Q^2} \right) \cdot \left(\frac{\alpha_s(\mu_R^2)}{\pi} \right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right), \quad (9.10)$$

where $\overline{c}_1(\mu_R^2/Q^2) \equiv c_1$, $\overline{c}_2(\mu_R^2/Q^2) = c_2 + \pi b_0 c_1 \ln(\mu_R^2/Q^2)$, $\overline{c}_3(\mu_R^2/Q^2) = c_3 + (2b_0 c_2 \pi + b_1 c_1 \pi^2) \ln(\mu_R^2/Q^2) + b_0^2 c_1 \pi^2 \ln^2(\mu_R^2/Q^2)$, *etc.*. Given an infinite number of terms in the α_s expansion, the μ_R dependence of the $\overline{c}_n(\mu_R^2/Q^2)$ coefficients will exactly cancel that of $\alpha_s(\mu_R^2)$, and the final result will be independent of the choice of μ_R : physical observables do not depend on unphysical scales.

With just terms up to $n = N$, a residual μ_R dependence will remain, which implies an uncertainty on the prediction of $R(Q)$ due to the arbitrariness of the scale choice. This uncertainty will be $\mathcal{O}(\alpha_s^{N+1})$, *i.e.* of the same order as the neglected terms. For this reason it is standard to use QCD predictions’ scale dependence as an estimate of the uncertainties due to neglected terms. One usually takes a central value for $\mu_R \sim Q$, in order to avoid the poor convergence of the perturbative series that results from the large $\ln^{n-1}(\mu_R^2/Q^2)$ terms in the \overline{c}_n coefficients when $\mu_R \ll Q$ or $\mu_R \gg Q$.

9.2.1.1. Processes with initial-state hadrons:

Deep Inelastic Scattering. To illustrate the key features of QCD cross sections in processes with initial-state hadrons, let us consider deep-inelastic scattering (DIS), $ep \rightarrow e + X$, where an electron e with four-momentum k emits a highly off-shell photon (momentum q) that interacts with the proton (momentum p). For photon virtualities $Q^2 \equiv -q^2$ far above the squared proton mass (but far below the Z mass), the differential cross section in terms of the kinematic variables Q^2 , $x = Q^2/(2p \cdot q)$ and $y = (q \cdot p)/(k \cdot p)$ is

$$\frac{d^2\sigma}{dx dQ^2} = \frac{4\pi\alpha}{2xQ^4} \left[(1 + (1-y)^2)F_2(x, Q^2) - y^2 F_L(x, Q^2) \right], \quad (9.11)$$

where α is the electromagnetic coupling and $F_2(x, Q^2)$ and $F_L(x, Q^2)$ are proton structure functions, which encode the interaction between the photon (in given polarization states) and the proton. In the presence of parity-violating interactions (*e.g.* νp scattering) an additional F_3 structure function is present. For an extended review, including equations for the full electroweak and polarized cases, see Sec. 18 of this *Review*.

Structure functions are not calculable in perturbative QCD, nor is any other cross section that involves initial-state hadrons. To zeroth order in α_s , the structure functions are given directly in terms of non-perturbative parton (quark or gluon) distribution functions (PDFs),

$$F_2(x, Q^2) = x \sum_q e_q^2 f_{q/p}(x), \quad F_L(x, Q^2) = 0, \quad (9.12)$$

^{††} The situation is significantly worse near thresholds, *e.g.* the $\bar{t}\bar{t}$ production threshold. An overview of some of the effective field theory techniques used in such cases is to be found for example in Ref. 23.

where $f_{q/p}(x)$ is the PDF for quarks of type q inside the proton, *i.e.* the number density of quarks of type q inside a fast-moving proton that carry a fraction x of its longitudinal momentum (the quark flavor index q , here, is not to be confused with the photon momentum q in the lines preceding Eq. (9.11)). Since PDFs are non-perturbative, and difficult to calculate in lattice QCD [24], they must be extracted from data.

The above result, with PDFs $f_{q/p}(x)$ that are independent of the scale Q , corresponds to the “quark-parton model” picture in which the photon interacts with point-like free quarks, or equivalently, one has incoherent elastic scattering between the electron and individual constituents of the proton. As a consequence, in this picture also F_2 and F_L are independent of Q . When including higher orders in pQCD, Eq. (9.12) becomes

$$F_2(x, Q^2) = x \sum_{n=0}^{\infty} \frac{\alpha_s^n(\mu_R^2)}{(2\pi)^n} \sum_{i=q,g} \int_x^1 \frac{dz}{z} C_{2,i}^{(n)}(z, Q^2, \mu_R^2, \mu_F^2) f_{i/p}\left(\frac{x}{z}, \mu_F^2\right) + \mathcal{O}\left(\frac{\Lambda^2}{Q^2}\right). \quad (9.13)$$

Just as in Eq. (9.10), we have a series in powers $\alpha_s(\mu_R^2)$, each term involving a coefficient $C_{2,i}^{(n)}$ that can be calculated using Feynman graphs. An important difference relative to Eq. (9.10) stems from the fact that the quark’s momentum, when it interacts with the photon, can differ from its momentum when it was extracted from the proton, because it may have radiated gluons in between. As a result, the $C_{2,i}^{(n)}$ coefficients are functions that depend on the ratio, z , of these two momenta, and one must integrate over z . At zeroth order, $C_{2,q}^{(0)} = e_q^2 \delta(1-z)$ and $C_{2,g}^{(0)} = 0$.

The majority of the emissions that modify a parton’s momentum are collinear (parallel) to that parton, and don’t depend on the fact that the parton is destined to interact with a photon. It is natural to view these emissions as modifying the proton’s structure rather than being part of the coefficient function for the parton’s interaction with the photon. Technically, one uses a procedure known as *collinear factorization* to give a well-defined meaning to this distinction, most commonly through the $\overline{\text{MS}}$ factorization scheme, defined in the context of dimensional regularization. The $\overline{\text{MS}}$ factorization scheme involves an arbitrary choice of *factorization scale*, μ_F , whose meaning can be understood roughly as follows: emissions with transverse momenta above μ_F are included in the $C_{2,q}^{(n)}(z, Q^2, \mu_R^2, \mu_F^2)$; emissions with transverse momenta below μ_F are accounted for within the PDFs, $f_{i/p}(x, \mu_F^2)$. While collinear factorization is generally believed to be valid for suitable (sufficiently inclusive) observables in processes with hard scales, Ref. 35, which reviews the factorization proofs in detail, is cautious in the statements it makes about their exhaustivity, notably for the hadron-collider processes that we shall discuss below. Further discussion is to be found in Refs. 36,37.

The PDFs’ resulting dependence on μ_F is described by the Dokshitzer-Gribov-Lipatov-Altarelli-Parisi (DGLAP) equations [25], which to leading order (LO) read*

$$\mu^2 \frac{\partial f_{i/p}(x, \mu_F^2)}{\partial \mu_F^2} = \sum_j \frac{\alpha_s(\mu_F^2)}{2\pi} \int_x^1 \frac{dz}{z} P_{i \leftarrow j}^{(1)}(z) f_{j/p}\left(\frac{x}{z}, \mu_F^2\right), \quad (9.14)$$

with, for example, $P_{q \leftarrow g}^{(1)}(z) = T_R(z^2 + (1-z)^2)$. The other LO splitting functions are listed in Sec. 18 of this *Review*, while results up

* LO is generally taken to mean the lowest order at which a quantity is non-zero. This definition is nearly always unambiguous, the one major exception being for the case of the hadronic branching ratio of virtual photons, Z , τ , etc., for which two conventions exist: LO can either mean the lowest order that contributes to the hadronic branching fraction, *i.e.* the term “1” in Eq. (9.7); or it can mean the lowest order at which the hadronic branching ratio becomes sensitive to the coupling, $n = 1$ in Eq. (9.8), as is relevant when extracting the value of the coupling from a measurement of the branching ratio. Because of this ambiguity, we avoided use of the term “LO” in that context.

to next-to-leading order (NLO), α_s^2 , and next-to-next-to-leading order (NNLO), α_s^3 , are given in Refs. 26 and 27 respectively. The coefficient functions are also μ_F dependent, for example $C_{2,i}^{(1)}(x, Q^2, \mu_R^2, \mu_F^2) = C_{2,i}^{(1)}(x, Q^2, \mu_R^2, Q^2) - \ln\left(\frac{\mu_F^2}{Q^2}\right) \sum_j \int_x^1 \frac{dz}{z} C_{2,j}^{(0)}\left(\frac{x}{z}\right) P_{j \leftarrow i}^{(1)}(z)$. For the electromagnetic component of DIS with light quarks and gluons they are known to $\mathcal{O}(\alpha_s^3)$ (N³LO) [28]. For weak currents they are known fully to α_s^2 (NNLO) [29] with substantial results known also at N³LO [30]. For heavy quark production they are known to $\mathcal{O}(\alpha_s^2)$ [31] (NLO insofar as the series starts at $\mathcal{O}(\alpha_s)$), with work ongoing towards NNLO [32,33].

As with the renormalization scale, the choice of factorization scale is arbitrary, but if one has an infinite number of terms in the perturbative series, the μ_F -dependences of the coefficient functions and PDFs will compensate each other fully. Given only N terms of the series, a residual $\mathcal{O}(\alpha_s^{N+1})$ uncertainty is associated with the ambiguity in the choice of μ_F . As with μ_R , varying μ_F provides an input in estimating uncertainties on predictions. In inclusive DIS predictions, the default choice for the scales is usually $\mu_R = \mu_F = Q$.

Hadron-hadron collisions. The extension to processes with two initial-state hadrons is straightforward, and for example the total (inclusive) cross section for W boson production in collisions of hadrons h_1 and h_2 can be written as

$$\sigma(h_1 h_2 \rightarrow W + X) = \sum_{n=0}^{\infty} \alpha_s^n(\mu_R^2) \sum_{i,j} \int dx_1 dx_2 f_{i/h_1}(x_1, \mu_F^2) f_{j/h_2}(x_2, \mu_F^2) \times \hat{\sigma}_{ij \rightarrow W+X}^{(n)}(x_1 x_2 s, \mu_R^2, \mu_F^2), \quad (9.15)$$

where s is the squared center-of-mass energy of the collision. At LO, $n = 0$, the hard (partonic) cross section $\hat{\sigma}_{ij \rightarrow W+X}^{(0)}(x_1 x_2 s, \mu_R^2, \mu_F^2)$ is simply proportional to $\delta(x_1 x_2 s - M_W^2)$, in the narrow W -boson width approximation (see Sec. 44 of this *Review* for detailed expressions for this and other hard scattering cross sections). It is non-zero only for choices of i, j that can directly give a W , such as $i = u, j = \bar{d}$. At higher orders, $n \geq 1$, new partonic channels contribute, such as gq , and there is no restriction $x_1 x_2 s = M_W^2$.

Equation 9.15 involves a collinear factorization between hard cross section and PDFs, just like Eq. (9.13). As long as the same factorization scheme is used in DIS and pp or $p\bar{p}$ (usually the $\overline{\text{MS}}$ scheme), then PDFs extracted in DIS can be directly used in pp and $p\bar{p}$ predictions [34,35] (with the anti-quark distributions in an anti-proton being the same as the quark distributions in a proton). Note that Eq. (9.15) only holds to within contributions that are suppressed by powers of m_p^2/m_W^2 .

Fully inclusive hard cross sections are known to NNLO, *i.e.* corrections up to relative order α_s^2 , for Drell-Yan (DY) lepton-pair and vector-boson production [38,39], Higgs-boson production via gluon fusion [39–41], Higgs-boson production in association with a vector boson [42] and Higgs-boson production via vector-boson fusion [43] (in an approximation that factorizes the production of the two vector bosons). A review of fully inclusive Higgs-related results is to be found in Ref. 44.

Photoproduction. γp (and $\gamma\gamma$) collisions are similar to pp collisions, with the subtlety that the photon can behave in two ways: there is “direct” photoproduction, in which the photon behaves as a point-like particle and takes part directly in the hard collision, with hard subprocesses such as $\gamma g \rightarrow q\bar{q}$; there is also resolved photoproduction, in which the photon behaves like a hadron, with non-perturbative partonic substructure and a corresponding PDF for its quark and gluon content, $f_{i/\gamma}(x, Q^2)$.

While useful to understand the general structure of γp collisions, the distinction between direct and resolved photoproduction is not well defined beyond leading order, as discussed for example in Ref. 45.

The high-energy limit. In situations in which the total center-of-mass energy \sqrt{s} is much larger than other scales in the problem (*e.g.* Q in DIS, m_b for $b\bar{b}$ production in pp collisions, etc.), each power of α_s beyond LO can be accompanied by a power of $\ln(s/Q^2)$ (or $\ln(s/m_b^2)$, etc.). This is known as the high-energy or Balitsky-Fadin-Kuraev-Lipatov (BFKL) limit [46–48]. Currently it is possible to account

for the dominant and first subdominant [49,50] power of $\ln s$ at each order of α_s , and also to estimate further subdominant contributions that are numerically large (see Refs. 51–53 and references therein).

Physically, the summation of all orders in α_s can be understood as leading to a growth with s of the gluon density in the proton. At sufficiently high energies this implies non-linear effects, whose treatment has been the subject of intense study (see for example Refs. 54, 55 and references thereto). Note that it is not straightforward to relate these results to the genuinely non-perturbative total, elastic and diffractive cross sections for hadron-hadron scattering (experimental results for which are summarized in section Chap. 46 of this *Review*).

9.2.2. Non fully inclusive cross-sections :

QCD final states always consist of hadrons, while perturbative QCD calculations deal with partons. Physically, an energetic parton fragments (“showers”) into many further partons, which then, on later timescales, undergo a transition to hadrons (“hadronization”). Fixed-order perturbation theory captures only a small part of these dynamics.

This does not matter for the fully inclusive cross sections discussed above: the showering and hadronization stages are “unitary”, *i.e.* they do not change the overall probability of hard scattering, because they occur long after it has taken place.

Less inclusive measurements, in contrast, may be affected by the extra dynamics. For those sensitive just to the main directions of energy flow (jet rates, event shapes, cf. Sec. 9.3.1) fixed order perturbation theory is often still adequate, because showering and hadronization don’t substantially change the overall energy flow. This means that one can make a prediction using just a small number of partons, which should correspond well to a measurement of the same observable carried out on hadrons. For observables that instead depend on distributions of individual hadrons (which, *e.g.*, are the inputs to detector simulations), it is mandatory to account for showering and hadronization. The range of predictive techniques available for QCD final states reflects this diversity of needs of different measurements.

While illustrating the different methods, we shall for simplicity mainly use expressions that hold for e^+e^- scattering. The extension to cases with initial-state partons will be mostly straightforward (space constraints unfortunately prevent us from addressing diffraction and exclusive hadron-production processes; extensive discussion is to be found in Refs. 56, 57).

9.2.2.1. Preliminaries: Soft and collinear limits:

Before examining specific predictive methods, it is useful to be aware of a general property of QCD matrix elements in the soft and collinear limits. Consider a squared tree-level matrix element $|M_n^2(p_1, \dots, p_n)|$ for the process $e^+e^- \rightarrow n$ partons with momenta p_1, \dots, p_n , and a corresponding phase-space integration measure $d\Phi_n$. If particle n is a gluon, and additionally it becomes collinear (parallel) to another particle i and its momentum tends to zero (it becomes “soft”), the matrix element simplifies as follows,

$$\lim_{\theta_{in} \rightarrow 0, E_n \rightarrow 0} d\Phi_n |M_n^2(p_1, \dots, p_n)| = d\Phi_{n-1} |M_{n-1}^2(p_1, \dots, p_{n-1})| \frac{\alpha_s C_i}{\pi} \frac{d\theta_{in}^2}{\theta_{in}^2} \frac{dE_n}{E_n}, \quad (9.16)$$

where $C_i = C_F$ (C_A) if i is a quark (gluon). This formula has non-integrable divergences both for the inter-parton angle $\theta_{in} \rightarrow 0$ and for the gluon energy $E_n \rightarrow 0$, which are mirrored also in the structure of divergences in loop diagrams. These divergences are important for at least two reasons: firstly, they govern the typical structure of events (inducing many emissions either with low energy or at small angle with respect to hard partons); secondly, they will determine which observables can be calculated within perturbative QCD.

9.2.2.2. Fixed-order predictions:

Let us consider an observable \mathcal{O} that is a function $\mathcal{O}_n(p_1, \dots, p_n)$ of the four-momenta of the n particles in an event (whether partons or hadrons). In what follows, we shall consider the cross section for events weighted with the value of the observable, $\sigma_{\mathcal{O}}$. As examples, if $\mathcal{O}_n \equiv 1$ for all n , then $\sigma_{\mathcal{O}}$ is just the total cross section; if $\mathcal{O}_n \equiv \hat{\tau}(p_1, \dots, p_n)$ where $\hat{\tau}$ is the value of the Thrust for that event (see Sec. 9.3.1.2), then the average value of the Thrust is $\langle \tau \rangle = \sigma_{\mathcal{O}} / \sigma_{\text{tot}}$; if $\mathcal{O}_n \equiv \delta(\tau - \hat{\tau}(p_1, \dots, p_n))$ then one gets the differential cross section as a function of the Thrust, $\sigma_{\mathcal{O}} \equiv d\sigma/d\tau$.

In the expressions below, we shall omit to write the non-perturbative power correction term, which for most common observables is proportional to a single power of Λ/Q .

LO. If the observable \mathcal{O} is non-zero only for events with at least n particles, then the LO QCD prediction for the weighted cross section in e^+e^- annihilation is

$$\sigma_{\mathcal{O},LO} = \alpha_s^{n-2} (\mu_R^2)^2 \int d\Phi_n |M_n^2(p_1, \dots, p_n)| \mathcal{O}_n(p_1, \dots, p_n), \quad (9.17)$$

where the squared tree-level matrix element, $|M_n^2(p_1, \dots, p_n)|$, includes relevant symmetry factors, has been summed over all subprocesses (*e.g.* $e^+e^- \rightarrow q\bar{q}q\bar{q}$, $e^+e^- \rightarrow q\bar{q}gg$) and has had all factors of α_s extracted in front. In processes other than e^+e^- collisions, the powers of the coupling are often brought inside the integrals, with the scale μ_R chosen event by event, as a function of the event kinematics.

Other than in the simplest cases (see the review on Cross Sections in this *Review*), the matrix elements in Eq. (9.17) are usually calculated automatically with programs such as CompHEP [58], MadGraph [59], Alpgen [60], Comix/Sherpa [61], and Helac/Phegas [62]. Some of these (CompHEP, MadGraph) use formulas obtained from direct evaluations of Feynman diagrams. Others (Alpgen, Helac/Phegas and Comix/Sherpa) use methods designed to be particularly efficient at high multiplicities, such as Berends-Giele recursion [63] (see also the reviews [64,65]), which builds up amplitudes for complex processes from simpler ones.

The phase-space integration is usually carried out by Monte Carlo sampling, in order to deal with the sometimes complicated cuts that are used in corresponding experimental measurements. Because of the divergences in the matrix element, Eq. (9.16), the integral converges only if the observable vanishes for kinematic configurations in which one of the n particles is arbitrarily soft or it is collinear to another particle. As an example, the cross section for producing any configuration of n partons will lead to an infinite integral, whereas a finite result will be obtained for the cross section for producing n deposits of energy (or jets, see Sec. 9.3.1.1), each above some energy threshold and well separated from each other in angle.

LO calculations can be carried out for $2 \rightarrow n$ processes with $n \lesssim 6-10$. The exact upper limit depends on the process, the method used to evaluate the matrix elements (recursive methods are more efficient), and the extent to which the phase-space integration can be optimized to work around the large variations in the values of the matrix elements.

NLO. Given an observable that is non-zero starting from n particles, its prediction at NLO involves supplementing the LO result with the $(n+1)$ -particle tree-level matrix element ($|M_{n+1}^2|$), and the interference of a n -particle tree-level and n -particle 1-loop amplitude ($2\text{Re}(M_n M_{n,1\text{-loop}}^*)$),

$$\begin{aligned} \sigma_{\mathcal{O}}^{NLO} &= \sigma_{\mathcal{O}}^{LO} + \alpha_s^{n-1} (\mu_R^2) \int d\Phi_{n+1} \\ &|M_{n+1}^2(p_1, \dots, p_{n+1})| \mathcal{O}_{n+1}(p_1, \dots, p_{n+1}) \\ &+ \alpha_s^{n-1} (\mu_R^2) \int d\Phi_n 2\text{Re}[M_n(p_1, \dots, p_n) \\ &M_{n,1\text{-loop}}^*(p_1, \dots, p_n)] \mathcal{O}_n(p_1, \dots, p_n). \end{aligned} \quad (9.18)$$

Relative to LO calculations, two important issues appear in the NLO calculations. Firstly, the extra complexity of loop-calculations relative to tree-level calculations means that their automation is at a comparatively early stage (see below). Secondly, loop amplitudes

are infinite in 4 dimensions, while tree-level amplitudes are finite, but their *integrals* are infinite, due to the divergences of Eq. (9.16). These two sources of infinities have the same soft and collinear origins and cancel after the integration only if the observable \mathcal{O} satisfies the property of infrared and collinear safety,

$$\begin{aligned} \mathcal{O}_{n+1}(p_1, \dots, p_s, \dots, p_n) &\rightarrow \mathcal{O}_n(p_1, \dots, p_n) && \text{if } p_s \rightarrow 0 \\ \mathcal{O}_{n+1}(p_1, \dots, p_a, p_b, \dots, p_n) &\rightarrow \mathcal{O}_n(p_1, \dots, p_a + p_b, \dots, p_n) \\ &&& \text{if } p_a \parallel p_b. \end{aligned} \quad (9.19)$$

Examples of infrared safe quantities include event-shape distributions and jet cross sections (with appropriate jet algorithms, see below). Unsafe quantities include the distribution of the momentum of the hardest QCD particle (which is not conserved under collinear splitting), observables that require the complete absence of radiation in some region of phase-space (e.g. rapidity gaps or 100% isolation cuts, which are affected by soft emissions), or the particle multiplicity (affected by both soft and collinear emissions). The non-cancellation of divergences at NLO due to infrared or collinear unsafety compromises the usefulness not only of the NLO calculation, but also that of a LO calculation, since LO is only an acceptable approximation if one can prove that higher order terms are smaller. Infrared and collinear unsafety usually also imply large non-perturbative effects.

As with LO calculations, the phase-space integrals in Eq. (9.18) are usually carried out by Monte Carlo integration, so as to facilitate the study of arbitrary observables. Various methods exist to obtain numerically efficient cancellation among the different infinities. These include notably dipole [66], FKS [67] and antenna [68] subtraction.

NLO calculations have existed for a while for a wide range of $2 \rightarrow n$ processes with $n \leq 3$, as reviewed in Ref. 69. Some of the corresponding codes are public, and those that provide access to multiple processes include NLOJet++ [70] for e^+e^- , DIS, and hadron-hadron processes involving just light partons in the final state, MCFM [71] for hadron-hadron processes with vector bosons and/or heavy quarks in the final state, VBFNLO for vector-boson fusion, di- and tri-boson processes [72], and the Phox family [73] for processes with photons in the final state. One forefront of NLO calculations is $2 \rightarrow 4$ and $2 \rightarrow 5$ processes in pp scattering (and for $1 \rightarrow 5$ in $e^+e^- \rightarrow \gamma/Z \rightarrow \text{hadrons}$ [74]), where recent results include $t\bar{t}b\bar{b}$ [80,81], $t\bar{t}+2\text{jets}$ [82] and $b\bar{b}b\bar{b}$ [83], $pp \rightarrow W/Z+3\text{jets}$ [75,76,77] and $pp \rightarrow W/Z+4\text{jets}$ [78,79] as well as $W^+W^-b\bar{b}$ [84] and $W^+W^\pm+2\text{jets}$ [85]. A related forefront is automation: a number of the above results have been obtained with partially automated approaches. A first example of full automation applied to a large number of processes has been presented recently in Ref. 86, and a public automated code is described in Ref. 87. A number of the above calculations have made use of unitarity-type techniques [88] and powerful integrand reduction methods (notably Ref. 89), which have seen significant development over the past few years, as reviewed in Refs. 65,90.

NNLO. Conceptually, NNLO and NLO calculations are similar, except that one must add a further order in α_s , consisting of: the squared $(n+2)$ -parton tree-level amplitude, the interference of the $(n+1)$ -parton tree-level and 1-loop amplitudes, the interference of the n -parton tree-level and 2-loop amplitudes, and the squared n -parton 1-loop amplitude.

Each of these elements involves large numbers of soft and collinear divergences, satisfying relations analogous to Eq. (9.16) that now involve multiple collinear or soft particles and higher loop orders (see e.g. Refs. 88,91,92). Arranging for the cancellation of the divergences after numerical Monte Carlo integration is one of the significant challenges of NNLO calculations, as is the determination of the relevant 2-loop amplitudes. At the time of writing, the processes for which fully exclusive NNLO calculations exist include the 3-jet cross section in e^+e^- collisions [93,94] (for which NNLO means α_s^3), as well as vector-boson [95,96], Higgs-boson [97,98], WH [99] and di-photon [100] production in pp and $p\bar{p}$ collisions.

9.2.2.3. Resummation:

Many experimental measurements place tight constraints on emissions in the final state, for example, in e^+e^- events, that one minus the Thrust should be less than some value $\tau \ll 1$, or in $pp \rightarrow Z$ events that the Z -boson transverse momentum should be much smaller than its mass, $p_{t,Z} \ll M_Z$. A further example is the production of heavy particles or jets near threshold (so that little energy is left over for real emissions) in DIS and pp collisions.

In such cases, the constraint vetoes a significant part of the integral over the soft and collinear divergence of Eq. (9.16). As a result, there is only a partial cancellation between real emission terms (subject to the constraint) and loop (virtual) contributions (not subject to the constraint), causing each order of α_s to be accompanied by a large coefficient $\sim L^2$, where e.g. $L = \ln \tau$ or $L = \ln(M_Z/p_{t,Z})$. One ends up with a perturbative series whose terms go as $\sim (\alpha_s L^2)^n$. It is not uncommon that $\alpha_s L^2 \gg 1$, so that the perturbative series converges very poorly if at all.** In such cases one may carry out a “resummation,” which accounts for the dominant logarithmically enhanced terms to all orders in α_s , by making use of known properties of matrix elements for multiple soft and collinear emissions, and of the all-orders properties of the divergent parts of virtual corrections, following original works such as Refs. 101–110 and also through soft-collinear effective theory [111,112] (cf. also the review in Ref. 113).

For cases with double logarithmic enhancements (two powers of logarithm per power of α_s), there are two classification schemes for resummation accuracy. Writing the cross section including the constraint as $\sigma(L)$ and the unconstrained (total) cross section as σ_{tot} , the series expansion takes the form

$$\sigma(L) \simeq \sigma_{\text{tot}} \sum_{n=0}^{\infty} \sum_{k=0}^{2n} R_{nk} \alpha_s^n (\mu_R^2)^k L^k, \quad L \gg 1 \quad (9.20)$$

and leading log (LL) resummation means that one accounts for all terms with $k = 2n$, next-to-leading-log (NLL) includes additionally all terms with $k = 2n - 1$, etc. Often $\sigma(L)$ (or its Fourier or Mellin transform) *exponentiates* †,

$$\sigma(L) \simeq \sigma_{\text{tot}} \exp \left[\sum_{n=1}^{\infty} \sum_{k=0}^{n+1} G_{nk} \alpha_s^n (\mu_R^2)^k L^k \right], \quad L \gg 1, \quad (9.21)$$

where one notes the different upper limit on k ($\leq n+1$) compared to Eq. (9.20). This is a more powerful form of resummation: the G_{12} term alone reproduces the full LL series in Eq. (9.20). With the form Eq. (9.21) one still uses the nomenclature LL, but this now means that all terms with $k = n+1$ are included, and NLL implies all terms with $k = n$, etc.

For a large number of observables, NLL resummations are available in the sense of Eq. (9.21) (see Refs. 117–119 and references therein). NNLL has been achieved for the DY and Higgs-boson p_t distributions [120,121,122,123] (in addition the NLL ResBos program [124] is still widely used), the back-to-back energy-energy correlation in e^+e^- [125], the production of top anti-top pairs near threshold [126–128] (and references therein), high- p_t W and Z production [129], and an event-shape type observable known as the beam Thrust [130]. Finally, the parts believed to be dominant in the N³LL resummation are available for the Thrust variable and

** To be precise one should distinguish two causes of the divergence of perturbative series. That which interests us here is associated with the presence of a new large parameter (e.g. ratio of scales). Nearly all perturbative series also suffer from “renormalon” divergences $\alpha_s^n n!$ (reviewed in Ref. 16), which however have an impact only at very high perturbative orders and have a deep connection with non-perturbative uncertainties.

† Whether or not this happens depends on the quantity being resummed. A classic example involves jet rates in e^+e^- collisions as a function of a jet-resolution parameter y_{cut} . The logarithms of $1/y_{\text{cut}}$ exponentiate for the k_t (Durham) jet algorithm [114], but not [115] for the JADE algorithm [116] (both are discussed below in Sec. 9.3.1.1).

heavy-jet mass in e^+e^- annihilations [131,132] (confirmed for Thrust at NNLL in Ref. 133), and for Higgs- and vector-boson production near threshold [134,135] in hadron collisions (NNLL in Refs. 136,137). The inputs and methods involved in these various calculations are somewhat too diverse to discuss in detail here, so we recommend that the interested reader consult the original references for further details.

9.2.2.4. Fragmentation functions:

Since the parton-hadron transition is non-perturbative, it is not possible to perturbatively calculate quantities such as the energy-spectra of specific hadrons in high-energy collisions. However, one can factorize perturbative and non-perturbative contributions via the concept of fragmentation functions. These are the final-state analogue of the parton distribution functions that are used for initial-state hadrons.

It should be added that if one ignores the non-perturbative difficulties and just calculates the energy and angular spectrum of partons in perturbative QCD with some low cutoff scale $\sim \Lambda$ (using resummation to sum large logarithms of \sqrt{s}/Λ), then this reproduces many features of the corresponding hadron spectra. This is often taken to suggest that hadronization is “local” in momentum space.

Sec. 19 of this *Review* provides further information (and references) on these topics, including also the question of heavy-quark fragmentation.

9.2.2.5. Parton-shower Monte Carlo generators:

Parton-shower Monte Carlo (MC) event generators like PYTHIA [138–140], HERWIG [141–143], SHERPA [144], and ARIADNE [145] provide fully exclusive simulations of QCD events. Because they provide access to “hadron-level” events they are a crucial tool for all applications that involve simulating the response of detectors to QCD events. Here we give only a brief outline of how they work and refer the reader to Chap. 38 and Ref. 146 for a full overview.

The MC generation of an event involves several stages. It starts with the random generation of the kinematics and partonic channels of whatever *hard scattering process* the user has requested at some high scale Q_0 . This is followed by a *parton shower*, usually based on the successive random generation of gluon emissions (or $g \rightarrow q\bar{q}$ splittings). Each is generated at a scale lower than the previous emission, following a (soft and collinear resummed) perturbative QCD distribution that depends on the momenta of all previous emissions. Common choices of scale for the ordering of emissions are virtuality, transverse momentum or angle. Parton showering stops at a scale of order 1 GeV, at which point a *hadronization model* is used to convert the resulting partons into hadrons. One widely-used model involves stretching a color “string” across quarks and gluons, and breaking it up into hadrons [147,148]. Another breaks each gluon into a $q\bar{q}$ pair and then groups quarks and anti-quarks into colorless “clusters”, which then give the hadrons [141]. For pp and γp processes, modeling is also needed to treat the collision between the two hadron remnants, which generates an *underlying event* (UE), usually implemented via additional $2 \rightarrow 2$ scatterings (“multiple parton interactions”) at a scale of a few GeV, following Ref. 149.

A deficiency of the soft and collinear approximations that underlie parton showers is that they may fail to reproduce the full pattern of hard wide-angle emissions, important, for example, in many new physics searches. It is therefore common to use LO multi-parton matrix elements to generate hard high-multiplicity partonic configurations as additional starting points for the showering, supplemented with some prescription (CKKW [150], MLM [151]) for consistently merging samples with different initial multiplicities.

MCs, as described above, generate cross sections for the requested hard process that are correct at LO. For a number of processes there also exist MC implementations that are correct to NLO, using the MC@NLO [152] or POWHEG [153] prescriptions. Techniques also exist to combine NLO accuracy for a low order process, with LO accuracy for higher multiplicity processes [154,155].

9.2.3. Accuracy of predictions :

Estimating the accuracy of perturbative QCD predictions is not an exact science. It is often said that LO calculations are accurate to within a factor of two. This is based on experience with NLO corrections in the cases where these are available. In processes involving new partonic scattering channels at NLO and/or large ratios of scales (such as the production of high- p_t jets containing B -hadrons), the NLO to LO K -factors can be substantially larger than 2.

For calculations beyond LO, a conservative approach to estimate the perturbative uncertainty is to take it to be the last known perturbative order; a more widely used method is to estimate it from the change in the prediction when varying the renormalization and factorization scales around a central value Q that is taken close to the physical scale of the process. A conventional range of variation is $Q/2 < \mu_R, \mu_F < 2Q$, however this should not be assumed to give uncertainty estimates of guaranteed reliability.††

There does not seem to be a broad consensus on whether μ_R and μ_F should be kept identical or varied independently. One option is to vary them independently with the restriction $\frac{1}{2}\mu_R < \mu_F < 2\mu_R$ [160]. This limits the risk of misleadingly small uncertainties due to fortuitous cancellations between the μ_F and μ_R dependence when both are varied together, while avoiding the appearance of large logarithms of μ_R^2/μ_F^2 when both are varied completely independently.

Calculations that involve resummations usually have an additional source of uncertainty associated with the choice of argument of the logarithms being resummed, e.g. $\ln(2\frac{p_{t,Z}}{M_Z})$ as opposed to $\ln(\frac{1}{2}\frac{p_{t,Z}}{M_Z})$. In addition to varying renormalization and factorization scales, it is therefore also advisable to vary the argument of the logarithm by a factor of two in either direction with respect to the “natural” argument.

The accuracy of QCD predictions is limited also by non-perturbative corrections, which typically scale as a power of Λ/Q . For measurements that are directly sensitive to the structure of the hadronic final state the corrections are usually linear in Λ/Q . The non-perturbative corrections are further enhanced in processes with a significant underlying event (*i.e.* in pp and $p\bar{p}$ collisions) and in cases where the perturbative cross sections fall steeply as a function of p_t or some other kinematic variable.

Non-perturbative corrections are commonly estimated from the difference between Monte Carlo events at the parton level and after hadronization. An issue to be aware of with this procedure is that “parton level” is not a uniquely defined concept. For example, in an event generator it depends on a (somewhat arbitrary and tunable) internal cutoff scale that separates the parton showering from the hadronization. In contrast no such cutoff scale exists in a NLO or NNLO partonic calculation. For this reason there are widespread reservations as to the appropriateness of deriving hadronization corrections from a Monte Carlo program and then applying them to NLO or NNLO prediction. There exist alternative methods for estimating hadronization corrections, which attempt to analytically deduce non-perturbative effects in one observable based on measurements of other observables (see the reviews [16,161]). While they directly address the problem of different possible definitions of parton level, it should also be said that they are far less flexible than Monte Carlo programs and not always able to provide equally good descriptions of the data.

9.3. Experimental QCD

Since we are not able to directly measure partons (quarks or gluons), but only hadrons and their decay products, a central issue for every experimental test of QCD is establishing a correspondence between observables obtained at the partonic and the hadronic level. The only theoretically sound correspondence is achieved by means of *infrared and collinear safe* quantities, which allow one to obtain finite predictions at any order of perturbative QCD.

†† A number of prescriptions also exist for setting the scale automatically, e.g. Refs. 156–159, eliminating uncertainties from scale variation, though not from the truncation of the perturbative series itself.

As stated above, the simplest case of infrared and collinear safe observables are total cross sections. More generally, when measuring fully inclusive observables, the final state is not analyzed at all regarding its (topological, kinematical) structure or its composition. Basically the relevant information consists in the rate of a process ending up in a partonic or hadronic final state. In e^+e^- annihilation, widely used examples are the ratios of partial widths or branching ratios for the electroweak decay of particles into hadrons or leptons, such as Z or τ decays, (cf. Sec. 9.2.1). Such ratios are often favored over absolute cross sections or partial widths because of large cancellations of experimental and theoretical systematic uncertainties. The strong suppression of non-perturbative effects, $\mathcal{O}(\Lambda^4/Q^4)$, is one of the attractive features of such observables, however, at the same time the sensitivity to radiative QCD corrections is small, which for example affects the statistical uncertainty when using them for the determination of the strong coupling constant. In the case of τ decays not only the hadronic branching ratio is of interest, but also moments of the spectral functions of hadronic tau decays, which sample different parts of the decay spectrum and thus provide additional information. Other examples of fully inclusive observables are structure functions (and related sum rules) in DIS. These are extensively discussed in Sec. 18 of this *Review*.

On the other hand, often the structure or composition of the final state are analyzed and cross sections differential in one or more variables characterizing this structure are of interest. Examples are jet rates, jet substructure, event shapes or transverse momentum distributions of jets or vector bosons in hadron collisions. The case of fragmentation functions, *i.e.* the measurement of hadron production as a function of the hadron momentum relative to some hard scattering scale, is discussed in Sec. 19 of this *Review*.

It is worth mentioning that, besides the correspondence between the parton and hadron level, also a correspondence between the hadron level and the actually measured quantities in the detector has to be established. The simplest examples are corrections for finite experimental acceptance and efficiencies. Whereas acceptance corrections essentially are of theoretical nature, since they involve extrapolations from the measurable (partial) to the full phase space, other corrections such as for efficiency, resolution and response, are of experimental nature. For example, measurements of differential cross sections such as jet rates require corrections in order to relate, *e.g.* the energy deposits in a calorimeter to the jets at the hadron level. Typically detector simulations and/or data driven methods are used in order to obtain these corrections. Care should be taken here in order to have a clear separation between the parton-to-hadron level and hadron-to-detector level corrections. Finally, for the sake of an easy comparison to the results of other experiments and/or theoretical calculations, it is suggested to provide, whenever possible, measurements corrected for detector effects and/or all necessary information related to the detector response (*e.g.* the detector response matrix).

9.3.1. Hadronic final-state observables :

9.3.1.1. Jets:

In hard interactions, final-state partons and hadrons appear predominantly in collimated bunches. These bunches are generically called *jets*. To a first approximation, a jet can be thought of as a hard parton that has undergone soft and collinear showering and then hadronization. Jets are used both for testing our understanding and predictions of high-energy QCD processes, and also for identifying the hard partonic structure of decays of massive particles like top quarks.

In order to map observed hadrons onto a set of jets, one uses a *jet definition*. The mapping involves explicit choices: for example when a gluon is radiated from a quark, for what range of kinematics should the gluon be part of the quark jet, or instead form a separate jet? Good jet definitions are infrared and collinear safe, simple to use in theoretical and experimental contexts, applicable to any type of inputs (parton or hadron momenta, charged particle tracks, and/or energy deposits in the detectors) and lead to jets that are not too sensitive to non-perturbative effects. An extensive treatment of the topic of jet definitions is given in Ref. 162 (for e^+e^- collisions) and Refs. 163, 164 (for pp or $p\bar{p}$ collisions). Here we briefly review the two main

classes: cone algorithms, extensively used at older hadron colliders, and sequential recombination algorithms, more widespread in e^+e^- and ep colliders and at the LHC.

Very generically, most (iterative) cone algorithms start with some seed particle i , sum the momenta of all particles j within a cone of opening-angle R , typically defined in terms of (pseudo-)rapidity and azimuthal angle. They then take the direction of this sum as a new seed and repeat until the cone is stable, and call the contents of the resulting stable cone a jet if its transverse momentum is above some threshold $p_{t,\min}$. The parameters R and $p_{t,\min}$ should be chosen according to the needs of a given analysis.

There are many variants of cone algorithm, and they differ in the set of seeds they use and the manner in which they ensure a one-to-one mapping of particles to jets, given that two stable cones may share particles (“overlap”). The use of seed particles is a problem w.r.t. infrared and collinear safety, and seeded algorithms are generally not compatible with higher-order (or sometimes even leading-order) QCD calculations, especially in multi-jet contexts, as well as potentially subject to large non-perturbative corrections and instabilities. Seeded algorithms (JetCLU, MidPoint, and various other experiment-specific iterative cone algorithms) are therefore to be deprecated. A modern alternative is to use a seedless variant, SIScone [165].

Sequential recombination algorithms at hadron colliders (and in DIS) are characterized by a distance $d_{ij} = \min(k_{t,i}^{2p}, k_{t,j}^{2p}) \Delta_{ij}^2 / R^2$ between all pairs of particles i, j , where Δ_{ij} is their distance in the rapidity-azimuthal plane, $k_{t,i}$ is the transverse momentum w.r.t. the incoming beams, and R is a free parameter. They also involve a “beam” distance $d_{iB} = k_{t,i}^{2p}$. One identifies the smallest of all the d_{ij} and d_{iB} , and if it is a d_{ij} , then i and j are merged into a new pseudo-particle (with some prescription, a recombination scheme, for the definition of the merged four-momentum). If the smallest distance is a d_{iB} , then i is removed from the list of particles and called a jet. As with cone algorithms, one usually considers only jets above some transverse-momentum threshold $p_{t,\min}$. The parameter p determines the kind of algorithm: $p = 1$ corresponds to the (*inclusive*-) k_t algorithm [114,166,167], $p = 0$ defines the *Cambridge-Aachen* algorithm [168,169], while for $p = -1$ we have the *anti- k_t* algorithm [170]. All these variants are infrared and collinear safe to all orders of perturbation theory. Whereas the former two lead to irregularly shaped jet boundaries, the latter results in cone-like boundaries. The *anti- k_t* algorithm has become the de-facto standard for the LHC experiments.

In e^+e^- annihilations the k_t algorithm [114] uses $y_{ij} = 2 \min(E_i^2, E_j^2) (1 - \cos \theta_{ij}) / Q^2$ as distance measure and repeatedly merges the pair with smallest y_{ij} , until all y_{ij} distances are above some threshold y_{cut} , the jet resolution parameter. The (pseudo)-particles that remain at this point are called the jets. Here it is y_{cut} (rather than R and $p_{t,\min}$) that should be chosen according to the needs of the analysis. As mentioned above, the k_t algorithm has the property that logarithms $\ln(1/y_{\text{cut}})$ exponentiate in resummation calculations. This is one reason why it is preferred over the earlier JADE algorithm [116], which uses the distance measure $y_{ij} = 2 E_i E_j (1 - \cos \theta_{ij}) / Q^2$.

Efficient implementations of the above algorithms are available through the *FastJet* package [171], which is also packaged within *SpartyJet* [172].

9.3.1.2. Event Shapes:

Event-shape variables are functions of the four momenta in the hadronic final state that characterize the topology of an event’s energy flow. They are sensitive to QCD radiation (and correspondingly to the strong coupling) insofar as gluon emission changes the shape of the energy flow.

The classic example of an event shape is the *Thrust* [173,174] in e^+e^- annihilations, defined as

$$\hat{\tau} = \max_{\vec{n}_\tau} \frac{\sum_i |\vec{p}_i \cdot \vec{n}_\tau|}{\sum_i |\vec{p}_i|}, \quad (9.22)$$

where \vec{p}_i are the momenta of the particles or the jets in the final-state and the maximum is obtained for the Thrust axis \vec{n}_τ . In the Born

limit of the production of a perfect back-to-back $q\bar{q}$ pair the limit $\hat{\tau} \rightarrow 1$ is obtained, whereas a perfectly symmetric many-particle configuration leads to $\hat{\tau} \rightarrow 1/2$. Further event shapes of similar nature have been defined and extensively measured at LEP and at HERA, and for their definitions and reviews we refer to Refs. 3,4,161,175,176. Phenomenological discussions of event shapes at hadron colliders can be found in Refs. 177–179. Very recently, measurements of hadronic event-shape distributions have been published by CDF [180] and CMS [181].

Event shapes are used for many purposes. These include measuring the strong coupling, tuning the parameters of Monte Carlo programs, investigating analytical models of hadronization and distinguishing QCD events from events that might involve decays of new particles (giving event-shape values closer to the spherical limit).

9.3.1.3. Jet substructure, quark vs. gluon jets:

Jet substructure, which can be resolved by finding subjets or by measuring jet shapes, is sensitive to the details of QCD radiation in the shower development inside a jet and has been extensively used to study differences in the properties of quark and gluon induced jets, strongly related to their different color charges. In general there is clear experimental evidence that gluon jets are “broader” and have a softer particle spectrum than (light-) quark jets, whereas b-quark jets are similar to gluon jets. As an example of an observable, the jet shape $\Psi(r/R)$ is the fractional transverse momentum contained within a sub-cone of cone-size r for jets of cone-size R . It is sensitive to the relative fractions of quark and gluon jets in an inclusive jet sample and receives contributions from soft-gluon initial-state radiation and beam remnant-remnant interactions. Therefore, it has been widely employed for validation and tuning of Monte Carlo models. CDF has measured the jet shape $\Psi(r/R)$ for an inclusive jet sample [182] as well as for b-jets [183]. Similar measurements in photo-production and DIS at HERA have been reported in Refs. 184–186. First measurements at the LHC have been presented by ATLAS [187]. Further discussions, references and recent summaries can be found in Refs. 176, 188 and Sec. 4 of Ref. 189.

The use of jet substructure has also been suggested in order to distinguish QCD jets from jets that originate from hadronic decays of boosted massive particles (high- p_t electroweak bosons, top quarks and hypothesized new particles). For reviews and detailed references, see Ref. 189 and sec. 5.3 of Ref. 163.

9.3.2. State of the art QCD measurements at colliders :

There exists an enormous wealth of data on QCD-related measurements in e^+e^- , ep , pp , and $p\bar{p}$ collisions, to which a short overview like this would not be able to do any justice. Extensive reviews of the subject have been published in Refs. 175, 176 for e^+e^- colliders, whereas for hadron colliders comprehensive overviews are given in Refs. 164, 190, and recent summaries can be found in, *e.g.* Refs. 191–194. Below we concentrate our discussion on measurements that are most sensitive to hard QCD processes, in particular jet production.

9.3.2.1. e^+e^- colliders: Analyses of jet production in e^+e^- collisions are mostly based on JADE data at center-of-mass energies between 14 and 44 GeV, as well as on LEP data at the Z resonance and up to 209 GeV. They cover the measurements of (differential or exclusive) jet rates (with multiplicities typically up to 4, 5 or 6 jets), the study of 3-jet events and particle production between the jets as a tool for testing hadronization models, as well as 4-jet production and angular correlations in 4-jet events. The latter are useful for measurements of the strong coupling constant and putting constraints on the QCD color factors, thus probing the non-abelian nature of QCD. There have also been extensive measurements of event shapes. The tuning of parton shower MC models, typically matched to matrix elements for 3-jet production, has led to good descriptions of the available, highly precise data. Especially for the large LEP data sample at the Z peak, the statistical errors are mostly negligible and the experimental systematic uncertainties are at the per-cent level or even below. These are usually dominated by the uncertainties related to the MC model dependence of the efficiency and acceptance corrections (often referred to as “detector corrections”).

9.3.2.2. DIS and photoproduction: Multi-jet production in ep collisions at HERA, both in the DIS and photoproduction regime, allows for tests of QCD factorization (one initial-state proton and its associated PDF versus the hard scattering which leads to high- p_t jets) and NLO calculations which exist for 2- and 3-jet final states. Sensitivity is also obtained to the product of the coupling constant and the gluon PDF. By now experimental uncertainties of the order of 5–10% have been achieved, mostly dominated by jet energy scale uncertainties, whereas statistical errors are negligible to a large extent. For comparison to theoretical predictions, at large jet p_t the PDF uncertainty dominates the theoretical error (typically of order 5–10%, in some regions of phase-space up to 20%), therefore jet observables become useful inputs for PDF fits. In general, for Q^2 above $\sim 100 \text{ GeV}^2$ the data are well described by NLO matrix element calculations, combined with DGLAP evolution equations. Results at lower values ($Q^2 < 100 \text{ GeV}^2$) point to the necessity of including NNLO effects. Also, at low values of Q^2 and x , in particular for large jet pseudo-rapidities, there are indications for the need of BFKL-type evolution, though the predictions for such schemes are still limited. In the case of photoproduction, the data-theory comparisons are hampered by the uncertainties related to the photon PDF.

A few examples of recent measurements can be found in Refs. 195–200 for DIS and in Refs. 201–205 for photoproduction.

9.3.2.3. Hadron colliders: Jet measurements at the TEVATRON have been published for data samples up to $\sim 2 \text{ fb}^{-1}$. Also, first results from the LHC have become available, for a center-of-mass energy of 7 TeV and sample sizes of up to $\sim 36 \text{ pb}^{-1}$. Among the most important cross sections measured is the inclusive jet production as a function of the jet transverse energy (E_t) or the jet transverse momentum (p_t), for several rapidity regions and for p_t up to 700 GeV at the TEVATRON and $\sim 1 \text{ TeV}$ at the LHC. The TEVATRON experiments have measurements based on the infrared- and collinear-safe k_t algorithm in addition to the more widely used Midpoint and JetCLU algorithms of the past, whereas the LHC experiments focus on the *anti- k_t* algorithm. Results by the CDF and D0 collaborations can be found in Refs. 206–208, whereas first measurements of ATLAS and CMS have been published in Refs. 209 and 210, respectively. In general we observe a good description of the data by the NLO QCD predictions. The experimental systematic uncertainties are dominated by the jet energy scale error, by now quoted to be in the range of 1 to 3% and thus leading to uncertainties of 10 to 60% on the cross section, increasing with p_t . The PDF uncertainties dominate the theoretical error. In fact, inclusive jet data are important inputs to global PDF fits, in particular for constraining the high- x gluon PDF.

A rather comprehensive summary, comparing NLO QCD predictions to data for inclusive jet production in DIS, pp , and $p\bar{p}$ collisions, is given in Ref. 211 and reproduced here in Fig. 9.1.

Dijet events are analyzed in terms of their invariant mass and angular distributions, which allow one to put stringent limits on deviations from the Standard Model, such as quark compositeness (some recent examples can be found in Refs. 212–217). Furthermore, dijet azimuthal correlations between the two leading jets, normalized to the total dijet cross section, are an extremely valuable tool for studying the spectrum of gluon radiation in the event. For example, results from the TEVATRON [218] and the LHC [219,220] show that the LO (non-trivial) prediction for this observable, with at most three partons in the final state, is not able to describe the data for an azimuthal separation below $2\pi/3$, where NLO contributions (with 4 partons) restore the agreement with data. In addition, this observable can be employed to tune Monte Carlo predictions of soft gluon radiation. Beyond dijet final states, recently measurements of the production of three or more jets have been performed [221–223], as a means of testing perturbative QCD predictions, tuning MC models, constraining PDFs or determining the strong coupling constant.

Similarly important tests of QCD arise from measurements of vector boson (photon, W , Z) production together with jets. A recent analysis of photon+jet production by D0 [224] indicates that NLO calculations, combined with modern PDF sets, are unable to describe the shape of the photon p_t across the entire measured range, showing the need for an improved and consistent theoretical description of this

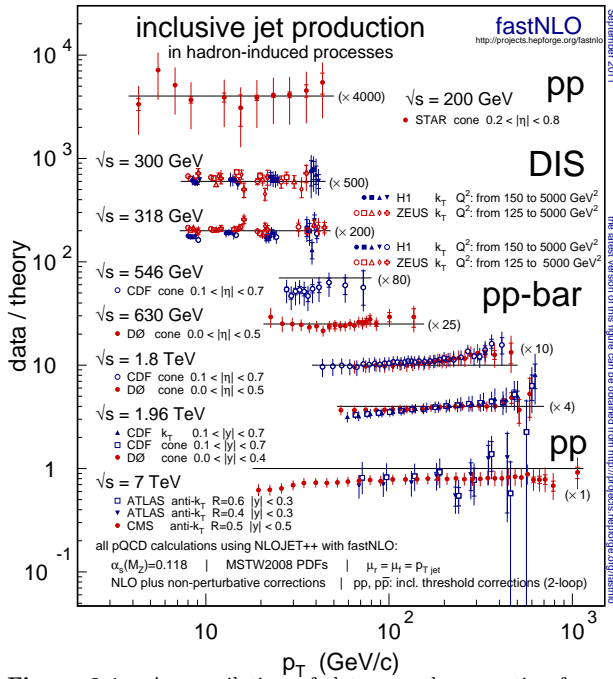

Figure 9.1: A compilation of data-over-theory ratios for inclusive jet cross sections as a function of jet transverse momentum (p_T), measured in different hadron-induced processes at different center-of-mass energies; from Ref. 211. The various ratios are scaled by arbitrary numbers (indicated between parentheses) for better readability of the plot. The theoretical predictions have been obtained at NLO accuracy, for parameter choices (coupling constant, PDFs, renormalization, and factorization scales) as indicated at the bottom of the figure.

process.

In the case of Z +jets, the Z momentum can be precisely reconstructed using the leptons, allowing for a precise determination of the Z p_T distribution, which is sensitive to QCD radiation both at high and low scales and thus probes perturbative as well as non-perturbative effects. For example, a recent D0 result [225] quotes experimental statistical and systematic uncertainties of the order of 10%, increasing up to 20% in the lowest momentum range. The data are compared to predictions from NLO QCD and from different Monte Carlo models, where, for example, LO matrix elements for up to three partons are matched to a parton shower. Whereas the total cross section is underestimated, the shape is well reproduced over a large phase-space region. Similar conclusions are drawn from further results on Z (or W) plus jets production, both from the TEVATRON [226–231] and the LHC [232,233]. A very important recent development is the completion of NLO calculations for vector boson plus 3jet [75–77] and 4jet production [78,79], which is relevant also for background estimations in the searches for new physics. This type of process is an example where jets need to be found with an infrared and collinear safe jet algorithm in order to obtain finite NLO predictions. This would not be possible with algorithms such as Midpoint or JetCLU, used in analyses at the TEVATRON [228,231]. There the measurements are compared to the NLO QCD prediction obtained with SIScone as jet algorithm. Besides this inconsistency, the agreement appears to be reasonably good.

Finally, examples of recent TEVATRON measurements of heavy quark (b , c) jet production, inclusive or in association with vector bosons, can be found in Refs. 234–240. Also, first results for vector boson production in association with b -jets have been obtained at the LHC [241,242]. It is worth noting that for W + b production there is some tension between the measurements and the NLO predictions, in particular in the case of the CDF result [239].

9.3.3. Tests of the non-abelian nature of QCD :

QCD is a gauge theory with $SU(3)$ as underlying gauge group. For a general gauge theory with a simple Lie group, the couplings of the fermion fields to the gauge fields and the self-interactions in the non-abelian case are determined by the coupling constant and Casimir operators of the gauge group, as introduced in Sec. 9.1. Measuring the eigenvalues of these operators, called color factors, probes the underlying structure of the theory in a gauge invariant way and provides evidence of the gluon self-interactions. Typically, cross sections can be expressed as functions of the color factors, for example $\sigma = f(\alpha_s C_F, C_A/C_F, n_f T_R/C_F)$. Sensitivity at leading order in perturbation theory can be achieved by measuring angular correlations in 4-jet events in e^+e^- annihilation or 3-jet events in DIS. Some sensitivity, although only at NLO, is also obtained from event-shape distributions. Scaling violations of fragmentation functions and the different subjet structure in quark and gluon induced jets also give access to these color factors. In order to extract absolute values, *e.g.* for C_F and C_A , certain assumptions have to be made for other parameters, such as T_R , n_f or α_s , since typically only combinations (ratios, products) of all the relevant parameters appear in the perturbative prediction. A recent compilation of results [176] quotes world average values of $C_A = 2.89 \pm 0.03(\text{stat}) \pm 0.21(\text{syst})$ and $C_F = 1.30 \pm 0.01(\text{stat}) \pm 0.09(\text{syst})$, with a correlation coefficient of 82%. These results are in perfect agreement with the expectations from $SU(3)$ of $C_A = 3$ and $C_F = 4/3$. An overview of the history and the current status of tests of Asymptotic Freedom, closely related to the non-abelian nature of QCD, can be found in Ref. 243.

9.3.4. Measurements of the strong coupling constant :

If the quark masses are fixed, there is only one free parameter in the QCD Lagrangian, the strong coupling constant α_s . The coupling constant in itself is not a physical observable, but rather a quantity defined in the context of perturbation theory, which enters predictions for experimentally measurable observables, such as R in Eq. (9.7).

Many experimental observables are used to determine α_s . Considerations in such determinations include:

- The observable's sensitivity to α_s as compared to the experimental precision. For example, for the e^+e^- cross section to hadrons (cf. R in Sec. 9.2.1), QCD effects are only a small correction, since the perturbative series starts at order α_s^0 ; 3-jet production or event shapes in e^+e^- annihilations are directly sensitive to α_s since they start at order α_s ; the hadronic decay width of heavy quarkonia, $\Gamma(\Upsilon \rightarrow \text{hadrons})$, is very sensitive to α_s since its leading order term is $\propto \alpha_s^3$.
- The accuracy of the perturbative prediction, or equivalently of the relation between α_s and the value of the observable. The minimal requirement is generally considered to be an NLO prediction. Some observables are predicted to NNLO (many inclusive observables, 3-jet rates and event shapes in e^+e^- collisions) or even N³LO (e^+e^- hadronic cross section and τ branching fraction to hadrons). In certain cases, fixed-order predictions are supplemented with resummation. The precise magnitude of theory uncertainties is usually estimated as discussed in Sec. 9.2.3.
- The size of uncontrolled non-perturbative effects (except for lattice-based determinations of α_s). Sufficiently inclusive quantities, like the e^+e^- cross section to hadrons, have small non-perturbative uncertainties $\sim \Lambda^4/Q^4$. Others, such as event-shape distributions, have uncertainties $\sim \Lambda/Q$.
- The scale at which the measurement is performed. An uncertainty δ on a measurement of $\alpha_s(Q^2)$, at a scale Q , translates to an uncertainty $\delta' = (\alpha_s^2(M_Z^2)/\alpha_s^2(Q^2)) \cdot \delta$ on $\alpha_s(M_Z^2)$. For example, this enhances the already important impact of precise low- Q measurements, such as from τ decays, in combinations performed at the M_Z scale.

In this review, we update the measurements of α_s summarized in the 2009 review, which was based on an analysis by Bethke [244], and we extract a new world average value of $\alpha_s(M_Z^2)$ from the most significant and complete results available today[#].

[#] The time evolution of α_s combinations can be followed by consult-

While in general we follow the same selection strategy and summary procedure as applied in the 2009 review, here we restrict the selection of results from which to calculate the world average value of $\alpha_s(M_Z^2)$ to those which are

- published in a peer-reviewed journal
- based on the most complete perturbative QCD predictions, i.e. to those using NNLO or higher order expansions.

While this excludes e.g. results from jet production in DIS at HERA and at the Tevatron, as well as those from heavy quarkonia decays for which calculations are available in NLO only, these NLO results will nevertheless be listed and cited in this review as they are important ingredients for the experimental evidence of the energy dependence of α_s , i.e. for Asymptotic Freedom, one of the key features of QCD.

In addition, here we add an intermediate step of pre-averaging results within certain sub-fields like e^+e^- -annihilation, DIS and hadronic τ -decays, and calculate the overall world average from those pre-averages rather than from individual measurements. This is done because in a number of sub-fields one observes that different determinations of the strong coupling from substantially similar datasets lead to values of α_s that are only marginally compatible with each other, or with the final world average value, which presumably is a reflection of the challenges of evaluating systematic uncertainties. In such cases, a pre-average value will be determined, with a symmetric, overall error that encompasses the central values of all individual determinations.

Hadronic τ decays

Several re-analyses of the hadronic τ decay width [17,246–250], based on the new N³LO predictions [17], have been performed, with different approaches towards the detailed treatment of the perturbative (fixed-order or contour-improved perturbative expansions) and non-perturbative contributions. We also include the result from τ decay and lifetime measurements, obtained in Sec. *Electroweak Model and constraints on New Physics* of this Review, which amounts, if converted to the τ -mass scale and for $n_f = 3$ quark flavours, to $\alpha_s(M_\tau) = 0.327^{+0.019}_{-0.016}$. This result and the one from Baikov et al. [17] include both fixed-order and contour-improved perturbation, while the others adhere to either one or the other of the two. All these results are summarized in Fig. 9.2(a). We note that there are more studies of α_s from τ -decays, [251–254], which are not yet available as peer-reviewed publications but which are compatible with the overall picture. Another recent study [255] argues that an improved treatment of non-perturbative effects results in values of α_s which are systematically lower than those discussed above. Results using the same analysis framework, but employing an updated version of the OPAL tau spectral function data are reported in Ref. 256, which at the time of writing was as yet unpublished.

We determine the pre-average result from τ -decays, to be used for calculating the final world average of $\alpha_s(M_Z^2)$, using the simple method defined above, as $\alpha_s(M_\tau^2) = 0.330 \pm 0.014$, which spans the range of central values obtained by the different groups. This value of $\alpha_s(M_\tau^2)$ corresponds, when evolved to the scale of the Z -boson, using the QCD 4-loop beta-function plus 3-loop matching at the charm- and the bottom-quark masses (see Sec. *Quark Masses* in this Review), to $\alpha_s(M_Z^2) = 0.1197 \pm 0.0016$, unchanged from its value in the 2009 review.

Lattice QCD

There are several recent results on α_s from lattice QCD, see also Sec. *Lattice QCD* in this Review. The HPQCD collaboration [257] computes Wilson loops and similar short-distance quantities with lattice QCD and analyzes them with NNLO perturbative QCD. This yields a value for α_s , but the lattice scale must be related to a physical energy/momentum scale. This is achieved with the $\Upsilon^{\prime}\Upsilon$ mass difference, however, many other quantities could be used as well [258]. HPQCD obtains $\alpha_s(M_Z^2) = 0.1184 \pm 0.0006$, where the uncertainty includes effects from truncating perturbation theory, finite lattice spacing and extrapolation of lattice data. An

independent perturbative analysis of a subset of the same lattice-QCD data yields $\alpha_s(M_Z^2) = 0.1192 \pm 0.0011$ [259]. Using another, independent methodology, the current-current correlator method, HPQCD obtains $\alpha_s(M_Z^2) = 0.1183 \pm 0.0007$ [257]. The analysis of Ref. 89, which avoids the staggered fermion treatment of Ref. 257, finds $\alpha_s(M_Z^2) = 0.1205 \pm 0.0008 \pm 0.0005^{+0.0000}_{-0.0017}$, where the first uncertainty is statistical and the others are from systematics. Since this approach uses a different discretization of lattice fermions and a different general methodology, it provides an independent cross check of other lattice extractions of α_s . Finally, the JLQCD collaboration - in an analysis of Adler functions - obtains $\alpha_s(M_Z^2) = 0.1181 \pm 0.0003^{+0.0014}_{-0.0012}$ [261]. A very recent but unpublished study of the ETM collaboration [262] used lattice data with u, d, s and c quarks in the sea, obtaining results which are compatible with those quoted above.

The published lattice results are summarized in Fig. 9.2(b). Since they are compatible with each other, we calculate a pre-average of lattice results using the same method as applied to determine the final world average value of the strong coupling, i.e. calculate a weighted average and a (correlated) error such that the overall χ^2 equals unity per degree of freedom - rather than using the simple method as applied in the case of τ decays. This gives $\alpha_s(M_Z^2) = 0.1185 \pm 0.0007$ which we take as result from the sub-field of lattice determinations.

Deep inelastic lepton-nucleon scattering (DIS)

Studies of DIS final states have led to a number of precise determinations of α_s : A combination [263] of precision measurements at HERA, based on NLO fits to inclusive jet cross sections in neutral current DIS at high Q^2 , quotes a combined result of $\alpha_s(M_Z^2) = 0.1198 \pm 0.0032$, which includes a theoretical uncertainty of ± 0.0026 . A combined analysis of non-singlet structure functions from DIS [264], based on QCD predictions up to N³LO in some of its parts, gave $\alpha_s(M_Z^2) = 0.1142 \pm 0.0023$, including a theoretical error of ± 0.0008 (BBG). Further studies of singlet and non-singlet structure functions, based on NNLO predictions, resulted in $\alpha_s(M_Z^2) = 0.1129 \pm 0.0014$ [265] (ABKM; updated in a recent unpublished note [266]) and in $\alpha_s(M_Z^2) = 0.1158 \pm 0.0035$ [267] (JR). The MSTW group [268], also including data on jet production at the Tevatron, obtains, at NNLO[#], $\alpha_s(M_Z^2) = 0.1171 \pm 0.0024$. Most recently, the NNPDF group [269] has presented a result, $\alpha_s(M_Z^2) = 0.1173 \pm 0.0011$, which is in line with the one from the MSTW group.

Summarizing these results from world data on structure functions, applying the same method as in the case of summarizing results from τ decays, leads to a pre-average value of $\alpha_s(M_Z^2) = 0.1151 \pm 0.0022$ (see Fig. 9.2(c)).

We note that criticism has been expressed on some of the above extractions. Among the issues raised, we mention the neglect of singlet contributions at $x \geq 0.3$ in pure non-singlet fits [270], the impact and detailed treatment of particular classes of data in the fits [270,271] and possible biases due to insufficiently flexible parametrizations of the PDFs [272].

Heavy quarkonia decays

The most recent extraction of the strong coupling constant from an analysis of radiative Υ decays [273] resulted in $\alpha_s(M_Z) = 0.119^{+0.006}_{-0.005}$. This determination is based on QCD in NLO only, so it will not be considered for the final extraction of the world average value of α_s ; it is, however, an important ingredient for the demonstration of Asymptotic Freedom as given in Fig. 9.4.

Hadronic final states of e^+e^- annihilations

Re-analyses of event shapes in e^+e^- -annihilation, measured at the Z peak and LEP2 energies up to 209 GeV, using NNLO predictions matched to NLL resummation, resulted in $\alpha_s(M_Z^2) = 0.1224 \pm 0.0039$ [274], with a dominant theoretical uncertainty of 0.0035, and in $\alpha_s(M_Z^2) = 0.1189 \pm 0.0043$ [275]. Similarly, an analysis of JADE data [276] at center-of-mass energies between 14 and 46 GeV gives $\alpha_s(M_Z^2) = 0.1172 \pm 0.0051$, with contributions from hadronization model (perturbative QCD) uncertainties of 0.0035 (0.0030). A precise determination of α_s from 3-jet production alone, in NNLO, resulted in

[#] Note that for jet production at the hadron collider, only NLO predictions are available, while for the structure functions full NNLO was utilized.

$\alpha_s(M_Z^2) = 0.1175 \pm 0.0025$ [277]. Computation of the NLO corrections to 5-jet production and comparison to the measured 5-jet rates at LEP [74] gave $\alpha_s(M_Z^2) = 0.1156^{+0.0041}_{-0.0034}$. More recently, a study using the world data of Thrust distributions and soft-collinear effective theory, including fixed order NNLO, gave $\alpha_s(M_Z^2) = 0.1135 \pm 0.0010$ [278]. We note that there is criticism on both classes of α_s extractions just described: those based on corrections of non-perturbative hadronisation effects using QCD-inspired Monte Carlo generators (since the parton level of a Monte Carlo is not defined in a manner equivalent to that of a fixed-order calculation), as well as the studies based on effective field theory, as their systematics have not yet been verified e.g. by using observables other than Thrust.

A summary of the e^+e^- results based on NNLO predictions is shown in Fig. 9.2(d). They average, according to the simple procedure defined above, to $\alpha_s(M_Z^2) = 0.1172 \pm 0.0037$.

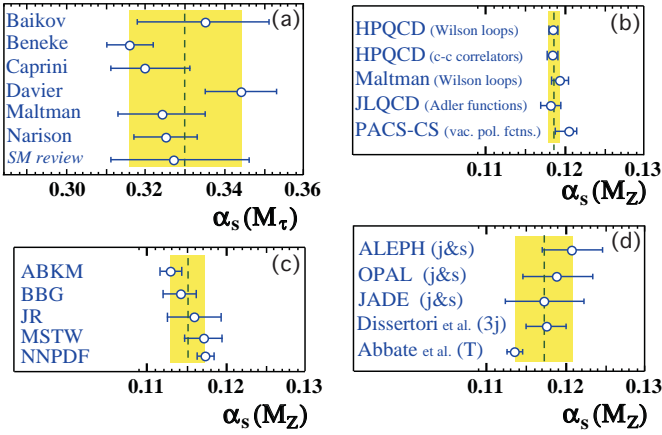

Figure 9.2: Summary of determinations of α_s from hadronic τ -decays (a), from lattice calculations (b), from DIS structure functions (c) and from event shapes and jet production in e^+e^- -annihilation (d). The shaded bands indicate the average values chosen to be included in the determination of the new world average of α_s .

Hadron collider jets

A determination of α_s from the p_T dependence of the inclusive jet cross section in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV, in the transverse momentum range of $50 < p_T < 145$ GeV, based on NLO ($\mathcal{O}(\alpha_s^3)$) QCD, led to $\alpha_s(M_Z^2) = 0.1161^{+0.0041}_{-0.0048}$ [279], which is the most precise α_s result obtained at a hadron collider. Experimental uncertainties from the jet energy calibration, the p_T resolution and the integrated luminosity dominate the overall error.

Electroweak precision fits

The N^3 LO calculation of the hadronic Z decay width was used in a revision of the global fit to electroweak precision data [280], resulting in $\alpha_s(M_Z^2) = 0.1193 \pm 0.0028$, claiming a negligible theoretical uncertainty. For this *Review* the value obtained in Sec. *Electroweak model and constraints on new physics* from data at the Z -pole, $\alpha_s(M_Z^2) = 0.1197 \pm 0.0028$ will be used instead, as it is based on a more constrained data set where QCD corrections directly enter through the hadronic decay width of the Z . We note that all these results from electroweak precision data, however, strongly depend on the strict validity of Standard Model predictions and the existence of the minimal Higgs mechanism to implement electroweak symmetry breaking. Any - even small - deviation of nature from this model could strongly influence this extraction of α_s .

Determination of the world average value of $\alpha_s(M_Z^2)$

A non-trivial exercise consists in the evaluation of a world-average value for $\alpha_s(M_Z^2)$. A certain arbitrariness and subjective component is inevitable because of the choice of measurements to be included in the average, the treatment of (non-Gaussian) systematic uncertainties of mostly theoretical nature, as well as the treatment of correlations among the various inputs, of theoretical as well as experimental origin.

In earlier reviews [243–245] an attempt was made to take account of such correlations, using methods as proposed, e.g., in Ref. 281, and - likewise - to treat cases of apparent incompatibilities or possibly underestimated systematic uncertainties in a meaningful and well defined manner:

The central value is determined as the weighted average of the different input values. An initial error of the central value is determined treating the uncertainties of all individual measurements as being uncorrelated and being of Gaussian nature, and the overall χ^2 to the central value is determined. If this initial χ^2 is larger than the number of degrees of freedom, i.e. larger than the number of individual inputs minus one, then all individual errors are enlarged by a common factor such that $\chi^2/\text{d.o.f.}$ equals unity. If the initial value of χ^2 is smaller than the number of degrees of freedom, an overall, a-priori unknown correlation coefficient is introduced and determined by requiring that the total $\chi^2/\text{d.o.f.}$ of the combination equals unity. In both cases, the resulting final overall uncertainty of the central value of α_s is larger than the initial estimate of a Gaussian error.

This procedure is only meaningful if the individual measurements are known not to be correlated to large degrees, i.e. if they are not - for instance - based on the same input data, and if the input values are largely compatible with each other and with the resulting central value, within their assigned uncertainties. The list of selected individual measurements discussed above, however, violates both these requirements: there are several measurements based on (partly or fully) identical data sets, and there are results which apparently do not agree with others and/or with the resulting central value, within their assigned uncertainty. Examples for the first case are results from the hadronic width of the τ lepton, from DIS processes and from jets and event shapes in e^+e^- final states. An example of the second case is the apparent disagreement between results from the τ width and those from DIS [264] or from Thrust distributions in e^+e^- annihilation [278].

Figure 9.3: Summary of values of $\alpha_s(M_Z^2)$ obtained for various sub-classes of measurements (see Fig. 9.2 (a) to (d)). The new world average value of $\alpha_s(M_Z^2) = 0.1184 \pm 0.0007$ is indicated by the dashed line and the shaded band.

Due to these obstacles, we have chosen to determine pre-averages for each class of measurements, and then to combine those to the final world average value of $\alpha_s(M_Z^2)$, using the methods of error treatment as just described. The five pre-averages are summarized in Fig. 9.3; we recall that these are exclusively obtained from extractions which are based on (at least) full NNLO QCD predictions, and are published in peer-reviewed journals at the time of completing this *Review*. From these, we determine the new world average value of

$$\alpha_s(M_Z^2) = 0.1184 \pm 0.0007, \quad (9.23)$$

with an uncertainty of well below 1 %.^{***} This world average value is - in spite of several new contributions to this determination - identical to and thus, in excellent agreement with the 2009 result [244]. For

^{***} The weighted average, treating all inputs as uncorrelated measurements with Gaussian errors, results in $\alpha_s(M_Z^2) = 0.11844 \pm 0.00059$ with $\chi^2/\text{d.o.f.} = 3.2/4$. Requiring $\chi^2/\text{d.o.f.}$ to reach unity leads to a common correlation factor of 0.19 which increases the overall error to 0.00072.

convenience, we also provide corresponding values for $\Lambda_{\overline{MS}}$ suitable for use with Eq. (9.5):

$$\Lambda_{\overline{MS}}^{(5)} = (213 \pm 8) \text{ MeV} , \quad (9.24a)$$

$$\Lambda_{\overline{MS}}^{(4)} = (296 \pm 10) \text{ MeV} , \quad (9.24b)$$

$$\Lambda_{\overline{MS}}^{(3)} = (339 \pm 10) \text{ MeV} , \quad (9.24c)$$

for $n_f = 5, 4$ and 3 quark flavors, respectively.

In order to further test and verify the sensitivity of the new average value of $\alpha_s(M_Z^2)$ to the different pre-averages and classes of α_s determinations, we give each of the averages obtained when leaving out one of the five input values:

$$\alpha_s(M_Z^2) = 0.1182 \pm 0.0007 \quad (\text{w/o } \tau \text{ results}), \quad (9.25a)$$

$$\alpha_s(M_Z^2) = 0.1183 \pm 0.0012 \quad (\text{w/o lattice results}), \quad (9.25b)$$

$$\alpha_s(M_Z^2) = 0.1187 \pm 0.0009 \quad (\text{w/o DIS results}), \quad (9.25c)$$

$$\alpha_s(M_Z^2) = 0.1185 \pm 0.0006 \quad (\text{w/o } e^+e^- \text{ results}), \text{ and} \quad (9.25d)$$

$$\alpha_s(M_Z^2) = 0.1184 \pm 0.0006 \quad (\text{w/o res. from e.w. prec. fit}), \quad (9.25e)$$

They are well within the error of the overall world average quoted above. Most notably, the result from lattice calculations, which has the smallest assigned error, agrees well with the exclusive average of the other results. However, it largely determines the size of the (small) overall uncertainty.

There are apparent systematic differences between the various structure function results, and also between the new result from Thrust in e^+e^- annihilation and the other determinations. Expressing this in terms of a χ^2 between a given measurement and the world average as obtained when *excluding* that particular measurement, the largest values are $\chi^2 = 12.6$ and $\chi^2 = 16.1$, corresponding to 3.5 and 4.0 standard deviations, for the measurements of [265] and [278], respectively. We note that such and other differences between some of the measurements have been extensively discussed at a specific workshop on measurements of α_s , however none of the explanations proposed so far have obtained enough of a consensus to definitely resolve the tensions between different extractions [282].

Notwithstanding these open issues, a rather stable and well defined world average value emerges from the compilation of current determinations of α_s :

$$\alpha_s(M_Z^2) = 0.1184 \pm 0.0007 .$$

The results also provide a clear signature and proof of the energy dependence of α_s , in full agreement with the QCD prediction of Asymptotic Freedom. This is demonstrated in Fig. 9.4, where results of $\alpha_s(Q^2)$ obtained at discrete energy scales Q , now also including those based just on NLO QCD, are summarized and plotted.

10. ELECTROWEAK MODEL AND CONSTRAINTS ON NEW PHYSICS

Revised December 2011 by J. Erler (U. Mexico and Institute for Advanced Study) and P. Langacker (Princeton University and Institute for Advanced Study).

- 10.1 Introduction
- 10.2 Renormalization and radiative corrections
- 10.3 Low energy electroweak observables
- 10.4 W and Z boson physics
- 10.5 Precision flavor physics
- 10.6 Experimental results
- 10.7 Constraints on new physics

10.1. Introduction

The standard model of the electroweak interactions (SM) [1] is based on the gauge group $SU(2) \times U(1)$, with gauge bosons W_μ^i , $i = 1, 2, 3$, and B_μ for the $SU(2)$ and $U(1)$ factors, respectively, and the corresponding gauge coupling constants g and g' . The left-handed fermion fields of the i^{th} fermion family transform as doublets

$\Psi_i = \begin{pmatrix} \nu_i \\ \ell_i^- \end{pmatrix}$ and $\begin{pmatrix} u_i \\ d_i' \end{pmatrix}$ under $SU(2)$, where $d_i' \equiv \sum_j V_{ij} d_j$, and V is the Cabibbo-Kobayashi-Maskawa mixing matrix. (Constraints on V and tests of universality are discussed in Ref. 2 and in the Section on “The CKM Quark-Mixing Matrix”. The extension of the formalism to allow an analogous leptonic mixing matrix is discussed in the Section on “Neutrino Mass, Mixing, and Oscillations”.) The right-handed fields are $SU(2)$ singlets. In the minimal model there are three fermion families.

A complex scalar Higgs doublet, $\phi \equiv \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix}$, is added to the model for mass generation through spontaneous symmetry breaking with potential* given by,

$$V(\phi) = \mu^2 \phi^\dagger \phi + \frac{\lambda^2}{2} (\phi^\dagger \phi)^2. \quad (10.1)$$

For μ^2 negative, ϕ develops a vacuum expectation value, $v/\sqrt{2}$, where $v \approx 246.22$ GeV, breaking part of the electroweak (EW) gauge symmetry, after which only one neutral Higgs scalar, H , remains in the physical particle spectrum. In non-minimal models there are additional charged and neutral scalar Higgs particles [3].

After the symmetry breaking the Lagrangian for the fermion fields, ψ_i , is

$$\begin{aligned} \mathcal{L}_F = & \sum_i \bar{\psi}_i \left(i \not{\partial} - m_i - \frac{gm_i H}{2M_W} \right) \psi_i \\ & - \frac{g}{2\sqrt{2}} \sum_i \bar{\Psi}_i \gamma^\mu (1 - \gamma^5) (T^+ W_\mu^+ + T^- W_\mu^-) \Psi_i \\ & - e \sum_i q_i \bar{\psi}_i \gamma^\mu \psi_i A_\mu \\ & - \frac{g}{2 \cos \theta_W} \sum_i \bar{\psi}_i \gamma^\mu (g_V^i - g_A^i \gamma^5) \psi_i Z_\mu. \end{aligned} \quad (10.2)$$

$\theta_W \equiv \tan^{-1}(g'/g)$ is the weak angle; $e = g \sin \theta_W$ is the positron electric charge; and $A \equiv B \cos \theta_W + W^3 \sin \theta_W$ is the photon field (γ). $W^\pm \equiv (W^1 \mp iW^2)/\sqrt{2}$ and $Z \equiv -B \sin \theta_W + W^3 \cos \theta_W$ are the charged and neutral weak boson fields, respectively. The Yukawa coupling of H to ψ_i in the first term in \mathcal{L}_F , which is flavor diagonal in the minimal model, is $gm_i/2M_W$. The boson masses in the EW sector are given (at tree level, *i.e.*, to lowest order in perturbation theory) by,

$$M_H = \lambda v, \quad (10.3a)$$

$$M_W = \frac{1}{2} g v = \frac{e v}{2 \sin \theta_W}, \quad (10.3b)$$

$$M_Z = \frac{1}{2} \sqrt{g^2 + g'^2} v = \frac{e v}{2 \sin \theta_W \cos \theta_W} = \frac{M_W}{\cos \theta_W}, \quad (10.3c)$$

$$M_\gamma = 0. \quad (10.3d)$$

* There is no generally accepted convention to write the quartic term. Our numerical coefficient simplifies Eq. (10.3a) below and the squared coupling preserves the relation between the number of external legs and the power counting of couplings at a given loop order. This structure also naturally emerges from physics beyond the SM, such as supersymmetry.

The second term in \mathcal{L}_F represents the charged-current weak interaction [4–7], where T^+ and T^- are the weak isospin raising and lowering operators. For example, the coupling of a W to an electron and a neutrino is

$$-\frac{e}{2\sqrt{2} \sin \theta_W} \left[W_\mu^- \bar{e} \gamma^\mu (1 - \gamma^5) \nu + W_\mu^+ \bar{\nu} \gamma^\mu (1 - \gamma^5) e \right]. \quad (10.4)$$

For momenta small compared to M_W , this term gives rise to the effective four-fermion interaction with the Fermi constant given by $G_F/\sqrt{2} = 1/2v^2 = g^2/8M_W^2$. CP violation is incorporated into the EW model by a single observable phase in V_{ij} .

The third term in \mathcal{L}_F describes electromagnetic interactions (QED) [8–10], and the last is the weak neutral-current interaction [5–7]. The vector and axial-vector couplings are

$$g_V^i \equiv t_{3L}(i) - 2q_i \sin^2 \theta_W, \quad (10.5a)$$

$$g_A^i \equiv t_{3L}(i), \quad (10.5b)$$

where $t_{3L}(i)$ is the weak isospin of fermion i ($+1/2$ for u_i and ν_i ; $-1/2$ for d_i and e_i) and q_i is the charge of ψ_i in units of e .

The first term in Eq. (10.2) also gives rise to fermion masses, and in the presence of right-handed neutrinos to Dirac neutrino masses. The possibility of Majorana masses is discussed in the Section on “Neutrino Mass, Mixing, and Oscillations”.

10.2. Renormalization and radiative corrections

In addition to the Higgs boson mass, M_H , the fermion masses and mixings, and the strong coupling constant, α_s , the SM has three parameters. A particularly useful set contains the Z mass**, the Fermi constant, and the fine structure constant, which will be discussed in turn:

The Z boson mass, $M_Z = 91.1876 \pm 0.0021$ GeV, has been determined from the Z lineshape scan at LEP 1 [11].

The Fermi constant, $G_F = 1.1663787(6) \times 10^{-5}$ GeV⁻², is derived from the muon lifetime formula***,

$$\frac{\hbar}{\tau_\mu} = \frac{G_F^2 m_\mu^5}{192\pi^3} F(\rho) \left[1 + H_1(\rho) \frac{\hat{\alpha}(m_\mu)}{\pi} + H_2(\rho) \frac{\hat{\alpha}^2(m_\mu)}{\pi^2} \right], \quad (10.6)$$

where $\rho = m_e^2/m_\mu^2$, and where

$$F(\rho) = 1 - 8\rho + 8\rho^3 - \rho^4 - 12\rho^2 \ln \rho = 0.99981295, \quad (10.7a)$$

$$\begin{aligned} H_1(\rho) = & \frac{25}{8} - \frac{\pi^2}{2} - \left(9 + 4\pi^2 + 12 \ln \rho \right) \rho \\ & + 16\pi^2 \rho^{3/2} + \mathcal{O}(\rho^2) = -1.80793, \end{aligned} \quad (10.7b)$$

$$\begin{aligned} H_2(\rho) = & \frac{156815}{5184} - \frac{518}{81} \pi^2 - \frac{895}{36} \zeta(3) + \frac{67}{720} \pi^4 + \frac{53}{6} \pi^2 \ln 2 \\ & - (0.042 \pm 0.002)_{\text{had}} - \frac{5}{4} \pi^2 \sqrt{\rho} + \mathcal{O}(\rho) = 6.64, \end{aligned} \quad (10.7c)$$

$$\hat{\alpha}(m_\mu)^{-1} = \alpha^{-1} + \frac{1}{3\pi} \ln \rho + \mathcal{O}(\alpha) = 135.901 \quad (10.7d)$$

The massless corrections to H_1 and H_2 have been obtained in Refs. 13 and 14, respectively, where the term in parentheses is from the hadronic vacuum polarization [14]. The mass corrections to H_1 have been known for some time [15], while those to H_2 are more recent [16]. Notice the term linear in m_e whose appearance was

** We emphasize that in the fits described in Sec. 10.6 and Sec. 10.7 the values of the SM parameters are affected by all observables that depend on them. This is of no practical consequence for α and G_F , however, since they are very precisely known.

*** In the spirit of the Fermi theory, we incorporated the small propagator correction, $3/5 m_\mu^2/M_W^2$, into Δr (see below). This is also the convention adopted by the MuLan collaboration [12]. While this breaks with historical consistency, the numerical difference was negligible in the past.

unforeseen and can be traced to the use of the muon pole mass in the prefactor [16]. The remaining uncertainty in G_F is experimental and has recently been reduced by an order of magnitude by the MuLan collaboration [12] at the PSI.

The fine structure constant, $\alpha = 1/137.035999074(44)$, is currently dominated by the e^\pm anomalous magnetic moment [10]. In most EW renormalization schemes, it is convenient to define a running α dependent on the energy scale of the process, with $\alpha^{-1} \sim 137$ appropriate at very low energy, *i.e.* close to the Thomson limit. (The running has also been observed [17] directly.) For scales above a few hundred MeV this introduces an uncertainty due to the low energy hadronic contribution to vacuum polarization. In the modified minimal subtraction ($\overline{\text{MS}}$) scheme [18] (used for this *Review*), and with $\alpha_s(M_Z) = 0.120$, we have $\hat{\alpha}(m_\tau)^{-1} = 133.471 \pm 0.014$ and $\hat{\alpha}(M_Z)^{-1} = 127.944 \pm 0.014$. (In this Section we denote quantities defined in the modified minimal subtraction ($\overline{\text{MS}}$) scheme by a caret; the exception is the strong coupling constant, α_s , which will always correspond to the $\overline{\text{MS}}$ definition and where the caret will be dropped.) The latter corresponds to a quark sector contribution (without the top) to the conventional (on-shell) QED coupling, $\alpha(M_Z) = \frac{\alpha}{1 - \Delta\alpha(M_Z)}$,

of $\Delta\alpha_{\text{had}}^{(5)}(M_Z) \approx 0.02772 \pm 0.00010$. These values are updated from Ref. 19 with $\Delta\alpha_{\text{had}}^{(5)}(M_Z)$ moved downwards and its uncertainty halved (partly due to a more precise charm quark mass). Its correlation with the μ^\pm anomalous magnetic moment (see Sec. 10.5), as well as the non-linear α_s dependence of $\hat{\alpha}(M_Z)$ and the resulting correlation with the input variable α_s , are fully taken into account in the fits. This is done by using as actual input (fit constraint) instead of $\Delta\alpha_{\text{had}}^{(5)}(M_Z)$ the analogous low energy contribution by the three light quarks, $\Delta\alpha_{\text{had}}^{(3)}(1.8 \text{ GeV}) = (55.50 \pm 0.78) \times 10^{-4}$ [20], and by calculating the perturbative and heavy quark contributions to $\hat{\alpha}(M_Z)$ in each call of the fits according to Ref. 19. Part of the uncertainty ($\pm 0.49 \times 10^{-4}$) is from e^+e^- annihilation data below 1.8 GeV and τ decay data (including uncertainties from isospin breaking effects), but uncalculated higher order perturbative ($\pm 0.41 \times 10^{-4}$) and non-perturbative ($\pm 0.44 \times 10^{-4}$) QCD corrections and the $\overline{\text{MS}}$ quark mass values (see below) also contribute. Various recent evaluations of $\Delta\alpha_{\text{had}}^{(5)}$ are summarized in Table 10.1, where the leading order relation[†] between the $\overline{\text{MS}}$ and on-shell definitions is given by,

$$\Delta\hat{\alpha}(M_Z) - \Delta\alpha(M_Z) = \frac{\alpha}{\pi} \left(\frac{100}{27} - \frac{1}{6} - \frac{7}{4} \ln \frac{M_Z^2}{M_W^2} \right) \approx 0.0072, \quad (10.8)$$

and where the first term is from fermions and the other two are from W^\pm loops which are usually excluded from the on-shell definition. Most of the older results relied on $e^+e^- \rightarrow$ hadrons cross-section measurements up to energies of 40 GeV, which were somewhat higher than the QCD prediction, suggested stronger running, and were less precise. The most recent results typically assume the validity of perturbative QCD (PQCD) at scales of 1.8 GeV and above, and are in reasonable agreement with each other. There is, however, some discrepancy between analyses based on $e^+e^- \rightarrow$ hadrons cross-section data and those based on τ decay spectral functions [20]. The latter utilize data from OPAL [43], CLEO [44], ALEPH [45], and Belle [46] and imply lower central values for the extracted M_H of about 6%. This discrepancy is smaller than in the past and at least some of it appears to be experimental. The dominant $e^+e^- \rightarrow \pi^+\pi^-$ cross-section was measured with the CMD-2 [47] and SND [48] detectors at the VEPP-2M e^+e^- collider at Novosibirsk and the results are (after an initial discrepancy due to a flaw in the Monte Carlo event generator used by SND) in good agreement with each other. As an alternative to cross-section scans, one can use the high statistics radiative return events at e^+e^- accelerators operating at resonances such as the Φ or the $\Upsilon(4S)$. The method [49] is systematics limited but dominates

[†] Eq. (10.8) is for illustration only. Higher order contributions are directly evaluated in the $\overline{\text{MS}}$ scheme using the FORTRAN package GAPP [21], including three-loop QED contributions of both leptons and quarks. The leptonic three-loop contribution in the on-shell scheme has been obtained in Ref. 22.

over the Novosibirsk data throughout. The BaBar collaboration [50] studied multi-hadron events radiatively returned from the $\Upsilon(4S)$, reconstructing the radiated photon and normalizing to $\mu^\pm\gamma$ final states. Their result is higher compared to VEPP-2M and in fact agrees quite well with the τ analysis including the energy dependence (shape). In contrast, the shape and smaller overall cross-section from the $\pi^+\pi^-$ radiative return results from the Φ obtained by the KLOE collaboration [51] differs significantly from what is observed by BaBar. The discrepancy originates from the kinematic region $\sqrt{s} \gtrsim 0.6 \text{ GeV}$, and is most pronounced for $\sqrt{s} \gtrsim 0.85 \text{ GeV}$. All measurements including older data [52] and multi-hadron final states (there are also discrepancies in the $e^+e^- \rightarrow 2\pi^+2\pi^-$ channel [20]) are accounted for and corrections have been applied for missing channels [20]. Further improvement of this dominant theoretical uncertainty in the interpretation of precision data will require better measurements of the cross-section for $e^+e^- \rightarrow$ hadrons below the charmonium resonances including multi-pion and other final states. To improve the precisions in $\hat{m}_c(\hat{m}_c)$ and $\hat{m}_b(\hat{m}_b)$ it would help to remeasure the threshold regions of the heavy quarks as well as the electronic decay widths of the narrow $c\bar{c}$ and $b\bar{b}$ resonances.

Further free parameters entering into Eq. (10.2) are the quark and lepton masses, where m_i is the mass of the i^{th} fermion ψ_i . For the quarks these are the current masses. For the light quarks, as described in the note on “Quark Masses” in the Quark Listings, $\hat{m}_u = 2.5_{-0.8}^{+0.6} \text{ MeV}$, $\hat{m}_d = 5.0_{-0.9}^{+0.7} \text{ MeV}$, and $\hat{m}_s = 100_{-20}^{+30} \text{ MeV}$. These are running $\overline{\text{MS}}$ masses evaluated at the scale $\mu = 2 \text{ GeV}$. For the heavier quarks we use QCD sum rule [53] constraints [54] and recalculate their masses in each call of our fits to account for their direct α_s dependence. We find[‡], $\hat{m}_c(\mu = \hat{m}_c) = 1.267_{-0.040}^{+0.032} \text{ GeV}$ and $\hat{m}_b(\mu = \hat{m}_b) = 4.197 \pm 0.025 \text{ GeV}$, with a correlation of 24%.

The top quark “pole” mass (the quotation marks are a reminder that quarks do not form asymptotic states), $m_t = 173.4 \pm 0.9 \text{ GeV}$, is an average of published and preliminary CDF and DØ results from run I and II [56] with first results by the CMS [57] and ATLAS [58] collaborations averaged in ignoring correlations. To gauge the possible impact of the neglect of correlations involving the LHC experiments, we also averaged the results conservatively assuming that the entire 0.75 GeV systematic of the Tevatron average is fully correlated with a 0.75 GeV component in both CMS and ATLAS. Incidentally, this yields correlations of similar size as those between the two Tevatron experiments and the two Runs and reduces the central value by 0.15 GeV. Within round-off we expect a more refined average to coincide with ours. Our average[§] differs slightly from the value, $m_t = 173.5 \pm 0.6 \pm 0.8 \text{ GeV}$, which appears in the top quark Listings in this *Review* and which is based exclusively on published results. We are working, however, with $\overline{\text{MS}}$ masses in all expressions to minimize theoretical uncertainties. Such a short distance mass definition (unlike the pole mass) is free from non-perturbative and renormalon [59] uncertainties. We therefore convert to the top quark $\overline{\text{MS}}$ mass,

$$\hat{m}_t(\mu = \hat{m}_t) = m_t \left[1 - \frac{4}{3} \frac{\alpha_s}{\pi} + \mathcal{O}(\alpha_s^2) \right], \quad (10.9)$$

using the three-loop formula [60]. This introduces an additional uncertainty which we estimate to 0.5 GeV (the size of the three-loop term) and add in quadrature to the experimental pole mass error. This is convenient because we use the pole mass as an external constraint while fitting to the $\overline{\text{MS}}$ mass. We are assuming that the kinematic

[‡] Other authors [55] advocate to evaluate and quote $\hat{m}_c(\mu = 3 \text{ GeV})$ instead. We use $\hat{m}_c(\mu = \hat{m}_c)$ because in the global analysis it is convenient to nullify any explicitly m_c dependent logarithms. Note also that our uncertainty for m_c (and to a lesser degree for m_b) is larger than the one in Ref. 55, for example. The reason is that we determine the continuum contribution for charm pair production using only resonance data and theoretical consistency across various sum rule moments, and then use any difference to the experimental continuum data as an additional uncertainty. We also include an uncertainty for the condensate terms which grows rapidly for higher moments in the sum rule analysis.

[§] At the time of writing this review, the efforts to establish a top quark averaging group involving both the Tevatron and the LHC were still in progress. Therefore we perform a simplified average ourselves.

mass extracted from the collider events corresponds within this uncertainty to the pole mass. Using the BLM optimized [61] version of the two-loop perturbative QCD formula [62] (as we did in previous editions of this *Review*) gives virtually identical results. In summary, we will use $m_t = 173.4 \pm 0.9$ (exp.) ± 0.5 (QCD) GeV = 173.4 ± 1.0 GeV (together with $M_H = 117$ GeV) for the numerical values quoted in Sec. 10.2–Sec. 10.5.

$\sin^2 \theta_W$ and M_W can be calculated from M_Z , $\hat{\alpha}(M_Z)$, and G_F , when values for m_t and M_H are given; conversely (as is done at present), M_H can be constrained by $\sin^2 \theta_W$ and M_W . The value of $\sin^2 \theta_W$ is extracted from neutral-current processes (see Sec. 10.3) and Z pole observables (see Sec. 10.4) and depends on the renormalization prescription. There are a number of popular schemes [63–70] leading to values which differ by small factors depending on m_t and M_H . The notation for these schemes is shown in Table 10.1.

Table 10.1: Notations used to indicate the various schemes discussed in the text. Each definition of $\sin^2 \theta_W$ leads to values that differ by small factors depending on m_t and M_H . Approximate values are also given for illustration.

Scheme	Notation	Value
On-shell	s_W^2	0.2231
NOV	$s_{M_Z}^2$	0.2310
$\overline{\text{MS}}$	\hat{s}_Z^2	0.2312
$\overline{\text{MS}}$ ND	\hat{s}_{ND}^2	0.2314
Effective angle	\hat{s}_f^2	0.2315

- (i) The on-shell scheme [63] promotes the tree-level formula $\sin^2 \theta_W = 1 - M_W^2/M_Z^2$ to a definition of the renormalized $\sin^2 \theta_W$ to all orders in perturbation theory, *i.e.*, $\sin^2 \theta_W \rightarrow s_W^2 \equiv 1 - M_W^2/M_Z^2$:

$$M_W = \frac{A_0}{s_W(1 - \Delta r)^{1/2}}, \quad M_Z = \frac{M_W}{c_W}, \quad (10.10)$$

where $c_W \equiv \cos \theta_W$, $A_0 = (\pi\alpha/\sqrt{2}G_F)^{1/2} = 37.28039(1)$ GeV, and Δr includes the radiative corrections relating α , $\alpha(M_Z)$, G_F , M_W , and M_Z . One finds $\Delta r \sim \Delta r_0 - \rho_t/\tan^2 \theta_W$, where $\Delta r_0 = 1 - \alpha/\hat{\alpha}(M_Z) = 0.06635(10)$ is due to the running of α , and $\rho_t = 3G_F m_t^2/8\sqrt{2}\pi^2 = 0.00943(m_t/173.4 \text{ GeV})^2$ represents the dominant (quadratic) m_t dependence. There are additional contributions to Δr from bosonic loops, including those which depend logarithmically on M_H . One has $\Delta r = 0.0358 \mp 0.0004 \pm 0.00010$, where the first uncertainty is from m_t and the second is from $\alpha(M_Z)$. Thus the value of s_W^2 extracted from M_Z includes an uncertainty (∓ 0.00012) from the currently allowed range of m_t . This scheme is simple conceptually. However, the relatively large ($\sim 3\%$) correction from ρ_t causes large spurious contributions in higher orders.

- (ii) A more precisely determined quantity $s_{M_Z}^2$ [64] can be obtained from M_Z by removing the (m_t, M_H) dependent term from Δr [65], *i.e.*,

$$s_{M_Z}^2(1 - s_{M_Z}^2) \equiv \frac{\pi\alpha(M_Z)}{\sqrt{2}G_F M_Z^2}. \quad (10.11)$$

Using $\alpha(M_Z)^{-1} = 128.93 \pm 0.02$ yields $s_{M_Z}^2 = 0.23102 \mp 0.00005$. The small uncertainty in $s_{M_Z}^2$ compared to other schemes is because the m_t dependence has been removed by definition. However, the m_t uncertainty reemerges when other quantities (*e.g.*, M_W or other Z pole observables) are predicted in terms of M_Z .

Both s_W^2 and $s_{M_Z}^2$ depend not only on the gauge couplings but also on the spontaneous-symmetry breaking, and both definitions are awkward in the presence of any extension of the SM which perturbs the value of M_Z (or M_W). Other definitions are motivated by the tree-level coupling constant definition $\theta_W = \tan^{-1}(g'/g)$:

- (iii) In particular, the modified minimal subtraction ($\overline{\text{MS}}$) scheme introduces the quantity $\sin^2 \hat{\theta}_W(\mu) \equiv \hat{g}'^2(\mu)/[\hat{g}^2(\mu) + \hat{g}'^2(\mu)]$, where the couplings \hat{g} and \hat{g}' are defined by modified minimal subtraction and the scale μ is conveniently chosen to be M_Z for many EW processes. The value of $\hat{s}_Z^2 = \sin^2 \hat{\theta}_W(M_Z)$ extracted from M_Z is less sensitive than s_W^2 to m_t (by a factor of $\tan^2 \theta_W$), and is less sensitive to most types of new physics than s_W^2 or $s_{M_Z}^2$. It is also very useful for comparing with the predictions of grand unification. There are actually several variant definitions of $\sin^2 \hat{\theta}_W(M_Z)$, differing according to whether or how finite $\alpha \ln(m_t/M_Z)$ terms are decoupled (subtracted from the couplings). One cannot entirely decouple the $\alpha \ln(m_t/M_Z)$ terms from all EW quantities because $m_t \gg m_b$ breaks SU(2) symmetry. The scheme that will be adopted here decouples the $\alpha \ln(m_t/M_Z)$ terms from the γ - Z mixing [18,66], essentially eliminating any $\ln(m_t/M_Z)$ dependence in the formulae for asymmetries at the Z pole when written in terms of \hat{s}_Z^2 . (A similar definition is used for $\hat{\alpha}$.) The various definitions are related by

$$\hat{s}_Z^2 = c(m_t, M_H)s_W^2 = \bar{c}(m_t, M_H)s_{M_Z}^2, \quad (10.12)$$

where $c = 1.0362 \pm 0.0004$ and $\bar{c} = 1.0009 \mp 0.0002$. The quadratic m_t dependence is given by $c \sim 1 + \rho_t/\tan^2 \theta_W$ and $\bar{c} \sim 1 - \rho_t/(1 - \tan^2 \theta_W)$, respectively. The expressions for M_W and M_Z in the $\overline{\text{MS}}$ scheme are

$$M_W = \frac{A_0}{\hat{s}_Z(1 - \Delta \hat{r}_W)^{1/2}}, \quad M_Z = \frac{M_W}{\hat{\rho}^{1/2} \hat{c}_Z}, \quad (10.13)$$

and one predicts $\Delta \hat{r}_W = 0.06951 \pm 0.00001 \pm 0.00010$. $\Delta \hat{r}_W$ has no quadratic m_t dependence, because shifts in M_W are absorbed into the observed G_F , so that the error in $\Delta \hat{r}_W$ is dominated by $\Delta r_0 = 1 - \alpha/\hat{\alpha}(M_Z)$ which induces the second quoted uncertainty. The quadratic m_t dependence has been shifted into $\hat{\rho} \sim 1 + \rho_t$, where including bosonic loops, $\hat{\rho} = 1.01051 \pm 0.00011$. Quadratic M_H effects are deferred to two-loop order, while the leading logarithmic M_H effect is a good approximation only for large M_H values which are clearly disfavored by the precision data. As an illustration, the shift in M_W due to a large M_H (for fixed M_Z) is given by

$$\Delta_H M_W = -\frac{11\alpha}{96\pi} \frac{M_W}{c_W^2 - s_W^2} \ln \frac{M_H^2}{M_W^2} + \mathcal{O}(\alpha^2) \\ \sim -200 \text{ MeV (for } M_H = 10 M_W). \quad (10.14)$$

- (iv) A variant $\overline{\text{MS}}$ quantity \hat{s}_{ND}^2 (used in the 1992 edition of this *Review*) does not decouple the $\alpha \ln(m_t/M_Z)$ terms [67]. It is related to \hat{s}_Z^2 by

$$\hat{s}_Z^2 = \hat{s}_{\text{ND}}^2 / \left(1 + \frac{\hat{\alpha}}{\pi} d\right), \quad (10.15a)$$

$$d = \frac{1}{3} \left(\frac{1}{\hat{s}_Z^2} - \frac{8}{3}\right) \left[\left(1 + \frac{\alpha_s}{\pi}\right) \ln \frac{m_t}{M_Z} - \frac{15\alpha_s}{8\pi}\right], \quad (10.15b)$$

Thus, $\hat{s}_Z^2 - \hat{s}_{\text{ND}}^2 \approx -0.0002$.

- (v) Yet another definition, the effective angle [68–70] \hat{s}_f^2 for the Z vector coupling to fermion f , is based on Z pole observables and described below.

Experiments are at such level of precision that complete $\mathcal{O}(\alpha)$ radiative corrections must be applied. For neutral-current and Z pole processes, these corrections are conveniently divided into two classes:

1. QED diagrams involving the emission of real photons or the exchange of virtual photons in loops, but not including vacuum polarization diagrams. These graphs often yield finite and gauge-invariant contributions to observable processes. However, they are dependent on energies, experimental cuts, *etc.*, and must be calculated individually for each experiment.
2. EW corrections, including $\gamma\gamma$, γZ , ZZ , and WW vacuum polarization diagrams, as well as vertex corrections, box graphs,

etc., involving virtual W and Z bosons. The one-loop corrections are included for all processes, and certain two-loop corrections are also important. In particular, two-loop corrections involving the top quark modify ρ_t in $\hat{\rho}$, Δr , and elsewhere by

$$\rho_t \rightarrow \rho_t [1 + R(M_H, m_t) \rho_t / 3]. \quad (10.16)$$

$R(M_H, m_t)$ is best described as an expansion in M_Z^2/m_t^2 . The unsuppressed terms were first obtained in Ref. 71, and are known analytically [72]. Contributions suppressed by M_Z^2/m_t^2 were first studied in Ref. 73 with the help of small and large Higgs mass expansions, which can be interpolated. These contributions are about as large as the leading ones in Refs. 71 and 72. The complete two-loop calculation of Δr (without further approximation) has been performed in Refs. 74 and 75 for fermionic and purely bosonic diagrams, respectively. Similarly, the EW two-loop calculation for the relation between \overline{s}_W^2 and s_W^2 is complete [76] including the recently obtained purely bosonic contribution [77]. For M_H above its lower direct limit, $-17 < R < -13$.

Mixed QCD-EW contributions to gauge boson self-energies of order $\alpha\alpha_s m_t^2$ [78] and $\alpha\alpha_s^2 m_t^2$ [79] increase the predicted value of m_t by 6%. This is, however, almost entirely an artifact of using the pole mass definition for m_t . The equivalent corrections when using the $\overline{\text{MS}}$ definition $\hat{m}_t(\hat{m}_t)$ increase m_t by less than 0.5%. The subleading $\alpha\alpha_s$ corrections [80] are also included. Further three-loop corrections of order $\alpha\alpha_s^2$ [81], $\alpha^3 m_t^6$ [82,83], and $\alpha^2 \alpha_s m_t^4$ (for $M_H = 0$) [82], are rather small. The same is true for $\alpha^3 M_H^4$ [84] corrections unless M_H approaches 1 TeV. Also known are the singlet contributions (pure gluonic intermediate states) of order $\alpha\alpha_s^2$ [85] and $\alpha\alpha_s^3$ [86]. Recently, the corresponding non-singlet contributions have been computed as well [87].

The leading EW two-loop terms for the $Z \rightarrow \bar{b}b$ -vertex of $\mathcal{O}(\alpha^2 m_t^4)$ have been obtained in Refs. 71 and 72, and the mixed QCD-EW contributions in Refs. 88 and 89. The authors of Ref. 90 completed the two-loop EW fermionic corrections to \overline{s}_b^2 . The $\mathcal{O}(\alpha\alpha_s)$ -vertex corrections involving massless quarks [91] add coherently, resulting in a sizable effect and shift $\alpha_s(M_Z)$ when extracted from Z lineshape observables (see Sec. 10.4) by $\approx +0.0007$.

Many of the EW corrections are absorbed into the renormalized Fermi constant defined in Eq. (10.6). Others modify the tree-level expressions for Z pole observables and neutral-current amplitudes. In particular, the relations in Eq. (10.5) now read,

$$\overline{g}_V^f = \sqrt{\rho_f} (t_{3L}^{(f)} - 2q_f \kappa_f \sin^2 \theta_W), \quad \overline{g}_A^f = \sqrt{\rho_f} t_{3L}^{(f)}, \quad (10.17)$$

where the EW radiative corrections have been absorbed into corrections $\rho_f - 1$ and $\kappa_f - 1$, which depend on the fermion f and on the renormalization scheme. In the on-shell scheme, the quadratic m_t dependence is given by $\rho_f \sim 1 + \rho_t$, $\kappa_f \sim 1 + \rho_t / \tan^2 \theta_W$, while in $\overline{\text{MS}}$, $\hat{\rho}_f \sim \hat{\kappa}_f \sim 1$, for $f \neq b$ ($\hat{\rho}_b \sim 1 - \frac{4}{3}\rho_t$, $\hat{\kappa}_b \sim 1 + \frac{2}{3}\rho_t$). In the $\overline{\text{MS}}$ scheme the normalization is changed according to $G_F M_Z^2 / 2\sqrt{2}\pi \rightarrow \hat{\alpha} / 4\hat{s}_Z^2 \hat{c}_Z^2$. (If one continues to normalize amplitudes by $G_F M_Z^2 / 2\sqrt{2}\pi$, as in the 1996 edition of this *Review*, then $\hat{\rho}_f$ contains an additional factor of $\hat{\rho}(1 - \Delta\hat{\rho}_W)\hat{\alpha}/\alpha$.) In practice, additional bosonic and fermionic loops, vertex corrections, leading higher order contributions, *etc.*, must be included. For example, in the $\overline{\text{MS}}$ scheme one has $\hat{\rho}_\ell = 0.9981$, $\hat{\kappa}_\ell = 1.0013$, $\hat{\rho}_b = 0.9869$, and $\hat{\kappa}_b = 1.0067$. It is convenient to define an effective angle $\overline{s}_f^2 \equiv \sin^2 \overline{\theta}_{Wf} \equiv \hat{\kappa}_f \hat{s}_Z^2 = \kappa_f s_W^2$, in terms of which \overline{g}_V^f and \overline{g}_A^f are given by $\sqrt{\rho_f}$ times their tree-level formulae. Because \overline{g}_V^f is very small, not only $A_{LR}^0 = A_e, A_{FB}^{(0,\ell)}$, and \mathcal{P}_τ , but also $A_{FB}^{(0,b)}, A_{FB}^{(0,c)}, A_{FB}^{(0,s)}$, and the hadronic asymmetries are mainly sensitive to \overline{s}_ℓ^2 . One finds that $\hat{\kappa}_f$ ($f \neq b$) is almost independent of (m_t, M_H) , so that one can write

$$\overline{s}_\ell^2 \sim \hat{s}_Z^2 + 0.00029. \quad (10.18)$$

Thus, the asymmetries determine values of \overline{s}_ℓ^2 and \hat{s}_Z^2 almost independent of m_t , while the κ 's for the other schemes are m_t dependent.

Table 10.2: Standard Model expressions for the neutral-current parameters for ν -hadron, ν - e , and e^- -scattering processes.

At tree level, $\rho = \kappa = 1$, $\lambda = 0$. If radiative corrections are included, $\rho_{\nu N} = 1.0082$, $\hat{\kappa}_{\nu N}(\langle Q^2 \rangle = -20 \text{ GeV}^2) = 0.9972$, $\hat{\kappa}_{\nu N}(\langle Q^2 \rangle = -35 \text{ GeV}^2) = 0.9965$, $\lambda_{uL} = -0.0031$, $\lambda_{dL} = -0.0025$ and $\lambda_R = 3.7 \times 10^{-5}$. For ν - e scattering, $\rho_{\nu e} = 1.0128$ and $\hat{\kappa}_{\nu e} = 0.9963$ (at $\langle Q^2 \rangle = 0$). For atomic parity violation and the polarized DIS experiment at SLAC, $\rho'_e = 0.9887$, $\rho_e = 1.0007$, $\hat{\kappa}'_e = 1.0038$, $\hat{\kappa}_e = 1.0297$, $\lambda' = -1.8 \times 10^{-5}$, $\lambda_u = -0.0118$ and $\lambda_d = 0.0029$. And for polarized Møller scattering with SLAC (JLab) kinematics, $\lambda_e = -0.0002$ ($\lambda_e = -0.0004$). The dominant m_t dependence is given by $\rho \sim 1 + \rho_t$, while $\hat{\kappa} \sim 1$ ($\overline{\text{MS}}$) or $\kappa \sim 1 + \rho_t / \tan^2 \theta_W$ (on-shell).

Quantity	Standard Model Expression
$\epsilon_L(u)$	$\rho_{\nu N} \left(\frac{1}{2} - \frac{2}{3} \hat{\kappa}_{\nu N} \hat{s}_Z^2 \right) + \lambda_{uL}$
$\epsilon_L(d)$	$\rho_{\nu N} \left(-\frac{1}{2} + \frac{1}{3} \hat{\kappa}_{\nu N} \hat{s}_Z^2 \right) + \lambda_{dL}$
$\epsilon_R(u)$	$\rho_{\nu N} \left(-\frac{2}{3} \hat{\kappa}_{\nu N} \hat{s}_Z^2 \right) + \lambda_R$
$\epsilon_R(d)$	$\rho_{\nu N} \left(\frac{1}{3} \hat{\kappa}_{\nu N} \hat{s}_Z^2 \right) + 2\lambda_R$
$g_V^{\nu e}$	$\rho_{\nu e} \left(-\frac{1}{2} + 2\hat{\kappa}_{\nu e} \hat{s}_Z^2 \right)$
$g_A^{\nu e}$	$\rho_{\nu e} \left(-\frac{1}{2} \right)$
C_{1u}	$\rho'_e \left(-\frac{1}{2} + \frac{4}{3} \hat{\kappa}'_e \hat{s}_Z^2 \right) + \lambda'$
C_{1d}	$\rho'_e \left(\frac{1}{2} - \frac{2}{3} \hat{\kappa}'_e \hat{s}_Z^2 \right) - 2\lambda'$
C_{2u}	$\rho_e \left(-\frac{1}{2} + 2\hat{\kappa}_e \hat{s}_Z^2 \right) + \lambda_u$
C_{2d}	$\rho_e \left(\frac{1}{2} - 2\hat{\kappa}_e \hat{s}_Z^2 \right) + \lambda_d$
C_{2e}	$\rho_e \left(\frac{1}{2} - 2\hat{\kappa}_e \hat{s}_Z^2 \right) + \lambda_e$

Throughout this *Review* we utilize EW radiative corrections from the program GAPP [21], which works entirely in the $\overline{\text{MS}}$ scheme, and which is independent of the package ZFITTER [70]. Another resource is the recently developed modular fitting toolkit Gfitter [92].

10.3. Low energy electroweak observables

In the following we discuss EW precision observables obtained at low momentum transfers [6], *i.e.* $Q^2 \ll M_Z^2$. It is convenient to write the four-fermion interactions relevant to ν -hadron, ν - e , as well as parity violating e -hadron and e - e neutral-current processes in a form that is valid in an arbitrary gauge theory (assuming massless left-handed neutrinos). One has,

$$-\mathcal{L}^{\nu h} = \frac{G_F}{\sqrt{2}} \bar{\nu} \gamma^\mu (1 - \gamma^5) \nu \times \sum_i [\epsilon_L(i) \bar{q}_i \gamma_\mu (1 - \gamma^5) q_i + \epsilon_R(i) \bar{q}_i \gamma_\mu (1 + \gamma^5) q_i], \quad (10.19)$$

$$-\mathcal{L}^{\nu e} = \frac{G_F}{\sqrt{2}} \bar{\nu}_\mu \gamma^\mu (1 - \gamma^5) \nu_\mu \bar{e} \gamma_\mu (g_V^{\nu e} - g_A^{\nu e} \gamma^5) e, \quad (10.20)$$

$$-\mathcal{L}^{eh} = -\frac{G_F}{\sqrt{2}} \sum_i [C_{1i} \bar{e} \gamma_\mu \gamma^5 e \bar{q}_i \gamma^\mu q_i + C_{2i} \bar{e} \gamma_\mu e \bar{q}_i \gamma^\mu \gamma^5 q_i], \quad (10.21)$$

$$-\mathcal{L}^{ee} = -\frac{G_F}{\sqrt{2}} C_{2e} \bar{e} \gamma_\mu \gamma^5 e \bar{e} \gamma^\mu e, \quad (10.22)$$

where one must include the charged-current contribution for ν_e - e and $\bar{\nu}_{e-e}$ and the parity-conserving QED contribution for electron scattering.

The SM expressions for $\epsilon_{L,R}(i)$, $g_{V,A}^{\nu e}$, and C_{ij} are given in Table 10.2. Note, that $g_{V,A}^{\nu e}$ and the other quantities are coefficients of effective four-Fermi operators, which differ from the quantities defined in Eq. (10.5) in the radiative corrections and in the presence of possible physics beyond the SM.

10.3.1. Neutrino scattering: For a general review on ν -scattering we refer to Ref. 93 (nonstandard neutrino scattering interactions are surveyed in Ref. 94).

The cross-section in the laboratory system for $\nu_{\mu}e \rightarrow \nu_{\mu}e$ or $\bar{\nu}_{\mu}e \rightarrow \bar{\nu}_{\mu}e$ elastic scattering [95] is

$$\frac{d\sigma_{\nu,\bar{\nu}}}{dy} = \frac{G_F^2 m_e E_\nu}{2\pi} \left[(g_V^{\nu e} \pm g_A^{\nu e})^2 + (g_V^{\nu e} \mp g_A^{\nu e})^2 (1-y)^2 - (g_V^{\nu e 2} - g_A^{\nu e 2}) \frac{y m_e}{E_\nu} \right], \quad (10.23)$$

where the upper (lower) sign refers to $\nu_{\mu}(\bar{\nu}_{\mu})e$, and $y \equiv T_e/E_\nu$ (which runs from 0 to $(1 + m_e/2E_\nu)^{-1}$) is the ratio of the kinetic energy of the recoil electron to the incident ν or $\bar{\nu}$ energy. For $E_\nu \gg m_e$ this yields a total cross-section

$$\sigma = \frac{G_F^2 m_e E_\nu}{2\pi} \left[(g_V^{\nu e} \pm g_A^{\nu e})^2 + \frac{1}{3} (g_V^{\nu e} \mp g_A^{\nu e})^2 \right]. \quad (10.24)$$

The most accurate measurements [95–100] of $\sin^2 \theta_W$ from ν -lepton scattering (see Sec. 10.6) are from the ratio $R \equiv \sigma_{\nu_{\mu}e}/\sigma_{\bar{\nu}_{\mu}e}$ in which many of the systematic uncertainties cancel. Radiative corrections (other than m_t effects) are small compared to the precision of present experiments and have negligible effect on the extracted $\sin^2 \theta_W$. The most precise experiment (CHARM II) [98] determined not only $\sin^2 \theta_W$ but $g_{V,A}^{\nu e}$ as well, which are shown in Fig. 10.1. The cross-sections for $\nu_e e$ and $\bar{\nu}_e e$ may be obtained from Eq. (10.23) by replacing $g_{V,A}^{\nu e}$ by $g_{V,A}^{\nu e} + 1$, where the 1 is due to the charged-current contribution.

Figure 10.1: Allowed contours in $g_A^{\nu e}$ vs. $g_V^{\nu e}$ from neutrino-electron scattering and the SM prediction as a function of the weak mixing angle \hat{s}_Z^2 . (The SM best fit value $\hat{s}_Z^2 = 0.23116$ is also indicated.) The $\nu_e e$ [99] and $\bar{\nu}_e e$ [100] constraints are at 1σ , while each of the four equivalent $\nu_{\mu}(\bar{\nu}_{\mu})e$ [95–98] solutions ($g_{V,A} \rightarrow -g_{V,A}$ and $g_{V,A} \rightarrow g_{A,V}$) are at 90% C.L. The global best fit region (shaded) almost exactly coincides with the corresponding $\nu_{\mu}(\bar{\nu}_{\mu})e$ region. The solution near $g_A = 0, g_V = -0.5$ is eliminated by $e^+e^- \rightarrow \ell^+\ell^-$ data under the weak additional assumption that the neutral current is dominated by the exchange of a single Z boson.

A precise determination of the on-shell $s_{W,V}^2$, which depends only very weakly on m_t and M_H , is obtained from deep inelastic scattering (DIS) of neutrinos from (approximately) isoscalar targets [101]. The ratio $R_{\nu} \equiv \sigma_{\nu N}^{NC}/\sigma_{\nu N}^{CC}$ of neutral-to-charged-current cross-sections has

been measured to 1% accuracy by CDHS [102] and CHARM [103] at CERN. CCFR [104] at Fermilab has obtained an even more precise result, so it is important to obtain theoretical expressions for R_{ν} and $R_{\bar{\nu}} \equiv \sigma_{\bar{\nu}N}^{NC}/\sigma_{\bar{\nu}N}^{CC}$ to comparable accuracy. Fortunately, many of the uncertainties from the strong interactions and neutrino spectra cancel in the ratio. A large theoretical uncertainty is associated with the c -threshold, which mainly affects σ^{CC} . Using the slow rescaling prescription [105] the central value of $\sin^2 \theta_W$ from CCFR varies as $0.0111(m_c [\text{GeV}] - 1.31)$, where m_c is the effective mass which is numerically close to the $\overline{\text{MS}}$ mass $\hat{m}_c(\hat{m}_c)$, but their exact relation is unknown at higher orders. For $m_c = 1.31 \pm 0.24$ GeV (determined from ν -induced dimuon production [106]) this contributes ± 0.003 to the total uncertainty $\Delta \sin^2 \theta_W \sim \pm 0.004$. (The experimental uncertainty is also ± 0.003 .) This uncertainty largely cancels, however, in the Paschos-Wolfenstein ratio [107],

$$R^- = \frac{\sigma_{\nu N}^{NC} - \sigma_{\bar{\nu}N}^{NC}}{\sigma_{\nu N}^{CC} - \sigma_{\bar{\nu}N}^{CC}}. \quad (10.25)$$

It was measured by Fermilab's NuTeV collaboration [108] for the first time, and required a high-intensity and high-energy anti-neutrino beam.

A simple zeroth-order approximation is

$$R_{\nu} = g_L^2 + g_R^2 r, \quad R_{\bar{\nu}} = g_L^2 + \frac{g_R^2}{r}, \quad R^- = g_L^2 - g_R^2, \quad (10.26)$$

where

$$g_L^2 \equiv \epsilon_L(u)^2 + \epsilon_L(d)^2 \approx \frac{1}{2} - \sin^2 \theta_W + \frac{5}{9} \sin^4 \theta_W, \quad (10.27a)$$

$$g_R^2 \equiv \epsilon_R(u)^2 + \epsilon_R(d)^2 \approx \frac{5}{9} \sin^4 \theta_W, \quad (10.27b)$$

and $r \equiv \sigma_{\bar{\nu}N}^{CC}/\sigma_{\nu N}^{CC}$ is the ratio of $\bar{\nu}$ to ν charged-current cross-sections, which can be measured directly. (In the simple parton model, ignoring hadron energy cuts, $r \approx (\frac{1}{3} + \epsilon)/(\frac{1}{3} - \epsilon)$, where $\epsilon \sim 0.125$ is the ratio of the fraction of the nucleon's momentum carried by anti-quarks to that carried by quarks.) In practice, Eq. (10.26) must be corrected for quark mixing, quark sea effects, c -quark threshold effects, non-isoscalarity, $W-Z$ propagator differences, the finite muon mass, QED and EW radiative corrections. Details of the neutrino spectra, experimental cuts, x and Q^2 dependence of structure functions, and longitudinal structure functions enter only at the level of these corrections and therefore lead to very small uncertainties. CCFR quotes $s_W^2 = 0.2236 \pm 0.0041$ for $(m_t, M_H) = (175, 150)$ GeV with very little sensitivity to (m_t, M_H) .

The NuTeV collaboration found $s_W^2 = 0.2277 \pm 0.0016$ (for the same reference values), which was 3.0σ higher than the SM prediction [108]. The deviation was in g_L^2 (initially 2.7σ low) while g_R^2 was consistent with the SM. Since then a number of experimental and theoretical developments changed the interpretation of the measured cross section ratios, affecting the extracted $g_{L,R}^2$ (and thus s_W^2) including their uncertainties and correlation. In the following paragraph we give a semi-quantitative and preliminary discussion of these effects, but we stress that the precise impact of them needs to be evaluated carefully by the collaboration with a new and self-consistent set of PDFs, including new radiative corrections, while simultaneously allowing isospin breaking and asymmetric strange seas. This is an effort which is currently on its way and until it is completed we do not include the NuTeV constraints on $g_{L,R}^2$ in our default set of fits.

(i) In the original analysis NuTeV worked with a symmetric strange quark sea but subsequently measured [109] the difference between the strange and antistrange momentum distributions, $S^- \equiv \int_0^1 dx x [s(x) - \bar{s}(x)] = 0.00196 \pm 0.00143$, from dimuon events utilizing the first complete next-to-leading order QCD description [110] and parton distribution functions (PDFs) according to Ref. 111. The global PDF fits in Ref. 112 give somewhat smaller values, $S^- = 0.0013(9)$ [$S^- = 0.0010(13)$], where the semi-leptonic charmed-hadron branching ratio, $B_{\mu} = 8.8 \pm 0.5\%$, has [not] been used as an external constraint. The resulting S^- also depends on the PDF

model used and on whether theoretical arguments (see Ref. 113 and references therein) are invoked favoring a zero crossing of $x[s(x) - \bar{s}(x)]$ at values much larger than seen by NuTeV and suggesting an effect of much smaller and perhaps negligible size. (ii) The measured branching ratio for K_{e3} decays enters crucially in the determination of the $\nu_e(\bar{\nu}_e)$ contamination of the $\nu_\mu(\bar{\nu}_\mu)$ beam. This branching ratio has moved from $4.82 \pm 0.06\%$ at the time of the original publication [108] to the current value of $5.07 \pm 0.04\%$, *i.e.*, a change by more than 4σ . This moves s_W^2 about one standard deviation further away from the SM prediction while reducing the $\nu_e(\bar{\nu}_e)$ uncertainty. (iii) PDFs seem to violate isospin symmetry at levels much stronger than generally expected [114]. A minimum χ^2 set of PDFs [115] allowing charge symmetry violation for both valence quarks [$d_V^p(x) \neq u_V^n(x)$] and sea quarks [$\bar{d}^p(x) \neq \bar{u}^n(x)$] shows a reduction in the NuTeV discrepancy by about 1σ . But isospin symmetry violating PDFs are currently not well constrained phenomenologically and within uncertainties the NuTeV anomaly could be accounted for in full or conversely made larger [115]. Still, the leading contribution from quark mass differences turns out to be largely model-independent [116] (at least in sign) and a shift, $\delta s_W^2 = -0.0015 \pm 0.0003$ [113], has been estimated. (iv) QED splitting effects also violate isospin symmetry with an effect on s_W^2 whose sign (reducing the discrepancy) is model-independent. The corresponding shift of $\delta s_W^2 = -0.0011$ has been calculated in Ref. 117 but has a large uncertainty. (v) Nuclear shadowing effects [118] are likely to affect the interpretation of the NuTeV result at some level, but the NuTeV collaboration argues that their data are dominated by values of Q^2 at which nuclear shadowing is expected to be relatively small. However, another nuclear effect, the isovector EMC effect [119], is much larger (because it affects all neutrons in the nucleus, not just the excess ones) and model-independently works to reduce the discrepancy. It is estimated to lead to a shift of $\delta s_W^2 = -0.0019 \pm 0.0006$ [113]. It would be important to verify and quantify this kind of effect experimentally, *e.g.*, in polarized electron scattering. (vi) The extracted s_W^2 may also shift at the level of the quoted uncertainty when analyzed using the most recent QED and EW radiative corrections [120,121], as well as QCD corrections to the structure functions [122]. However, these are scheme-dependent and in order to judge whether they are significant they need to be adapted to the experimental conditions and kinematics of NuTeV, and have to be obtained in terms of observable variables and for the differential cross-sections. In addition, there is the danger of double counting some of the QED splitting effects. (vii) New physics could also affect $g_{L,R}^2$ [123] but it is difficult to convincingly explain the entire effect that way.

10.3.2. Parity violation :

The SLAC polarized electron-deuteron DIS experiment [124] measured the right-left asymmetry,

$$A = \frac{\sigma_R - \sigma_L}{\sigma_R + \sigma_L}, \quad (10.28)$$

where $\sigma_{R,L}$ is the cross-section for the deep-inelastic scattering of a right- or left-handed electron: $e_{R,L}N \rightarrow eX$. In the quark parton model,

$$\frac{A}{Q^2} = a_1 + a_2 \frac{1 - (1 - y)^2}{1 + (1 - y)^2}, \quad (10.29)$$

where $Q^2 > 0$ is the momentum transfer and y is the fractional energy transfer from the electron to the hadrons. For the deuteron or other isoscalar targets, one has, neglecting the s -quark and anti-quarks,

$$a_1 = \frac{3G_F}{5\sqrt{2}\pi\alpha} \left(C_{1u} - \frac{1}{2}C_{1d} \right) \approx \frac{3G_F}{5\sqrt{2}\pi\alpha} \left(-\frac{3}{4} + \frac{5}{3}\sin^2\theta_W \right), \quad (10.30a)$$

$$a_2 = \frac{3G_F}{5\sqrt{2}\pi\alpha} \left(C_{2u} - \frac{1}{2}C_{2d} \right) \approx \frac{9G_F}{5\sqrt{2}\pi\alpha} \left(\sin^2\theta_W - \frac{1}{4} \right). \quad (10.30b)$$

In another polarized-electron scattering experiment on deuterons, but in the quasi-elastic kinematic regime, the SAMPLE experiment [125] at MIT-Bates extracted the combination $C_{2u} - C_{2d}$ at Q^2 values of 0.1 GeV^2 and 0.038 GeV^2 . What was actually determined were

nucleon form factors from which the quoted results were obtained by the removal of a multi-quark radiative correction [126]. Other linear combinations of the C_{iq} have been determined in polarized-lepton scattering at CERN in μ -C DIS, at Mainz in e -Be (quasi-elastic), and at Bates in e -C (elastic). See the review articles in Refs. 127 and 128 for more details. Recent polarized electron asymmetry experiments, *i.e.*, SAMPLE, the PVA4 experiment at Mainz, and the HAPPEX and G0 experiments at Jefferson Lab, have focussed on the strange quark content of the nucleon. These are reviewed in Ref. 129, where it is shown that they can also provide significant constraints on C_{1u} and C_{1d} which complement those from atomic parity violation (see Fig. 10.2).

Figure 10.2: Constraints on the effective couplings, C_{1u} and C_{1d} , from recent (PVES) and older polarized parity violating electron scattering, and from atomic parity violation (APV) at 1σ , as well as the 90% C.L. global best fit (shaded) and the SM prediction as a function of the weak mixing angle \hat{s}_W^2 . (The SM best fit value $\hat{s}_W^2 = 0.23116$ is also indicated.)

The parity violating asymmetry, A_{PV} , in fixed target polarized Moller scattering, $e^-e^- \rightarrow e^-e^-$, is defined as in Eq. (10.28) and reads [130],

$$\frac{A_{PV}}{Q^2} = -2C_{2e} \frac{G_F}{\sqrt{2}\pi\alpha} \frac{1 - y}{1 + y^4 + (1 - y)^4}, \quad (10.31)$$

where y is again the energy transfer. It has been measured at low $Q^2 = 0.026 \text{ GeV}^2$ in the SLAC E158 experiment [131], with the result $A_{PV} = (-1.31 \pm 0.14_{\text{stat.}} \pm 0.10_{\text{syst.}}) \times 10^{-7}$. Expressed in terms of the weak mixing angle in the $\overline{\text{MS}}$ scheme, this yields $\hat{s}^2(Q^2) = 0.2403 \pm 0.0013$, and established the scale dependence of the weak mixing angle (see Fig. 10.3) at the level of 6.4 standard deviations. One can also define the so-called weak charge of the electron (*cf.* Eq. (10.32) below) as $Q_W(e) \equiv -2C_{2e} = -0.0403 \pm 0.0053$ (the implications are discussed in Ref. 133).

In a similar experiment and at about the same Q^2 , Qweak at Jefferson Lab [136] will be able to measure the weak charge of the proton, $Q_W(p) = -2[2C_{1u} + C_{1d}]$, and $\sin^2\theta_W$ in polarized ep scattering with relative precisions of 4% and 0.3%, respectively.

There are precise experiments measuring atomic parity violation (APV) [137] in cesium [138,139] (at the 0.4% level [138]), thallium [140], lead [141], and bismuth [142]. The EW physics is contained in the weak charges which are defined by,

$$Q_W(Z, N) \equiv -2[C_{1u}(2Z + N) + C_{1d}(Z + 2N)] \approx Z(1 - 4\sin^2\theta_W) - N. \quad (10.32)$$

E.g., $Q_W(^{133}\text{Cs})$ is extracted by measuring experimentally the ratio of the parity violating amplitude, E_{PNC} , to the Stark vector transition

Figure 10.3: Scale dependence of the weak mixing angle defined in the $\overline{\text{MS}}$ scheme [132] (for the scale dependence of the weak mixing angle defined in a mass-dependent renormalization scheme, see Ref. 133). The minimum of the curve corresponds to $Q = M_W$, below which we switch to an effective theory with the W^\pm bosons integrated out, and where the β -function for the weak mixing angle changes sign. At the location of the W boson mass and each fermion mass there are also discontinuities arising from scheme dependent matching terms which are necessary to ensure that the various effective field theories within a given loop order describe the same physics. However, in the $\overline{\text{MS}}$ scheme these are very small numerically and barely visible in the figure provided one decouples quarks at $Q = \hat{m}_q(\hat{m}_q)$. The width of the curve reflects the theory uncertainty from strong interaction effects which at low energies is at the level of $\pm 7 \times 10^{-5}$ [132]. Following the estimate [135] of the typical momentum transfer for parity violation experiments in Cs, the location of the APV data point is given by $\mu = 2.4$ MeV. For NuTeV we display the updated value from Ref. 134 and chose $\mu = \sqrt{20}$ GeV which is about half-way between the averages of $\sqrt{Q^2}$ for ν and $\bar{\nu}$ interactions at NuTeV. The Tevatron measurements are strongly dominated by invariant masses of the final state dilepton pair of $\mathcal{O}(M_Z)$ and can thus be considered as additional Z pole data points. However, for clarity we displayed the point horizontally to the right. Similar remarks apply to the first measurement at the LHC by the CMS collaboration.

polarizability, β , and by calculating theoretically E_{PNC} in terms of Q_W . One can then write,

$$Q_W = N \left(\frac{\text{Im } E_{\text{PNC}}}{\beta} \right)_{\text{exp.}} \left(\frac{|e| a_B Q_W}{\text{Im } E_{\text{PNC}} N} \right)_{\text{th.}} \left(\frac{\beta}{a_B^3} \right)_{\text{exp.+th.}} \left(\frac{a_B^2}{|e|} \right).$$

The uncertainties associated with atomic wave functions are quite small for cesium [143]. The semi-empirical value of β used in early analyses added another source of theoretical uncertainty [144]. However, the ratio of the off-diagonal hyperfine amplitude to the polarizability was subsequently measured directly by the Boulder group [145]. Combined with the precisely known hyperfine amplitude [146] one finds, $\beta = 26.991 \pm 0.046$, in excellent agreement with the earlier results, reducing the overall theory uncertainty (while slightly increasing the experimental error). The recent state-of-the-art many body calculation [147] yields, $\text{Im } E_{\text{PNC}} = (0.8906 \pm 0.0026) \times 10^{-11} |e| a_B Q_W / N$, while the two measurements [138,139] combine to give $\text{Im } E_{\text{PNC}} / \beta = -1.5924 \pm 0.0055$ mV/cm, and we obtain $Q_W(^{133}\text{Cs}) = -73.20 \pm 0.35$. Thus, the various theoretical efforts in Refs. 147 and 148 together with an update of the SM calculation [149] including a very recent dispersion analysis of the γZ -box contribution [150] removed an earlier 2.3σ deviation from the SM (see the year 2000 edition of this *Review*). The theoretical uncertainties are 3% for thallium [151] but larger for the other atoms. The Boulder experiment in cesium also observed the parity-violating weak corrections to the nuclear electromagnetic vertex (the anapole moment [152]).

In the future it could be possible to further reduce the theoretical

wave function uncertainties by taking the ratios of parity violation in different isotopes [137,153]. There would still be some residual uncertainties from differences in the neutron charge radii, however [154]. Experiments in hydrogen and deuterium are another possibility for reducing the atomic theory uncertainties [155], while measurements of single trapped radium ions are promising [156] because of the much larger parity violating effect.

10.4. W and Z boson physics

10.4.1. e^+e^- scattering below the Z pole :

The forward-backward asymmetry for $e^+e^- \rightarrow \ell^+\ell^-$, $\ell = \mu$ or τ , is defined as

$$A_{FB} \equiv \frac{\sigma_F - \sigma_B}{\sigma_F + \sigma_B}, \quad (10.33)$$

where σ_F (σ_B) is the cross-section for ℓ^- to travel forward (backward) with respect to the e^- direction. A_{FB} and R , the total cross-section relative to pure QED, are given by

$$R = F_1, \quad A_{FB} = \frac{3 F_2}{4 F_1}, \quad (10.34)$$

where

$$F_1 = 1 - 2\chi_0 g_V^e g_V^\ell \cos \delta_R + \chi_0^2 (g_V^{e2} + g_A^{e2}) (g_V^{\ell 2} + g_A^{\ell 2}), \quad (10.35a)$$

$$F_2 = -2\chi_0 g_A^e g_A^\ell \cos \delta_R + 4\chi_0^2 g_A^e g_A^\ell g_V^e g_V^\ell, \quad (10.35b)$$

$$\tan \delta_R = \frac{M_Z \Gamma_Z}{M_Z^2 - s}, \quad \chi_0 = \frac{G_F}{2\sqrt{2}\pi\alpha} \frac{s M_Z^2}{[(M_Z^2 - s)^2 + M_Z^2 \Gamma_Z^2]^{1/2}}, \quad (10.36)$$

and where \sqrt{s} is the CM energy. Eqs. (10.35) are valid at tree level. If the data are radiatively corrected for QED effects (as described in Sec. 10.2), then the remaining EW corrections can be incorporated [157,158] (in an approximation adequate for existing PEP, PETRA, and TRISTAN data, which are well below the Z pole) by replacing χ_0 by $\chi(s) \equiv (1 + \rho_\ell) \chi_0(s) \alpha/\alpha(s)$, where $\alpha(s)$ is the running QED coupling, and evaluating g_V in the $\overline{\text{MS}}$ scheme and formulae for $e^+e^- \rightarrow \text{hadrons}$ may be found in Ref. 159.

10.4.2. Z pole physics :

At LEP 1 and the SLC, there were high-precision measurements of various Z pole observables [11,160–166], as summarized in Table 10.4. These include the Z mass and total width, Γ_Z , and partial widths $\Gamma(f\bar{f})$ for $Z \rightarrow f\bar{f}$ where fermion $f = e, \mu, \tau$, hadrons, b , or c . It is convenient to use the variables $M_Z, \Gamma_Z, R_\ell \equiv \Gamma(\text{had})/\Gamma(\ell^+\ell^-)$ ($\ell = e, \mu, \tau$), $\sigma_{\text{had}} \equiv 12\pi \Gamma(e^+e^-) \Gamma(\text{had})/M_Z^2 \Gamma_Z^2$, $R_b \equiv \Gamma(b\bar{b})/\Gamma(\text{had})$, and $R_c \equiv \Gamma(c\bar{c})/\Gamma(\text{had})$, most of which are weakly correlated experimentally. ($\Gamma(\text{had})$ is the partial width into hadrons.) The three values for R_ℓ are not inconsistent with lepton universality (although R_τ is somewhat low compared to R_e and R_μ), but we use the general analysis in which the three observables are treated as independent. Similar remarks apply to $A_{FB}^{0,\ell}$ defined in Eq. (10.39) ($A_{FB}^{0,\tau}$ is somewhat high). $\mathcal{O}(\alpha^3)$ QED corrections introduce a large anti-correlation (-30%) between Γ_Z and σ_{had} . The anti-correlation between R_b and R_c is -18% [11]. The R_ℓ are insensitive to m_t except for the $Z \rightarrow b\bar{b}$ vertex and final state corrections and the implicit dependence through $\sin^2 \theta_W$. Thus, they are especially useful for constraining α_s . The width for invisible decays [11], $\Gamma(\text{inv}) = \Gamma_Z - 3\Gamma(\ell^+\ell^-) - \Gamma(\text{had}) = 499.0 \pm 1.5$ MeV, can be used to determine the number of neutrino flavors much lighter than $M_Z/2$, $N_\nu = \Gamma(\text{inv})/\Gamma^{\text{theory}}(\nu\bar{\nu}) = 2.984 \pm 0.009$ for $(m_t, M_H) = (173.4, 117)$ GeV.

There were also measurements of various Z pole asymmetries. These include the polarization or left-right asymmetry

$$A_{LR} \equiv \frac{\sigma_L - \sigma_R}{\sigma_L + \sigma_R}, \quad (10.37)$$

where σ_L (σ_R) is the cross-section for a left-(right)-handed incident electron. A_{LR} was measured precisely by the SLD collaboration at

the SLC [162], and has the advantages of being extremely sensitive to $\sin^2 \theta_W$ and that systematic uncertainties largely cancel. In addition, SLD extracted the final-state couplings (defined below), A_b , A_c [11], A_s [163], A_τ , and A_μ [164], from left-right forward-backward asymmetries, using

$$A_{LR}^{FB}(f) = \frac{\sigma_{LF}^f - \sigma_{LB}^f - \sigma_{RF}^f + \sigma_{RB}^f}{\sigma_{LF}^f + \sigma_{LB}^f + \sigma_{RF}^f + \sigma_{RB}^f} = \frac{3}{4} A_f, \quad (10.38)$$

where, for example, σ_{LF}^f is the cross-section for a left-handed incident electron to produce a fermion f traveling in the forward hemisphere. Similarly, A_τ was measured at LEP 1 [11] through the negative total τ polarization, \mathcal{P}_τ , and A_e was extracted from the angular distribution of \mathcal{P}_τ . An equation such as (10.38) assumes that initial state QED corrections, photon exchange, γ - Z interference, the tiny EW boxes, and corrections for $\sqrt{s} \neq M_Z$ are removed from the data, leaving the pure EW asymmetries. This allows the use of effective tree-level expressions,

$$A_{LR} = A_e P_e, \quad A_{FB} = \frac{3}{4} A_f \frac{A_e + P_e}{1 + P_e A_e}, \quad (10.39)$$

where

$$A_f \equiv \frac{2\hat{g}_V^f \hat{g}_A^f}{\hat{g}_V^{f2} + \hat{g}_A^{f2}}. \quad (10.40)$$

Figure 10.4: 1σ (39.35% C.L.) contours for the Z -pole observables \hat{g}_A^f and \hat{g}_V^f , $f = e, \mu, \tau$ obtained at LEP and SLC [11], compared to the SM expectation as a function of \hat{s}_Z^2 . (The SM best fit value $\hat{s}_Z^2 = 0.23116$ is also indicated.) Also shown is the 90% CL allowed region in $\hat{g}_{A,V}^\ell$ obtained assuming lepton universality.

P_e is the initial e^- polarization, so that the second equality in Eq. (10.38) is reproduced for $P_e = 1$, and the Z pole forward-backward asymmetries at LEP 1 ($P_e = 0$) are given by $A_{FB}^{(0,f)} = \frac{3}{4} A_e A_f$ where $f = e, \mu, \tau, b, c, s$ [165], and q , and where $A_{FB}^{(0,q)}$ refers to the hadronic charge asymmetry. Corrections for t -channel exchange and s/t -channel interference cause $A_{FB}^{(0,e)}$ to be strongly anti-correlated with R_e (-37%). The correlation between $A_{FB}^{(0,b)}$ and $A_{FB}^{(0,c)}$ amounts to 15%. The initial state coupling, A_e , was also determined through the left-right charge asymmetry [166] and in polarized Bhabha scattering [164] at the SLC.

As an example of the precision of the Z -pole observables, the values of \hat{g}_A^f and \hat{g}_V^f , $f = e, \mu, \tau, \ell$, extracted from the LEP and SLC lineshape and asymmetry data is shown in Fig. 10.4, which should be compared with Fig. 10.1. (The two sets of parameters coincide in the SM at tree-level.)

As for hadron colliders, the forward-backward asymmetry, A_{FB} , for e^+e^- final states (with invariant masses restricted to or dominated

by values around M_Z) in $p\bar{p}$ collisions has been measured by the DØ [167] and CDF [168] collaborations and values for \hat{s}_ℓ^2 were extracted, which combine to $\hat{s}_\ell^2 = 0.23200 \pm 0.00076$ (assuming common PDF uncertainties). By varying the invariant mass and the scattering angle (and assuming the electron couplings), information on the effective Z couplings to light quarks, $\hat{g}_{V,A}^{u,d}$, could also be obtained [167,169], but with large uncertainties and mutual correlations and not independently of \hat{s}_ℓ^2 above. Similar analyses have also been reported by the H1 and ZEUS collaborations at HERA [170] and by the LEP collaborations [11]. This kind of measurement is harder in the pp environment due to the difficulty to assign the initial quark and antiquark in the underlying Drell-Yan process to the protons. Nevertheless, the CMS collaboration [171] already reported a first measurement, $\hat{s}_Z^2 = 0.2287 \pm 0.0032$.

10.4.3. LEP 2 :

LEP 2 [172] ran at several energies above the Z pole up to ~ 209 GeV. Measurements were made of a number of observables, including the cross-sections for $e^+e^- \rightarrow ff$ for $f = q, \mu^-, \tau^-$; the differential cross-sections for $f = e^-, \mu^-, \tau^-$; R_q for $q = b, c$; $A_{FB}(f)$ for $f = \mu, \tau, b, c$; W branching ratios; and WW , $WW\gamma$, ZZ , single W , and single Z cross-sections. They are in good agreement with the SM predictions, with the exceptions of the total hadronic cross-section (1.7σ high), R_b (2.1σ low), and $A_{FB}(b)$ (1.6σ low). Also, the negative result of the direct search for the SM Higgs boson excluded M_H values below 114.4 GeV at the 95% CL [173]. This result is complementary to and can be combined with [174] the limits inferred from the EW precision data.

The Z boson properties are extracted assuming the SM expressions for the γ - Z interference terms. These have also been tested experimentally by performing more general fits [172,175] to the LEP 1 and LEP 2 data. Assuming family universality this approach introduces three additional parameters relative to the standard fit [11], describing the γ - Z interference contribution to the total hadronic and leptonic cross-sections, $j_{\text{had}}^{\text{tot}}$ and j_ℓ^{tot} , and to the leptonic forward-backward asymmetry, j_ℓ^{fb} . *E.g.*,

$$j_{\text{had}}^{\text{tot}} \sim g_V^\ell g_V^{\text{had}} = 0.277 \pm 0.065, \quad (10.41)$$

which is in agreement with the SM expectation [11] of 0.21 ± 0.01 . These are valuable tests of the SM; but it should be cautioned that new physics is not expected to be described by this set of parameters, since (i) they do not account for extra interactions beyond the standard weak neutral-current, and (ii) the photonic amplitude remains fixed to its SM value.

Strong constraints on anomalous triple and quartic gauge couplings have been obtained at LEP 2 and the Tevatron as described in the Gauge & Higgs Bosons Particle Listings.

10.4.4. W and Z decays :

The partial decay width for gauge bosons to decay into massless fermions $f_1 \bar{f}_2$ (the numerical values include the small EW radiative corrections and final state mass effects) is given by

$$\Gamma(W^+ \rightarrow e^+ \nu_e) = \frac{G_F M_W^3}{6\sqrt{2}\pi} \approx 226.36 \pm 0.05 \text{ MeV}, \quad (10.42a)$$

$$\Gamma(W^+ \rightarrow u_i \bar{d}_j) = \frac{CG_F M_W^3}{6\sqrt{2}\pi} |V_{ij}|^2 \approx 706.34 \pm 0.16 \text{ MeV} |V_{ij}|^2, \quad (10.42b)$$

$$\Gamma(Z \rightarrow \psi_i \bar{\psi}_i) = \frac{CG_F M_Z^3}{6\sqrt{2}\pi} [g_V^{i2} + g_A^{i2}] \begin{cases} 167.22 \pm 0.01 \text{ MeV} (\nu\bar{\nu}), \\ 84.00 \pm 0.01 \text{ MeV} (e^+e^-), \\ 300.26 \pm 0.05 \text{ MeV} (u\bar{u}), \\ 383.04 \pm 0.05 \text{ MeV} (d\bar{d}), \\ 375.98 \mp 0.03 \text{ MeV} (b\bar{b}). \end{cases} \quad (10.42c)$$

For leptons $C = 1$, while for quarks

$$C = 3 \left[1 + \frac{\alpha_s(M_V)}{\pi} + 1.409 \frac{\alpha_s^2}{\pi^2} - 12.77 \frac{\alpha_s^3}{\pi^3} - 80.0 \frac{\alpha_s^4}{\pi^4} \right], \quad (10.43)$$

where the 3 is due to color and the factor in brackets represents the universal part of the QCD corrections [176] for massless quarks [177]. The $\mathcal{O}(\alpha_s^4)$ contribution in Eq. (10.43) is recent [178]. The $Z \rightarrow f\bar{f}$ widths contain a number of additional corrections: which are different for vector and axial-vector partial widths and are included through order α_s^3 and $\hat{m}_q^4(M_Z^2)$ unless they are tiny; and singlet contributions starting from two-loop order which are large, strongly top quark mass dependent, family universal, and flavor non-universal [181]. The QED factor $1 + 3\alpha_q^2/4\pi$, as well as two-loop order $\alpha\alpha_s$ and α^2 self-energy corrections [182] are also included. Working in the on-shell scheme, *i.e.*, expressing the widths in terms of $G_F M_{W,Z}^3$, incorporates the largest radiative corrections from the running QED coupling [63,183]. EW corrections to the Z widths are then incorporated by replacing $g_{V,A}^2$ by $\bar{g}_{V,A}^2$. Hence, in the on-shell scheme the Z widths are proportional to $\rho_i \sim 1 + \rho_t$. The $\overline{\text{MS}}$ normalization accounts also for the leading EW corrections [68]. There is additional (negative) quadratic m_t dependence in the $Z \rightarrow b\bar{b}$ vertex corrections [184] which causes $\Gamma(b\bar{b})$ to decrease with m_t . The dominant effect is to multiply $\Gamma(b\bar{b})$ by the vertex correction $1 + \delta\rho_{b\bar{b}}$, where $\delta\rho_{b\bar{b}} \sim 10^{-2}(-\frac{1}{2}\frac{m_t^2}{M_Z^2} + \frac{1}{5})$.

In practice, the corrections are included in ρ_b and κ_b , as discussed in Sec. 10.2.

For three fermion families the total widths are predicted to be

$$\Gamma_Z \approx 2.4960 \pm 0.0002 \text{ GeV}, \quad \Gamma_W \approx 2.0915 \pm 0.0005 \text{ GeV}. \quad (10.44)$$

We have assumed $\alpha_s(M_Z) = 0.1200$. An uncertainty in α_s of ± 0.002 introduces an additional uncertainty of 0.06% in the hadronic widths, corresponding to ± 1 MeV in Γ_Z . These predictions are to be compared with the experimental results, $\Gamma_Z = 2.4952 \pm 0.0023$ GeV [11] and $\Gamma_W = 2.085 \pm 0.042$ GeV [185] (see the Gauge & Higgs Boson Particle Listings for more details).

10.5. Precision flavor physics

In addition to cross-sections, asymmetries, parity violation, W and Z decays, there is a large number of experiments and observables testing the flavor structure of the SM. These are addressed elsewhere in this *Review*, and are generally not included in this Section. However, we identify three precision observables with sensitivity to similar types of new physics as the other processes discussed here. The branching fraction of the flavor changing transition $b \rightarrow s\gamma$ is of comparatively low precision, but since it is a loop-level process (in the SM) its sensitivity to new physics (and SM parameters, such as heavy quark masses) is enhanced. A discussion can be found in earlier editions of this *Review*. The τ -lepton lifetime and leptonic branching ratios are primarily sensitive to α_s and not affected significantly by many types of new physics. However, having an independent and reliable low energy measurement of α_s in a global analysis allows the comparison with the Z lineshape determination of α_s which shifts easily in the presence of new physics contributions. By far the most precise observable discussed here is the anomalous magnetic moment of the muon (the electron magnetic moment is measured to even greater precision and can be used to determine α , but its new physics sensitivity is suppressed by an additional factor of m_e^2/m_μ^2). Its combined experimental and theoretical uncertainty is comparable to typical new physics contributions.

The extraction of α_s from the τ lifetime [186] is standing out from other determinations because of a variety of independent reasons: (i) the τ -scale is low, so that upon extrapolation to the Z scale (where it can be compared to the theoretically clean Z lineshape determinations) the α_s error shrinks by about an order of magnitude; (ii) yet, this scale is high enough that perturbation theory and the operator product expansion (OPE) can be applied; (iii) these observables are fully inclusive and thus free of fragmentation and hadronization effects that would have to be modeled or measured; (iv) duality violation (DV) effects are most problematic near the branch cut but there they are suppressed by a double zero at $s = m_\tau^2$; (v) there are data [43] to constrain non-perturbative effects both within ($\delta_{D=6,8}$) and breaking (δ_{DV}) the OPE; (vi) a complete four-loop order QCD calculation is available [178]; (vii) large effects associated

with the QCD β -function can be re-summed [187] in what has become known as contour improved perturbation theory (CIPT). However, while there is no doubt that CIPT shows faster convergence in the lower (calculable) orders, doubts have been cast on the method by the observation that at least in a specific model [188], which includes the exactly known coefficients and theoretical constraints on the large-order behavior, ordinary fixed order perturbation theory (FOPT) may nevertheless give a better approximation to the full result. We therefore use the expressions [54,177,178,189],

$$\tau_\tau = \hbar \frac{1 - \mathcal{B}_\tau^s}{\Gamma_\tau^e + \Gamma_\tau^\mu + \Gamma_\tau^{ud}} = 291.13 \pm 0.43 \text{ fs}, \quad (10.45)$$

$$\Gamma_\tau^{ud} = \frac{G_F^2 m_\tau^5 |V_{ud}|^2}{64\pi^3} S(m_\tau, M_Z) \left(1 + \frac{3}{5} \frac{m_\tau^2 - m_\mu^2}{M_W^2} \right) \times \left[1 + \frac{\alpha_s(m_\tau)}{\pi} + 5.202 \frac{\alpha_s^2}{\pi^2} + 26.37 \frac{\alpha_s^3}{\pi^3} + 127.1 \frac{\alpha_s^4}{\pi^4} + \frac{\hat{\alpha}}{\pi} \left(\frac{85}{24} - \frac{\pi^2}{2} \right) + \delta_q \right], \quad (10.46)$$

and Γ_τ^e and Γ_τ^μ can be taken from Eq. (10.6) with obvious replacements. The relative fraction of decays with $\Delta S = -1$, $\mathcal{B}_\tau^s = 0.0286 \pm 0.0007$, is based on experimental data since the value for the strange quark mass, $\hat{m}_s(m_\tau)$, is not well known and the QCD expansion proportional to \hat{m}_s^2 converges poorly and cannot be trusted. $S(m_\tau, M_Z) = 1.01907 \pm 0.0003$ is a logarithmically enhanced EW correction factor with higher orders re-summed [190]. δ_q contains the dimension six and eight terms in the OPE, as well as DV effects, $\delta_{D=6,8} + \delta_{DV} = -0.004 \pm 0.012$ [191]. Depending on how $\delta_{D=6}$, $\delta_{D=8}$, and δ_{DV} are extracted, there are strong correlations not only between them, but also with the gluon condensate ($D = 4$) and possibly $D > 8$ terms. These latter are suppressed in Eq. (10.46) by additional factors of α_s , but not so for more general weight functions. A simultaneous fit to all non-perturbative terms [191] (as is necessary if one wants to avoid *ad hoc* assumptions) indicates that the α_s errors may have been underestimated in the past. Higher statistics τ decay data [45] and spectral functions from e^+e^- annihilation (providing a larger fit window and thus more discriminatory power and smaller correlations) are likely to reduce the δ_q error in the future. Also included in δ_q are quark mass effects and the $D = 4$ condensate contributions. An uncertainty of similar size arises from the truncation of the FOPT series and is conservatively taken as the α_s^4 term (this is re-calculated in each call of the fits, leading to an α_s -dependent and thus asymmetric error) until a better understanding of the numerical differences between FOPT and CIPT has been gained. Our perturbative error covers almost the entire range from using CIPT to assuming that the nearly geometric series in Eq. (10.46) continues to higher orders. The experimental uncertainty in Eq. (10.45), is from the combination of the two leptonic branching ratios with the direct τ_τ . Included are also various smaller uncertainties (± 0.5 fs) from other sources which are dominated by the evolution from the Z scale. In total we obtain a $\sim 2\%$ determination of $\alpha_s(M_Z) = 0.1193_{-0.0020}^{+0.0022}$, which corresponds to $\alpha_s(m_\tau) = 0.327_{-0.016}^{+0.019}$, and updates the result of Refs. 54 and 192. For more details, see Refs. 191 and 193 where the τ spectral functions are used as additional input.

The world average of the muon anomalous magnetic moment[‡],

$$a_\mu^{\text{exp}} = \frac{g_\mu - 2}{2} = (1165920.80 \pm 0.63) \times 10^{-9}, \quad (10.47)$$

is dominated by the final result of the E821 collaboration at BNL [194]. The QED contribution has been calculated to four

[‡] In what follows, we summarize the most important aspects of $g_\mu - 2$, and give some details about the evaluation in our fits. For more details see the dedicated contribution by A. Höcker and W. Marciano in this *Review*. There are some small numerical differences (at the level of 0.1 standard deviation), which are well understood and mostly arise because internal consistency of the fits requires the calculation of all observables from analytical expressions and common inputs and fit parameters, so that an independent evaluation is necessary for this Section. Note, that in the spirit of a global analysis based on all available information we have chosen here to average in the τ decay data, as well.

loops [195] (fully analytically to three loops [196,197]), and the leading logarithms are included to five loops [198,199]. The estimated SM EW contribution [200–202], $a_\mu^{\text{EW}} = (1.52 \pm 0.03) \times 10^{-9}$, which includes leading two-loop [201] and three-loop [202] corrections, is at the level of twice the current uncertainty.

The limiting factor in the interpretation of the result are the uncertainties from the two- and three-loop hadronic contribution. *E.g.*, Ref. 20 obtained the value $a_\mu^{\text{had}} = (69.23 \pm 0.42) \times 10^{-9}$ which combines CMD-2 [47] and SND [48] $e^+e^- \rightarrow$ hadrons cross-section data with radiative return results from BaBar [50] and KLOE [51]. This value suggests a 3.6σ discrepancy between Eq. (10.47) and the SM prediction. An alternative analysis [20] using τ decay data and isospin symmetry (CVC) yields $a_\mu^{\text{had}} = (70.15 \pm 0.47) \times 10^{-9}$. This result implies a smaller conflict (2.4σ) with Eq. (10.47). Thus, there is also a discrepancy between the spectral functions obtained from the two methods. For example, if one uses the e^+e^- data and CVC to predict the branching ratio for $\tau^- \rightarrow \nu_\tau \pi^- \pi^0$ decays [20] we obtain an average of $\mathcal{B}_{\text{CVC}} = 24.93 \pm 0.13 \pm 0.22_{\text{CVC}}$, while the average of the directly measured branching ratio yields 25.51 ± 0.09 , which is 2.3σ higher. It is important to understand the origin of this difference, but two observations point to the conclusion that at least some of it is experimental: (i) There is also a direct discrepancy of 1.9σ between \mathcal{B}_{CVC} derived from BaBar (which is not inconsistent with τ decays) and KLOE. (ii) Isospin violating corrections have been studied in detail in Ref. 203 and found to be largely under control. The largest effect is due to higher-order EW corrections [204] but introduces a negligible uncertainty [190]. Nevertheless, a_μ^{had} is often evaluated excluding the τ decay data arguing [205] that CVC breaking effects (*e.g.*, through a relatively large mass difference between the ρ^\pm and ρ^0 vector mesons) may be larger than expected. (This may also be relevant [205] in the context of the NuTeV result discussed above.) Experimentally [45], this mass difference is indeed larger than expected, but then one would also expect a significant width difference which is contrary to observation [45]. Fortunately, due to the suppression at large s (from where the conflicts originate) these problems are less pronounced as far as a_μ^{had} is concerned. In the following we view all differences in spectral functions as (systematic) fluctuations and average the results.

An additional uncertainty is induced by the hadronic three-loop light-by-light scattering contribution. Two recent and inherently different model calculations yield $a_\mu^{\text{LBS}} = (+1.36 \pm 0.25) \times 10^{-9}$ [206] and $a_\mu^{\text{LBS}} = +1.37^{+0.15}_{-0.27} \times 10^{-9}$ [207] which are higher than previous evaluations [208,209]. The sign of this effect is opposite [208] to the one quoted in the 2002 edition of this *Review*, and has subsequently been confirmed by two other groups [209]. There is also the upper bound $a_\mu^{\text{LBS}} < 1.59 \times 10^{-9}$ [207] but this requires an *ad hoc* assumption, too. The recent Ref. 210 quotes the value $a_\mu^{\text{LBS}} = (+1.05 \pm 0.26) \times 10^{-9}$, which we shift by 2×10^{-11} to account for the more accurate charm quark treatment of Ref. 207. We also increase the error to cover all evaluations, and we will use $a_\mu^{\text{LBS}} = (+1.07 \pm 0.32) \times 10^{-9}$ in the fits.

Other hadronic effects at three-loop order contribute [211] $a_\mu^{\text{had}}(\alpha^3) = (-1.00 \pm 0.06) \times 10^{-9}$. Correlations with the two-loop hadronic contribution and with $\Delta\alpha(M_Z)$ (see Sec. 10.2) were considered in Ref. 197 which also contains analytic results for the perturbative QCD contribution.

Altogether, the SM prediction is

$$a_\mu^{\text{theory}} = (1165918.41 \pm 0.48) \times 10^{-9}, \quad (10.48)$$

where the error is from the hadronic uncertainties excluding parametric ones such as from α_s and the heavy quark masses. Using a correlation of about 84% from the data input to the vacuum polarization integrals [20], we estimate the correlation of the total (experimental plus theoretical) uncertainty in a_μ with $\Delta\alpha(M_Z)$ as 24%. The overall 3.0σ discrepancy between the experimental and theoretical a_μ values could be due to fluctuations (the E821 result is statistics dominated) or underestimates of the theoretical uncertainties. On the other hand, $g_\mu - 2$ is also affected by many types of new physics, such as supersymmetric models with large $\tan\beta$ and moderately light

Table 10.3: Principal non- Z pole observables, compared with the SM best fit predictions. The first M_W value is from the Tevatron [214] and the second one from LEP 2 [172]. e -DIS [129] and the ν -DIS constraints from CDHS [102], CHARM [103], and CCFR [104] are included, as well, but not shown in the Table. The world averages for $g_{V,A}^{\nu e}$ are dominated by the CHARM II [98] results, $g_V^{\nu e} = -0.035 \pm 0.017$ and $g_A^{\nu e} = -0.503 \pm 0.017$. The errors are the total (experimental plus theoretical) uncertainties. The τ_τ value is the τ lifetime world average computed by combining the direct measurements with values derived from the leptonic branching ratios [54]; in this case, the theory uncertainty is included in the SM prediction. In all other SM predictions, the uncertainty is from M_Z , M_H , m_t , m_b , m_c , $\hat{\alpha}(M_Z)$, and α_s , and their correlations have been accounted for. The column denoted Pull gives the standard deviations for the principal fit with M_H free, while the column denoted Dev. (Deviation) is for $M_H = 124.5$ GeV [215] fixed.

Quantity	Value	Standard Model	Pull	Dev.
m_t [GeV]	173.4 ± 1.0	173.5 ± 1.0	-0.1	-0.3
M_W [GeV]	80.420 ± 0.031	80.381 ± 0.014	1.2	1.6
	80.376 ± 0.033		-0.2	0.2
$g_V^{\nu e}$	-0.040 ± 0.015	-0.0398 ± 0.0003	0.0	0.0
$g_A^{\nu e}$	-0.507 ± 0.014	-0.5064 ± 0.0001	0.0	0.0
$Q_W(e)$	-0.0403 ± 0.0053	-0.0474 ± 0.0005	1.3	1.3
$Q_W(\text{Cs})$	-73.20 ± 0.35	-73.23 ± 0.02	0.1	0.1
$Q_W(\text{Ti})$	-116.4 ± 3.6	-116.88 ± 0.03	0.1	0.1
τ_τ [fs]	291.13 ± 0.43	290.75 ± 2.51	0.1	0.1
$\frac{1}{2}(g_\mu - 2 - \frac{\alpha}{\pi})$	$(4511.07 \pm 0.77) \times 10^{-9}$	$(4508.70 \pm 0.09) \times 10^{-9}$	3.0	3.0

superparticle masses [212]. Thus, the deviation could also arise from physics beyond the SM.

10.6. Global fit results

In this section we present the results of global fits to the experimental data discussed in Sec. 10.3–Sec. 10.5. For earlier analyses see Refs. 128 and 213.

The values for m_t [56–58], M_W [172,214], neutrino scattering [96–104], the weak charges of the electron [131], cesium [138,139] and thallium [140], the muon anomalous magnetic moment [194], and the τ lifetime are listed in Table 10.3. Likewise, the principal Z pole observables can be found in Table 10.4 where the LEP 1 averages of the ALEPH, DELPHI, L3, and OPAL results include common systematic errors and correlations [11]. The heavy flavor results of LEP 1 and SLD are based on common inputs and correlated, as well [11]. Note that the values of $\Gamma(\ell^+\ell^-)$, $\Gamma(\text{had})$, and $\Gamma(\text{inv})$ are not independent of Γ_Z , the R_ℓ , and σ_{had} and that the SM errors in those latter are largely dominated by the uncertainty in α_s . Also shown in both Tables are the SM predictions for the values of M_Z , M_H , $\alpha_s(M_Z)$, $\Delta\alpha_{\text{had}}^{(3)}$ and the heavy quark masses shown in Table 10.5. The predictions result from a global least-square (χ^2) fit to all data using the minimization package MINUIT [216] and the EW library GAPP [21]. In most cases, we treat all input errors (the uncertainties of the values) as Gaussian. The reason is not that we assume that theoretical and systematic errors are intrinsically bell-shaped (which they are not) but because in most cases the input errors are combinations of many different (including statistical) error sources, which should yield approximately Gaussian combined errors by the large number theorem. Thus, if either the statistical components dominate or there are many components of similar size. An exception is the theory dominated error on the τ lifetime, which we recalculate in each χ^2 -function call since it depends itself on α_s . Sizes and shapes of the output errors (the uncertainties of the predictions and the SM fit parameters) are fully determined by the fit, and 1σ errors are defined to correspond to $\Delta\chi^2 = \chi^2 - \chi_{\text{min}}^2 = 1$, and do not necessarily correspond to the 68.3% probability range or the 39.3% probability contour (for 2 parameters).

Table 10.4: Principal Z pole observables and their SM predictions (*cf.* Table 10.3). The first $\bar{s}_\ell^2(A_{FB}^{(0,g)})$ is the effective angle extracted from the hadronic charge asymmetry, the second is the combined value from $D\bar{O}$ [167] and CDF [168], and the third is from CMS [171]. The three values of A_e are (i) from A_{LR} for hadronic final states [162]; (ii) from A_{LR} for leptonic final states and from polarized Bhabba scattering [164]; and (iii) from the angular distribution of the τ polarization at LEP 1. The two A_τ values are from SLD and the total τ polarization, respectively.

Quantity	Value	Standard Model	Pull	Dev.

A_τ	0.136 ± 0.015		-0.8	-0.7
	0.1439 ± 0.0043		-0.8	-0.7
A_b	0.923 ± 0.020	0.9348 ± 0.0001	-0.6	-0.6
A_c	0.670 ± 0.027	0.6680 ± 0.0004	0.1	0.1
A_s	0.895 ± 0.091	0.9357 ± 0.0001	-0.4	-0.4

The agreement is generally very good. Despite the few discrepancies discussed in the following, the fit describes well the data with a $\chi^2/\text{d.o.f.} = 45.0/42$. The probability of a larger χ^2 is 35%. Only the final result for $g_\mu - 2$ from BNL and $A_{FB}^{(0,b)}$ from LEP 1 are currently showing large (3.0σ and 2.6σ) deviations. In addition, A_{LR}^0 (SLD) from hadronic final states differs by 1.8σ . g_L^2 from NuTeV is nominally in conflict with the SM, as well, but the precise status is under investigation (see Sec. 10.3).

A_b can be extracted from $A_{FB}^{(0,b)}$ when $A_e = 0.1501 \pm 0.0016$ is taken from a fit to leptonic asymmetries (using lepton universality). The result, $A_b = 0.881 \pm 0.017$, is 3.2σ below the SM prediction[§] and also 1.6σ below $A_b = 0.923 \pm 0.020$ obtained from $A_{LR}^{FB}(b)$ at SLD. Thus, it appears that at least some of the problem in $A_{FB}^{(0,b)}$ is experimental. Note, however, that the uncertainty in $A_{FB}^{(0,b)}$ is strongly statistics dominated. The combined value, $A_b = 0.899 \pm 0.013$ deviates by 2.8σ .

[§] Alternatively, one can use $A_\ell = 0.1481 \pm 0.0027$, which is from LEP 1 alone and in excellent agreement with the SM, and obtain $A_b = 0.893 \pm 0.022$ which is 1.9σ low. This illustrates that some of the discrepancy is related to the one in A_{LR} .

It would be difficult to account for this 4.0% deviation by new physics that enters only at the level of radiative corrections since about a 20% correction to $\bar{\kappa}_b$ would be necessary to account for the central value of A_b [217]. If this deviation is due to new physics, it is most likely of tree-level type affecting preferentially the third generation. Examples include the decay of a scalar neutrino resonance [218], mixing of the b quark with heavy exotics [219], and a heavy Z' with family-nonuniversal couplings [220,221]. It is difficult, however, to simultaneously account for R_b , which has been measured on the Z peak and off-peak [222] at LEP 1. An average of R_b measurements at LEP 2 at energies between 133 and 207 GeV is 2.1σ below the SM prediction, while $A_{FB}^{(b)}$ (LEP 2) is 1.6σ low [172].

The left-right asymmetry, $A_{LR}^0 = 0.15138 \pm 0.00216$ [162], based on all hadronic data from 1992–1998 differs 1.8σ from the SM expectation of 0.1475 ± 0.0010 . The combined value of $A_\ell = 0.1513 \pm 0.0021$ from SLD (using lepton-family universality and including correlations) is also 1.8σ above the SM prediction; but there is experimental agreement between this SLD value and the LEP 1 value, $A_\ell = 0.1481 \pm 0.0027$, obtained from a fit to $A_{FB}^{(0,\ell)}$, $A_e(\mathcal{P}_\tau)$, and $A_\tau(\mathcal{P}_\tau)$, again assuming universality.

The observables in Table 10.3 and Table 10.4, as well as some other less precise observables, are used in the global fits described below. In all fits, the errors include full statistical, systematic, and theoretical uncertainties. The correlations on the LEP 1 lineshape and τ polarization, the LEP/SLD heavy flavor observables, the SLD lepton asymmetries, and the deep inelastic and ν - e scattering observables, are included. The theoretical correlations between $\Delta\alpha_{\text{had}}^{(5)}$ and $g_\mu - 2$, and between the charm and bottom quark masses, are also accounted for.

The data allow a simultaneous determination of M_Z , M_H , m_t , and the strong coupling $\alpha_s(M_Z)$. (\hat{m}_c , \hat{m}_b , and $\Delta\alpha_{\text{had}}^{(3)}$ are also allowed to float in the fits, subject to the theoretical constraints [19,54] described in Sec. 10.2. These are correlated with α_s .) α_s is determined mainly from R_ℓ , Γ_Z , σ_{had} , and τ_τ and is only weakly correlated with the other variables. The global fit to all data, including the hadron collider average $m_t = 173.4 \pm 1.0$ GeV, yields the result in Table 10.5 (the $\overline{\text{MS}}$ top quark mass given there corresponds to $m_t = 173.5 \pm 1.0$ GeV). The weak mixing angle is determined to

$$\hat{s}_Z^2 = 0.23116 \pm 0.00012, \quad s_W^2 = 0.22296 \pm 0.00028,$$

while the corresponding effective angle is related by Eq. (10.18), *i.e.*, $\bar{s}_\ell^2 = 0.23146 \pm 0.00012$.

As described in Sec. 10.2 and the paragraph following Eq. (10.47) in Sec. 10.5, there is considerable stress in the experimental e^+e^- spectral functions and also conflict when these are compared with τ decay spectral functions. These are below or above the 2σ level (depending on what is actually compared) but not larger than the deviations of some other quantities entering our analyses. The number and size of these deviations are not inconsistent with what one would expect to happen as a result of random fluctuations. It is nevertheless instructive to study the effect of doubling the uncertainty in $\Delta\alpha_{\text{had}}^{(3)}(1.8\text{ GeV}) = (55.50 \pm 0.78) \times 10^{-4}$, (see Sec. 10.2) on the extracted Higgs mass. The result, $M_H = 95_{-23}^{+28}$ GeV, demonstrates that the uncertainty in $\Delta\alpha_{\text{had}}$ is currently of only secondary importance. Note also, that a shift of ± 0.0001 in $\Delta\alpha_{\text{had}}^{(3)}(1.8\text{ GeV})$ corresponds to a shift of ∓ 5 GeV in M_H or about one fifth of its total uncertainty. The hadronic contribution to $\alpha(M_Z)$ is correlated with $g_\mu - 2$ (see Sec. 10.5). The measurement of the latter is higher than the SM prediction, and its inclusion in the fit favors a larger $\alpha(M_Z)$ and a lower M_H (currently by about 4 GeV).

The weak mixing angle can be determined from Z pole observables, M_W , and from a variety of neutral-current processes spanning a very wide Q^2 range. The results (for the older low energy neutral-current data see Refs. 128 and 213) shown in Table 10.6 are in reasonable agreement with each other, indicating the quantitative success of the SM. The largest discrepancy is the value $\hat{s}_Z^2 = 0.23193 \pm 0.00028$ from the forward-backward asymmetries into bottom and charm quarks, which is 2.8σ above the value 0.23116 ± 0.00012 from the

global fit to all data. Similarly, $\hat{s}_Z^2 = 0.23067 \pm 0.00029$ from the SLD asymmetries (in both cases when combined with M_Z) is 1.8 σ low. The SLD result has the additional difficulty (within the SM) of implying very low and excluded [173] Higgs masses. This is also true for $\hat{s}_Z^2 = 0.23098 \pm 0.00022$ from M_W and M_Z and — as a consequence — for the global fit. We have therefore included in Table 10.3 and Table 10.4 an additional column (denoted Deviation) indicating the deviations if $M_H = 124.5$ GeV [215] is fixed.

Table 10.5: Principal SM fit result including mutual correlations (all masses in GeV). Note that $\hat{m}_c(\hat{m}_c)$ induces a significant uncertainty in the running of α beyond $\Delta\alpha_{\text{had}}^{(3)}$ (1.8 GeV) resulting in a relatively large correlation with M_H . Since this effect is proportional to the quark’s electric charge squared it is much smaller for $\hat{m}_b(\hat{m}_b)$.

The extracted Z pole value of $\alpha_s(M_Z)$ is based on a formula with negligible theoretical uncertainty if one assumes the exact validity of the SM. One should keep in mind, however, that this value, $\alpha_s(M_Z) = 0.1197 \pm 0.0028$, is very sensitive to such types of new physics as non-universal vertex corrections. In contrast, the value derived from τ decays, $\alpha_s(M_Z) = 0.1193_{-0.0020}^{+0.0022}$, is theory dominated but less sensitive to new physics. The two values are in remarkable agreement with each other. They are also in perfect agreement with the averages from jet-event shapes in e^+e^- annihilation

(0.1172 ± 0.0037) and lattice simulations (0.1185 ± 0.0007), whereas the DIS average (0.1150 ± 0.0021) is somewhat lower. For more details, other determinations, and references, see Section 9 on “Quantum Chromodynamics” in this *Review*. Using $\alpha(M_Z)$ and \hat{s}_Z^2 as inputs, one can predict $\alpha_s(M_Z)$ assuming grand unification. One predicts [223] $\alpha_s(M_Z) = 0.130 \pm 0.001 \pm 0.01$ for the simplest theories based on the minimal supersymmetric extension of the SM, where the first (second) uncertainty is from the inputs (thresholds).

This is slightly larger, but consistent with the experimental $\alpha_s(M_Z) = 0.1196 \pm 0.0017$ from the Z lineshape and the τ lifetime, as well as with most other determinations. Non-supersymmetric unified theories predict the low value $\alpha_s(M_Z) = 0.073 \pm 0.001 \pm 0.001$. See also the note on “Supersymmetry” in the Searches Particle Listings.

Figure 10.5: One-standard-deviation (39.35%) uncertainties in M_H as a function of m_t for various inputs, and the 90% CL region ($\Delta\chi^2 = 4.605$) allowed by all data. $\alpha_s(M_Z) = 0.1185$ is assumed except for the fits including the Z lineshape or low energy data. The bright (yellow) bands are excluded by one experiment and the remaining (gray) regions are ruled out by more than one experiment (95% CL).

The data indicate a preference for a small Higgs mass. There is a strong correlation between the quadratic m_t and logarithmic M_H terms in $\hat{\rho}$ in all of the indirect data except for the $Z \rightarrow b\bar{b}$ vertex. Therefore, observables (other than R_b) which favor m_t values higher than the Tevatron range favor lower values of M_H . M_W has additional M_H dependence through $\Delta\hat{r}_W$ which is not coupled to m_t^2 effects. The strongest individual pulls toward smaller M_H are from M_W and

Figure 10.6: One-standard-deviation (39.35%) region in M_W as a function of m_t for the direct and indirect precision data, and the 90% CL region ($\Delta\chi^2 = 4.605$) allowed by all precision data. The SM predictions are also indicated, where the blue bands for Higgs masses between 115.5 and 127 GeV and beyond 600 GeV are currently allowed at the 95% CL. The yellow bands are excluded by one experiment and the remaining (gray) regions are ruled out by more than one experiment (95% CL).

A_{LR}^0 , while $A_{FB}^{(0,b)}$ favors higher values. The difference in χ^2 for the global fit is $\Delta\chi^2 = \chi^2(M_H = 314 \text{ GeV}) - \chi_{\min}^2 = 25$. Hence, the data favor a small value of M_H , as in supersymmetric extensions of the SM. The central value of the global fit result, $M_H = 99_{-23}^{+28}$ GeV, is below the direct lower bound from LEP 2, $M_H \geq 114.4$ GeV (95% CL) [173], which was very recently extended slightly by ATLAS to $M_H \geq 115.5$ GeV [224].

The 90% central confidence range from all precision data is

$$68 \text{ GeV} \leq M_H \leq 155 \text{ GeV}. \quad (10.49)$$

Including the results of the direct searches at LEP 2 [173] and the Tevatron [225] as extra contributions to the likelihood function reduces the 95% upper limit to $M_H \leq 150$ GeV. As two further refinements, we account for (i) theoretical uncertainties from uncalculated higher order contributions by allowing the T parameter (see next subsection) subject to the constraint $T = 0 \pm 0.02$, (ii) the M_H dependence of the correlation matrix which gives slightly more weight to lower Higgs masses [226]. The resulting limits at 95 (90, 99)% CL are, respectively,

$$M_H \leq 175 \text{ (148, 210) GeV}. \quad (10.50)$$

In their Higgs searches in pp collisions with CM energy of 7 TeV, both ATLAS [224] and CMS [227] find results consistent with Eq. (10.50) and currently report $\gtrsim 2 \sigma$ excess fluctuation near $M_H = 119.5$ GeV (CMS only), $M_H = 124$ GeV (CMS), and $M_H = 126$ GeV (ATLAS only). Of course, these excesses do not constitute a discovery. However, it is useful to take them at face value for comparison with the precision data in Table 10.3, Table 10.4, and Table 10.6. A combination of all available data yields (at the 68% CL) [215]

$$M_H = 124.5 \pm 0.8 \text{ GeV}. \quad (10.51)$$

The resulting probability distribution has a twin peak structure (besides a smaller maximum at $M_H = 118.5$ GeV) with almost equal probability at $M_H = 124$ GeV and $M_H = 125$ GeV [215].

One can also carry out a fit to the indirect data alone, *i.e.*, without including the constraint, $m_t = 173.4 \pm 1.0$ GeV, from the hadron colliders. (The indirect prediction is for the $\overline{\text{MS}}$ mass, $\hat{m}_t(\hat{m}_t) = 167.5_{-7.3}^{+8.9}$ GeV, which is in the end converted to the pole mass). One obtains $m_t = 177.5_{-7.8}^{+9.4}$ GeV, in perfect agreement with the direct Tevatron/LHC average. Using this indirect top mass value, the tendency for a light Higgs persists and Eq. (10.49) becomes $46 \text{ GeV} \leq M_H \leq 306 \text{ GeV}$. The relations between M_H and m_t for various observables are shown in Fig. 10.5.

One can also determine the radiative correction parameters Δr : from the global fit one obtains $\Delta r = 0.0352 \pm 0.0009$ and $\Delta\hat{r}_W =$

Table 10.7: Values of the model-independent neutral-current parameters, compared with the SM predictions. There is a second $g_{V,A}^{\nu e}$ solution, given approximately by $g_{V,A}^{\nu e} \leftrightarrow g_{A,V}^{\nu e}$, which is eliminated by e^+e^- data under the assumption that the neutral current is dominated by the exchange of a single Z boson. The ϵ_L , as well as the ϵ_R , are strongly correlated and non-Gaussian, so that for implementations we recommend the parametrization using g_i^2 and $\theta_i = \tan^{-1}[\epsilon_i(u)/\epsilon_i(d)]$, $i = L$ or R . The analysis of more recent low energy experiments in polarized electron scattering performed in Ref. 129 is included by means of the two orthogonal constraints, $\cos\gamma C_{1d} - \sin\gamma C_{1u} = 0.342 \pm 0.063$ and $\sin\gamma C_{1d} + \cos\gamma C_{1u} = -0.0285 \pm 0.0043$, where $\tan\gamma \approx 0.445$. In the SM predictions, the uncertainty is from M_Z , M_H , m_t , m_b , m_c , $\hat{\alpha}(M_Z)$, and α_s .

Quantity	Experimental Value	SM	Correlation		
$\epsilon_L(u)$	0.328 ± 0.016	0.3461(1)	non-Gaussian		
$\epsilon_L(d)$	-0.440 ± 0.011	-0.4292(1)

$Q_W(e) = -2C_{2e}$	-0.0403 ± 0.0053	-0.0474(5)			

0.06945 ± 0.00019 . M_W measurements [172,214] (when combined with M_Z) are equivalent to measurements of $\Delta r = 0.0342 \pm 0.0015$, which is 0.9σ below the result from all other data, $\Delta r = 0.0358 \pm 0.0011$. Fig. 10.6 shows the 1 σ contours in the M_W - m_t plane from the direct and indirect determinations, as well as the combined 90% CL region. The indirect determination uses M_Z from LEP 1 as input, which is defined assuming an s -dependent decay width. M_W then corresponds to the s -dependent width definition, as well, and can be directly compared with the results from the Tevatron and LEP 2 which have been obtained using the same definition. The difference to a constant width definition is formally only of $\mathcal{O}(\alpha^2)$, but is strongly enhanced since the decay channels add up coherently. It is about 34 MeV for M_Z and 27 MeV for M_W . The residual difference between working consistently with one or the other definition is about 3 MeV, *i.e.*, of typical size for non-enhanced $\mathcal{O}(\alpha^2)$ corrections [74–77].

Most of the parameters relevant to ν -hadron, ν - e , e -hadron, and e^-e^\pm processes are determined uniquely and precisely from the data in “model-independent” fits (*i.e.*, fits which allow for an arbitrary EW gauge theory). The values for the parameters defined in Eqs. (10.19)–(10.22) are given in Table 10.7 along with the predictions of the SM. The agreement is very good. (The ν -hadron results including the original NuTeV data can be found in the 2006 edition of this *Review*, and fits with modified NuTeV constraints in the 2008 and 2010 editions.) The off Z pole e^+e^- results are difficult to present in a model-independent way because Z propagator effects are non-negligible at TRISTAN, PETRA, PEP, and LEP 2 energies. However, assuming e - μ - τ universality, the low energy lepton asymmetries imply [159] $4(g_A^e)^2 = 0.99 \pm 0.05$, in good agreement with the SM prediction $\simeq 1$.

10.7. Constraints on new physics

The Z pole, W mass, and low energy data can be used to search for and set limits on deviations from the SM. We will mainly discuss the effects of exotic particles (with heavy masses $M_{\text{new}} \gg M_Z$ in an expansion in M_Z/M_{new}) on the gauge boson self-energies. (Brief remarks are made on new physics which is not of this type.) Most of the effects on precision measurements can be described by three gauge self-energy parameters S , T , and U . We will define these, as well as related parameters, such as ρ_0 , ϵ_i , and $\hat{\epsilon}_i$, to arise from new physics only. *I.e.*, they are equal to zero ($\rho_0 = 1$) exactly in the SM, and do not include any (loop induced) contributions that depend on m_t or M_H , which are treated separately. Our treatment differs from most of the original papers.

Many extensions of the SM can be described by the ρ_0 parameter,

$$\rho_0 \equiv \frac{M_W^2}{M_Z^2 \hat{c}_Z^2 \hat{\rho}}, \quad (10.52)$$

which describes new sources of SU(2) breaking that cannot be accounted for by the SM Higgs doublet or m_t effects. $\hat{\rho}$ is calculated as in Eq. (10.13) assuming the validity of the SM. In the presence of $\rho_0 \neq 1$, Eq. (10.52) generalizes the second Eq. (10.13) while the first remains unchanged. Provided that the new physics which yields $\rho_0 \neq 1$ is a small perturbation which does not significantly affect the radiative corrections, ρ_0 can be regarded as a phenomenological parameter which multiplies G_F in Eqs. (10.19)–(10.22), (10.36), and Γ_Z in Eq. (10.42c). There are enough data to determine ρ_0 , M_H , m_t , and α_s , simultaneously. From the global fit,

$$\rho_0 = 1.0004_{-0.0004}^{+0.0003}, \quad (10.53)$$

$$115.5 \text{ GeV} \leq M_H \leq 127 \text{ GeV}, \quad (10.54)$$

$$m_t = 173.4 \pm 1.0 \text{ GeV}, \quad (10.55)$$

$$\alpha_s(M_Z) = 0.1195 \pm 0.0017, \quad (10.56)$$

where the limits on M_H are nominal direct search bounds at the 95% CL [173,224,227]. In addition, the LHC is not yet sensitive to very large values of $M_H > 600$ GeV which are thus not ruled out either. In this very high mass scenario, we obtain,

$$\rho_0 = 1.0024_{-0.0003}^{+0.0010}, \quad (10.57)$$

$$0.6 \text{ TeV} \leq M_H \leq 1.2 \text{ TeV}, \quad (10.58)$$

$$\alpha_s(M_Z) = 0.1191 \pm 0.0016, \quad (10.59)$$

with the same m_t . Finally, if the direct search results are ignored entirely one finds $M_H = 189_{-114}^{+568}$ GeV and $\rho_0 = 1.0008_{-0.0011}^{+0.0020}$. The result in Eq. (10.53) is slightly above but consistent with the SM expectation, $\rho_0 = 1$. It can be used to constrain higher-dimensional Higgs representations to have vacuum expectation values of less than a few percent of those of the doublets. Indeed, the relation between M_W and M_Z is modified if there are Higgs multiplets with weak isospin $> 1/2$ with significant vacuum expectation values. For a general (charge-conserving) Higgs structure,

$$\rho_0 = \frac{\sum_i [t(i)t(i) - t_3(i)^2] |v_i|^2}{2 \sum_i t_3(i)^2 |v_i|^2}, \quad (10.60)$$

where v_i is the expectation value of the neutral component of a Higgs multiplet with weak isospin $t(i)$ and third component $t_3(i)$. In order to calculate to higher orders in such theories one must define a set of four fundamental renormalized parameters which one may conveniently choose to be α , G_F , M_Z , and M_W , since M_W and M_Z are directly measurable. Then \hat{s}_Z^2 and ρ_0 can be considered dependent parameters.

Eq. (10.53) can also be used to constrain other types of new physics. For example, non-degenerate multiplets of heavy fermions or scalars break the vector part of weak SU(2) and lead to a decrease in the value of M_Z/M_W . A non-degenerate SU(2) doublet ($\begin{smallmatrix} f_1 \\ f_2 \end{smallmatrix}$) yields a positive contribution to ρ_0 [228] of

$$\frac{C G_F}{8\sqrt{2}\pi^2} \Delta m^2, \quad (10.61)$$

where

$$\Delta m^2 \equiv m_1^2 + m_2^2 - \frac{4m_1^2 m_2^2}{m_1^2 - m_2^2} \ln \frac{m_1}{m_2} \geq (m_1 - m_2)^2, \quad (10.62)$$

and $C = 1$ (3) for color singlets (triplets). Thus, in the presence of such multiplets,

$$\rho_0 = 1 + \frac{3 G_F}{8\sqrt{2}\pi^2} \sum_i \frac{C_i}{3} \Delta m_i^2, \quad (10.63)$$

where the sum includes fourth-family quark or lepton doublets, ($\begin{smallmatrix} \nu \\ b \end{smallmatrix}$) or ($\begin{smallmatrix} E^0 \\ E^- \end{smallmatrix}$), right-handed (mirror) doublets, non-degenerate vector-like fermion doublets (with an extra factor of 2), and scalar doublets such as ($\begin{smallmatrix} \tilde{t} \\ \tilde{b} \end{smallmatrix}$) in Supersymmetry (in the absence of L - R mixing).

Eq. (10.53) taken together with Eq. (10.63) implies at the 95% CL,

$$\sum_i \frac{C_i}{3} \Delta m_i^2 \leq (52 \text{ GeV})^2. \quad (10.64)$$

Non-degenerate multiplets usually imply $\rho_0 > 1$. Similarly, heavy Z' bosons decrease the prediction for M_Z due to mixing and generally lead to $\rho_0 > 1$ [229]. On the other hand, additional Higgs doublets which participate in spontaneous symmetry breaking [230] or heavy lepton doublets involving Majorana neutrinos [231], both of which have more complicated expressions, as well as the vacuum expectation values of Higgs triplets or higher-dimensional representations can contribute to ρ_0 with either sign. Allowing for the presence of heavy degenerate chiral multiplets (the S parameter, to be discussed below) affects the determination of ρ_0 from the data, at present leading to a larger value (for fixed M_H).

A number of authors [232–237] have considered the general effects on neutral-current and Z and W boson observables of various types of heavy (*i.e.*, $M_{\text{new}} \gg M_Z$) physics which contribute to the W and Z self-energies but which do not have any direct coupling to the ordinary fermions. In addition to non-degenerate multiplets, which break the vector part of weak SU(2), these include heavy degenerate multiplets of chiral fermions which break the axial generators. The effects of one degenerate chiral doublet are small, but in Technicolor theories there may be many chiral doublets and therefore significant effects [232].

Such effects can be described by just three parameters, S , T , and U , at the (EW) one-loop level. (Three additional parameters are needed if the new physics scale is comparable to M_Z [238]. Further generalizations, including effects relevant to LEP 2, are described in Ref. 239.) T is proportional to the difference between the W and Z self-energies at $Q^2 = 0$ (*i.e.*, vector SU(2)-breaking), while S ($S+U$) is associated with the difference between the Z (W) self-energy at $Q^2 = M_{Z,W}^2$ and $Q^2 = 0$ (axial SU(2)-breaking). Denoting the contributions of new physics to the various self-energies by Π_{ij}^{new} , we have

$$\hat{\alpha}(M_Z) T \equiv \frac{\Pi_{WW}^{\text{new}}(0)}{M_W^2} - \frac{\Pi_{ZZ}^{\text{new}}(0)}{M_Z^2}, \quad (10.65a)$$

$$\begin{aligned} \hat{\alpha}(M_Z) S \equiv & \frac{\Pi_{ZZ}^{\text{new}}(M_Z^2) - \Pi_{ZZ}^{\text{new}}(0)}{4 \hat{s}_Z^2 \hat{c}_Z^2} - \frac{\Pi_{ZZ}^{\text{new}}(M_Z^2) - \Pi_{ZZ}^{\text{new}}(0)}{M_Z^2} \\ & - \frac{\hat{c}_Z^2 - \hat{s}_Z^2}{\hat{c}_Z \hat{s}_Z} \frac{\Pi_{Z\gamma}^{\text{new}}(M_Z^2)}{M_Z^2} - \frac{\Pi_{\gamma\gamma}^{\text{new}}(M_Z^2)}{M_Z^2}, \end{aligned} \quad (10.65b)$$

$$\begin{aligned} \hat{\alpha}(M_Z) (S+U) \equiv & \frac{\Pi_{WW}^{\text{new}}(M_Z^2) - \Pi_{WW}^{\text{new}}(0)}{4 \hat{s}_Z^2} - \frac{\Pi_{ZZ}^{\text{new}}(M_Z^2) - \Pi_{ZZ}^{\text{new}}(0)}{M_Z^2} \\ & - \frac{\hat{c}_Z}{\hat{s}_Z} \frac{\Pi_{Z\gamma}^{\text{new}}(M_Z^2)}{M_Z^2} - \frac{\Pi_{\gamma\gamma}^{\text{new}}(M_Z^2)}{M_Z^2}. \end{aligned} \quad (10.65c)$$

S , T , and U are defined with a factor proportional to $\hat{\alpha}$ removed, so that they are expected to be of order unity in the presence of new physics. In the $\overline{\text{MS}}$ scheme as defined in Ref. 66, the last two terms in Eqs. (10.65b) and (10.65c) can be omitted (as was done in some earlier

editions of this *Review*). These three parameters are related to other parameters (S_i , h_i , $\hat{\epsilon}_i$) defined in Refs. [66,233,234] by

$$\begin{aligned} T &= h_V = \hat{\epsilon}_1 / \hat{\alpha}(M_Z), \\ S &= h_{AZ} = S_Z = 4 \hat{s}_Z^2 \hat{\epsilon}_3 / \hat{\alpha}(M_Z), \\ U &= h_{AW} - h_{AZ} = S_W - S_Z = -4 \hat{s}_Z^2 \hat{\epsilon}_2 / \hat{\alpha}(M_Z). \end{aligned} \quad (10.66)$$

A heavy non-degenerate multiplet of fermions or scalars contributes positively to T as

$$\rho_0 - 1 = \frac{1}{1 - \hat{\alpha}(M_Z)T} - 1 \simeq \hat{\alpha}(M_Z)T, \quad (10.67)$$

where ρ_0 is given in Eq. (10.63). The effects of non-standard Higgs representations cannot be separated from heavy non-degenerate multiplets unless the new physics has other consequences, such as vertex corrections. Most of the original papers defined T to include the effects of loops only. However, we will redefine T to include all new sources of SU(2) breaking, including non-standard Higgs, so that T and ρ_0 are equivalent by Eq. (10.67).

A multiplet of heavy degenerate chiral fermions yields

$$S = \frac{C}{3\pi} \sum_i (t_{3L}(i) - t_{3R}(i))^2, \quad (10.68)$$

where $t_{3L,R}(i)$ is the third component of weak isospin of the left-(right-)handed component of fermion i and C is the number of colors. For example, a heavy degenerate ordinary or mirror family would contribute $2/3\pi$ to S . In Technicolor models with QCD-like dynamics, one expects [232] $S \sim 0.45$ for an iso-doublet of techni-fermions, assuming $N_{TC} = 4$ techni-colors, while $S \sim 1.62$ for a full techni-generation with $N_{TC} = 4$; T is harder to estimate because it is model-dependent. In these examples one has $S \geq 0$. However, the QCD-like models are excluded on other grounds (flavor changing neutral-currents, and too-light quarks and pseudo-Goldstone bosons [240]). In particular, these estimates do not apply to models of walking Technicolor [240], for which S can be smaller or even negative [241]. Other situations in which $S < 0$, such as loops involving scalars or Majorana particles, are also possible [242]. The simplest origin of $S < 0$ would probably be an additional heavy Z' boson [229], which could mimic $S < 0$. Supersymmetric extensions of the SM generally give very small effects. See Refs. 243 and 244 and the note on ‘‘Supersymmetry’’ in the Searches Particle Listings for a complete set of references.

Most simple types of new physics yield $U = 0$, although there are counter-examples, such as the effects of anomalous triple gauge vertices [234].

The SM expressions for observables are replaced by

$$\begin{aligned} M_Z^2 &= M_{Z0}^2 \frac{1 - \hat{\alpha}(M_Z)T}{1 - G_F M_{Z0}^2 S / 2\sqrt{2}\pi}, \\ M_W^2 &= M_{W0}^2 \frac{1}{1 - G_F M_{W0}^2 (S + U) / 2\sqrt{2}\pi}, \end{aligned} \quad (10.69)$$

where M_{Z0} and M_{W0} are the SM expressions (as functions of m_t and M_H) in the $\overline{\text{MS}}$ scheme. Furthermore,

$$\Gamma_Z = \frac{M_Z^3 \beta_Z}{1 - \hat{\alpha}(M_Z)T}, \quad \Gamma_W = M_W^3 \beta_W, \quad A_i = \frac{A_{i0}}{1 - \hat{\alpha}(M_Z)T}, \quad (10.70)$$

where β_Z and β_W are the SM expressions for the reduced widths Γ_{Z0}/M_{Z0}^3 and Γ_{W0}/M_{W0}^3 , M_Z and M_W are the physical masses, and A_i (A_{i0}) is a neutral-current amplitude (in the SM).

The data allow a simultaneous determination of \hat{s}_Z^2 (from the Z pole asymmetries), S (from M_Z), U (from M_W), T (mainly from Γ_Z), α_s (from R_ℓ , σ_{had} , and τ_τ), and m_t (from the hadron colliders), with little correlation among the SM parameters:

$$\begin{aligned} S &= 0.00_{-0.10}^{+0.11}, \\ T &= 0.02_{-0.12}^{+0.11}, \\ U &= 0.08 \pm 0.11, \end{aligned} \quad (10.71)$$

Figure 10.7: 1σ constraints (39.35%) on S and T from various inputs combined with M_Z . S and T represent the contributions of new physics only. (Uncertainties from m_t are included in the errors.) The contours assume $115.5 \text{ GeV} < M_H < 127 \text{ GeV}$ except for the larger (violet) one for all data which is for $600 \text{ GeV} < M_H < 1 \text{ TeV}$. Data sets not involving M_W are insensitive to U . Due to higher order effects, however, $U = 0$ has to be assumed in all fits. α_s is constrained using the τ lifetime as additional input in all fits. The long-dashed (magenta) contour from ν scattering is now consistent with the global average (see Sec. 10.3). The long-dash-dotted (orange) contour from polarized e scattering [129,131] is the upper tip of an elongated ellipse centered at around $S = -14$ and $T = -20$. At first sight it looks as if it is deviating strongly but it is off by only 1.8σ . This illusion arises because $\Delta\chi^2 > 0.77$ everywhere on the visible part of the contour.

and $\hat{s}_Z^2 = 0.23125 \pm 0.00016$, $\alpha_s(M_Z) = 0.1197 \pm 0.0018$, $m_t = 173.4 \pm 1.0 \text{ GeV}$, where the uncertainties are from the inputs. We have used $115.5 \text{ GeV} < M_H < 127 \text{ GeV}$ which is the allowed low mass window from LEP and the LHC. The SM parameters (U) can be determined with no (little) M_H dependence. On the other hand, S , T , and M_H cannot be obtained simultaneously from the precision data alone, because the Higgs boson loops themselves are resembled approximately by oblique effects. Negative (positive) contributions to the S (T) parameter can weaken or entirely remove the strong constraints on M_H from the SM fits. Specific models in which a large M_H is compensated by new physics are reviewed in Ref. 245. The parameters in Eqs. (10.71), which by definition are due to new physics only, are in reasonable agreement with the SM values of zero. Fixing $U = 0$ (as is also done in Fig. 10.7) moves S and T slightly upwards,

$$\begin{aligned} S &= 0.04 \pm 0.09, \\ T &= 0.07 \pm 0.08. \end{aligned} \quad (10.72)$$

The correlation between S and T in this fit amounts to 88%.

Using Eq. (10.67), the value of ρ_0 corresponding to T in Eq. (10.71) is 1.0001 ± 0.0009 , while the one corresponding to Eq. (10.72) is $1.0005_{-0.0006}^{+0.0007}$. The values of the $\hat{\epsilon}$ parameters defined in Eq. (10.66) are

$$\begin{aligned} \hat{\epsilon}_3 &= 0.0000 \pm 0.0008, \\ \hat{\epsilon}_1 &= 0.0001 \pm 0.0009 \\ \hat{\epsilon}_2 &= -0.0006 \pm 0.0009. \end{aligned} \quad (10.73)$$

Unlike the original definition, we defined the quantities in Eqs. (10.73) to vanish identically in the absence of new physics and to correspond directly to the parameters S , T , and U in Eqs. (10.71). There is a strong correlation (89%) between the S and T parameters. The U parameter is -49% (-70%) anti-correlated with S (T). The allowed regions in S - T are shown in Fig. 10.7. From Eqs. (10.71) one obtains $S \leq 0.17$ and $T \leq 0.20$ at 95% CL.

If one assumes that the excess Higgs candidates seen at the LHC are statistical fluctuations then (in the presence of new physics significantly affecting gauge boson self-energies) there is still the possibility for a heavy Higgs scenario. If one fixes $M_H = 600$ GeV (as is still allowed by direct searches) and requires the constraint $S \geq 0$ (as is appropriate in QCD-like Technicolor models) then $S \leq 0.13$ (Bayesian) or $S \leq 0.11$ (frequentist). This rules out simple Technicolor models with many techni-doublets and QCD-like dynamics.

The S parameter can also be used to constrain the number of fermion families, *under the assumption* that there are no new contributions to T or U and therefore that any new families are degenerate; then an extra generation of SM fermions is excluded at the 5.7σ level corresponding to $N_F = 2.91^{+0.19}_{-0.25}$ (with M_H in the allowed low mass window). This is in agreement with a fit to the number of light neutrinos, $N_\nu = 2.989 \pm 0.007$. However, the S parameter fits are valid even for a very heavy fourth family neutrino. This restriction can be relaxed by allowing T to vary as well, since $T > 0$ is expected from a non-degenerate extra family. Fixing $S = 2/3\pi$, the global fit favors a fourth family contribution to T of 0.21 ± 0.04 . However, the quality of the fit deteriorates ($\Delta\chi^2 = 3.8$ relative to the SM fit with M_H forced not to drop below its ATLAS bound of 115.5 GeV) so that this tuned T scenario is also disfavored but less so than in the past. In fact, tuned mass splittings of the extra leptons and quarks [246] can yield fits with only moderately higher χ^2 values (by about 1 unit) than for the SM. A more detailed analysis is also required if the extra neutrino (or the extra down-type quark) is close to its direct mass limit [247]. Thus, a fourth family is disfavored but not excluded by the current EW precision data. Similar remarks apply to a heavy mirror family [248] involving right-handed SU(2) doublets and left-handed singlets. A more recent and detailed discussion can be found in Ref. 249. One important consequence of a heavy fourth family is to increase the Higgs production cross section by gluon fusion by a factor ~ 9 , which considerably strengthens the exclusion limits from direct searches at the Tevatron [250] and LHC [251]. Additional heavy ordinary or mirror generations may also require large Yukawa and Higgs couplings that may lead to Landau poles at low scales [252]. In contrast, heavy degenerate non-chiral (also known as vector-like or exotic) multiplets, which are predicted in many grand unified theories [253] and other extensions of the SM, do not contribute to S , T , and U (or to ρ_0), and do not require large coupling constants. Such exotic multiplets may occur in partial families, as in E_6 models, or as complete vector-like families [254].

There is no simple parametrization to describe the effects of every type of new physics on every possible observable. The S , T , and U formalism describes many types of heavy physics which affect only the gauge self-energies, and it can be applied to all precision observables. However, new physics which couples directly to ordinary fermions, such as heavy Z' bosons [229], mixing with exotic fermions [255], or leptoquark exchange [172,256] cannot be fully parametrized in the S , T , and U framework. It is convenient to treat these types of new physics by parameterizations that are specialized to that particular class of theories (e.g., extra Z' bosons), or to consider specific models (which might contain, e.g., Z' bosons and exotic fermions with correlated parameters). Fits to Supersymmetric models are described in Ref. 244. Models involving strong dynamics (such as (extended) Technicolor) for EW breaking are considered in Ref. 257. The effects of compactified extra spatial dimensions at the TeV scale are reviewed in Ref. 258, and constraints on Little Higgs models in Ref. 259. The implications of non-standard Higgs sectors, e.g., involving Higgs singlets or triplets, are discussed in Ref. 260, while additional Higgs doublets are considered in Ref. 230. Limits on new four-Fermi operators and on leptoquarks using LEP 2 and lower energy data are given in Refs. 172 and 261. Constraints on various types of new physics are reviewed in Refs. [7,128,149,161,262,263], and implications for the LHC in Ref. 264.

An alternate formalism [265] defines parameters, ϵ_1 , ϵ_2 , ϵ_3 , and ϵ_b in terms of the specific observables M_W/M_Z , $\Gamma_{\ell\ell}$, $A_{FB}^{(0,\ell)}$, and R_b . The definitions coincide with those for $\hat{\epsilon}_i$ in Eqs. (10.65) and (10.66) for physics which affects gauge self-energies only, but the ϵ 's now parametrize arbitrary types of new physics. However, the ϵ 's are not related to other observables unless additional model-dependent

Table 10.8: 95% CL lower mass limits (in GeV) from low energy and Z pole data on various extra Z' gauge bosons, appearing in models of unification and string theory. More general parametrizations are described in Refs. 267 and 272. The EW results [273] are for Higgs sectors consisting of doublets and singlets only ($\rho_0 = 1$) with unspecified $U(1)'$ charges. The next two columns show the limits from ATLAS [274] and CMS [275] from the combination of both lepton channels. The CDF [276] and DØ [277] bounds from searches for $\bar{p}p \rightarrow \mu^+\mu^-$ and e^+e^- , respectively, are listed in the next two columns, followed by the LEP 2 $e^+e^- \rightarrow f\bar{f}$ bounds [172] (assuming $\theta = 0$). The Tevatron bounds would be moderately weakened if there are open supersymmetric or exotic decay channels [278]. The last column shows the 1σ ranges for M_H when it is left unconstrained in the EW fits.

Z'	EW	ATLAS	CMS	CDF	DØ	LEP 2	M_H
Z_χ	1,141	1,640	–	930	903	673	171^{+493}_{-89}
Z_ψ	147	1,490	1,620	917	891	481	97^{+31}_{-25}
Z_η	427	1,540	–	938	923	434	423^{+577}_{-350}
Z_{LR}	998	–	–	–	–	804	804^{+174}_{-35}
Z_S	1,257	1,600	–	858	822	–	149^{+353}_{-68}
Z_{SM}	1,403	1,830	1,940	1,071	1,023	1,787	331^{+669}_{-246}
Z_{string}	1,362	–	–	–	–	–	134^{+209}_{-58}

assumptions are made. Another approach [266] parametrizes new physics in terms of gauge-invariant sets of operators. It is especially powerful in studying the effects of new physics on non-Abelian gauge vertices. The most general approach introduces deviation vectors [262]. Each type of new physics defines a deviation vector, the components of which are the deviations of each observable from its SM prediction, normalized to the experimental uncertainty. The length (direction) of the vector represents the strength (type) of new physics.

One of the best motivated kinds of physics beyond the SM besides Supersymmetry are extra Z' bosons [267]. They do not spoil the observed approximate gauge coupling unification, and appear copiously in many Grand Unified Theories (GUTs), most Superstring models [268], as well as in dynamical symmetry breaking [257] and Little Higgs models [259]. For example, the SO(10) GUT contains an extra U(1) as can be seen from its maximal subgroup, $SU(5) \times U(1)_\chi$. Similarly, the E_6 GUT contains the subgroup $SO(10) \times U(1)_\psi$. The Z_ψ possesses only axial-vector couplings to the ordinary fermions, and its mass is generally less constrained. The Z_η boson is the linear combination $\sqrt{3/8}Z_\chi - \sqrt{5/8}Z_\psi$. The Z_{LR} boson occurs in left-right models with gauge group $SU(3)_C \times SU(2)_L \times SU(2)_R \times U(1)_{B-L} \subset SO(10)$, and the secluded Z_S emerges in a supersymmetric bottom-up scenario [269]. The sequential Z_{SM} boson is defined to have the same couplings to fermions as the SM Z boson. Such a boson is not expected in the context of gauge theories unless it has different couplings to exotic fermions than the ordinary Z boson. However, it serves as a useful reference case when comparing constraints from various sources. It could also play the role of an excited state of the ordinary Z boson in models with extra dimensions at the weak scale [258]. Finally, we consider a Superstring motivated Z_{string} boson appearing in a specific model [270]. The potential Z' boson is in general a superposition of the SM Z and the new boson associated with the extra U(1). The mixing angle θ satisfies,

$$\tan^2 \theta = \frac{M_{Z'_0}^2 - M_Z^2}{M_{Z'_1}^2 - M_{Z'_0}^2},$$

where $M_{Z'_0}$ is the SM value for M_Z in the absence of mixing. Note, that $M_Z < M_{Z'_1}$, and that the SM Z couplings are changed by the mixing. The couplings of the heavier Z' may also be modified by kinetic mixing [267,271]. If the Higgs U(1)' quantum numbers are

known, there will be an extra constraint,

$$\theta = C \frac{g_2}{g_1} \frac{M_Z^2}{M_{Z'}^2},$$

where $g_{1,2}$ are the $U(1)$ and $U(1)'$ gauge couplings with $g_2 = \sqrt{\frac{5}{3}} \sin \theta_W \sqrt{\lambda} g_1$ and $g_1 = \sqrt{g^2 + g'^2}$. $\lambda \sim 1$ (which we assume) if the GUT group breaks directly to $SU(3) \times SU(2) \times U(1) \times U(1)'$. C is a function of vacuum expectation values. For minimal Higgs sectors it can be found in Ref. 229. Table 10.8 shows the 95% CL lower mass limits [273] for $\rho_0 = 1$ and $114.4 \text{ GeV} \leq M_H \leq 1 \text{ TeV}$. The last column shows the 1σ ranges for M_H when it is left unconstrained. In cases of specific minimal Higgs sectors where C is known, the Z' mass limits from the EW precision data are generally pushed into the TeV region in which case they are still competitive with those from the LHC, and they are also competitive in the case of large g_2 [279]. The limits on $|\theta|$ are typically smaller than a few $\times 10^{-3}$. For more details see [267,273,280,281] and the note on “The Z' Searches” in the Gauge & Higgs Boson Particle Listings. Also listed in Table 10.8 are the direct lower limits on Z' production from the LHC [274,275] and the Tevatron [276,277], as well as the LEP 2 bounds [172].

Acknowledgments:

We are indebted to M. Davier, B. Malaescu, and K. Maltman for providing us with additional information about their work in a form suitable to be included in our fits. We also thank R. H. Bernstein, K. S. McFarland, H. Schellman, and G. P. Zeller for discussions on the NuTeV analysis. This work was supported in part by CONACyT (México) contract 82291-F and by PASPA (DGAPA-UNAM).

11. THE CKM QUARK-MIXING MATRIX

Revised March 2012 by A. Ceccucci (CERN), Z. Ligeti (LBNL), and Y. Sakai (KEK).

11.1. Introduction

The masses and mixings of quarks have a common origin in the Standard Model (SM). They arise from the Yukawa interactions with the Higgs condensate,

$$\mathcal{L}_Y = -Y_{ij}^d \overline{Q_{Li}^I} \phi d_{Rj}^I - Y_{ij}^u \overline{Q_{Li}^I} \epsilon \phi^* u_{Rj}^I + \text{h.c.}, \quad (11.1)$$

where $Y^{u,d}$ are 3×3 complex matrices, ϕ is the Higgs field, i, j are generation labels, and ϵ is the 2×2 antisymmetric tensor. Q_{Li}^I are left-handed quark doublets, and d_{Rj}^I and u_{Rj}^I are right-handed down- and up-type quark singlets, respectively, in the weak-eigenstate basis. When ϕ acquires a vacuum expectation value, $\langle \phi \rangle = (0, v/\sqrt{2})$, Eq. (11.1) yields mass terms for the quarks. The physical states are obtained by diagonalizing $Y^{u,d}$ by four unitary matrices, $V_{L,R}^{u,d}$, as $M_{\text{diag}}^f = V_L^f Y^f V_R^{f\dagger} (v/\sqrt{2})$, $f = u, d$. As a result, the charged-current W^\pm interactions couple to the physical u_{Lj} and d_{Lk} quarks with couplings given by

$$\frac{-g}{\sqrt{2}} (\overline{u}_L, \overline{c}_L, \overline{t}_L) \gamma^\mu W_\mu^+ V_{\text{CKM}} \begin{pmatrix} d_L \\ s_L \\ b_L \end{pmatrix} + \text{h.c.},$$

$$V_{\text{CKM}} \equiv V_L^u V_L^{d\dagger} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix}. \quad (11.2)$$

This Cabibbo-Kobayashi-Maskawa (CKM) matrix [1,2] is a 3×3 unitary matrix. It can be parameterized by three mixing angles and the CP -violating KM phase [2]. Of the many possible conventions, a standard choice has become [3]

$$V_{\text{CKM}} = \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13} \end{pmatrix}, \quad (11.3)$$

where $s_{ij} = \sin \theta_{ij}$, $c_{ij} = \cos \theta_{ij}$, and δ is the phase responsible for all CP -violating phenomena in flavor-changing processes in the SM. The angles θ_{ij} can be chosen to lie in the first quadrant, so $s_{ij}, c_{ij} \geq 0$.

It is known experimentally that $s_{13} \ll s_{23} \ll s_{12} \ll 1$, and it is convenient to exhibit this hierarchy using the Wolfenstein parameterization. We define [4–6]

$$s_{12} = \lambda = \frac{|V_{us}|}{\sqrt{|V_{ud}|^2 + |V_{us}|^2}}, \quad s_{23} = A\lambda^2 = \lambda \left| \frac{V_{cb}}{V_{us}} \right|,$$

$$s_{13}e^{i\delta} = V_{ub}^* = A\lambda^3(\rho + i\eta) = \frac{A\lambda^3(\bar{\rho} + i\bar{\eta})\sqrt{1 - A^2\lambda^4}}{\sqrt{1 - \lambda^2[1 - A^2\lambda^4(\bar{\rho} + i\bar{\eta})]}}. \quad (11.4)$$

These relations ensure that $\bar{\rho} + i\bar{\eta} = -(V_{ud}V_{ub}^*)/(V_{cd}V_{cb}^*)$ is phase-convention-independent, and the CKM matrix written in terms of λ , A , $\bar{\rho}$, and $\bar{\eta}$ is unitary to all orders in λ . The definitions of $\bar{\rho}, \bar{\eta}$ reproduce all approximate results in the literature. For example, $\bar{\rho} = \rho(1 - \lambda^2/2 + \dots)$ and we can write V_{CKM} to $\mathcal{O}(\lambda^4)$ either in terms of $\bar{\rho}, \bar{\eta}$ or, traditionally,

$$V_{\text{CKM}} = \begin{pmatrix} 1 - \lambda^2/2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1 - \lambda^2/2 & A\lambda^2 \\ A\lambda^3(1 - \rho - i\eta) & -A\lambda^2 & 1 \end{pmatrix} + \mathcal{O}(\lambda^4). \quad (11.5)$$

The CKM matrix elements are fundamental parameters of the SM, so their precise determination is important. The unitarity of the CKM matrix imposes $\sum_i V_{ij}V_{ik}^* = \delta_{jk}$ and $\sum_j V_{ij}V_{kj}^* = \delta_{ik}$. The six vanishing combinations can be represented as triangles in a complex plane, of which the ones obtained by taking scalar products of neighboring rows or columns are nearly degenerate. The areas of all triangles are the same, half of the Jarlskog invariant, J [7], which

Figure 11.1: Sketch of the unitarity triangle.

is a phase-convention-independent measure of CP violation, defined by $\text{Im}[V_{ij}V_{kl}V_{il}^*V_{kj}^*] = J \sum_{m,n} \epsilon_{ikm} \epsilon_{jln}$.

The most commonly used unitarity triangle arises from

$$V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0, \quad (11.6)$$

by dividing each side by the best-known one, $V_{cd}V_{cb}^*$ (see Fig. 1). Its vertices are exactly $(0,0)$, $(1,0)$, and, due to the definition in Eq. (11.4), $(\bar{\rho}, \bar{\eta})$. An important goal of flavor physics is to overconstrain the CKM elements, and many measurements can be conveniently displayed and compared in the $\bar{\rho}, \bar{\eta}$ plane.

Processes dominated by loop contributions in the SM are sensitive to new physics, and can be used to extract CKM elements only if the SM is assumed. We describe such measurements assuming the SM in Sec. 11.2 and 11.3, give the global fit results for the CKM elements in Sec. 11.4, and discuss implications for new physics in Sec. 11.5.

11.2. Magnitudes of CKM elements

11.2.1. $|V_{ud}|$:

The most precise determination of $|V_{ud}|$ comes from the study of superallowed $0^+ \rightarrow 0^+$ nuclear beta decays, which are pure vector transitions. Taking the average of the twenty most precise determinations [8] yields

$$|V_{ud}| = 0.97425 \pm 0.00022. \quad (11.7)$$

The error is dominated by theoretical uncertainties stemming from nuclear Coulomb distortions and radiative corrections. A precise determination of $|V_{ud}|$ is also obtained from the measurement of the neutron lifetime. The theoretical uncertainties are very small, but the determination is limited by the knowledge of the ratio of the axial-vector and vector couplings, $g_A = G_A/G_V$ [9]. The PIBETA experiment [10] has improved the measurement of the $\pi^+ \rightarrow \pi^0 e^+ \nu$ branching ratio to 0.6%, and quote $|V_{ud}| = 0.9728 \pm 0.0030$, in agreement with the more precise result listed above. The interest in this measurement is that the determination of $|V_{ud}|$ is very clean theoretically, because it is a pure vector transition and is free from nuclear-structure uncertainties.

11.2.2. $|V_{us}|$:

The product of $|V_{us}|$ and the form factor at $q^2 = 0$, $|V_{us}| f_+(0)$, has been extracted traditionally from $K_L^0 \rightarrow \pi e \nu$ decays in order to avoid isospin-breaking corrections ($\pi^0 - \eta$ mixing) that affect K^\pm semileptonic decay, and the complications induced by a second (scalar) form factor present in the muonic decays. The last round of measurements has led to enough experimental constraints to justify the comparison between different decay modes. Systematic errors related to the experimental quantities, *e.g.*, the lifetime of neutral or charged kaons, and the form factor determinations for electron and muonic decays, differ among decay modes, and the consistency between different determinations enhances the confidence in the final result. For this reason, we follow the prescription [11] to average $K_L^0 \rightarrow \pi e \nu$, $K_L^0 \rightarrow \pi \mu \nu$, $K^\pm \rightarrow \pi^0 e^\pm \nu$, $K^\pm \rightarrow \pi^0 \mu^\pm \nu$ and $K_S^0 \rightarrow \pi e \nu$. The average of these five decay modes yields $|V_{us}| f_+(0) = 0.21664 \pm 0.00048$. Results obtained from each decay

mode, and exhaustive references to the experimental data, are listed for instance in Ref. [9]. The form factor value $f_+(0) = 0.9644 \pm 0.0049$ [12] from a three-flavor unquenched lattice QCD calculation gives [9] $|V_{us}| = 0.2246 \pm 0.0012$. The broadly used classic calculation of $f_+(0)$ [13] is in good agreement with this value, while other calculations [14] differ by as much as 2%.

The calculation of the ratio of the kaon and pion decay constants enables one to extract $|V_{us}/V_{ud}|$ from $K \rightarrow \mu\nu(\gamma)$ and $\pi \rightarrow \mu\nu(\gamma)$, where (γ) indicates that radiative decays are included [15]. The KLOE measurement of the $K^+ \rightarrow \mu^+\nu(\gamma)$ branching ratio [16], combined with the lattice QCD calculation, $f_K/f_\pi = 1.189 \pm 0.007$ [17], leads to $|V_{us}| = 0.2259 \pm 0.0014$, where the accuracy is limited by the knowledge of the ratio of the decay constants. The average of these two determinations is quoted by Ref. 9 as

$$|V_{us}| = 0.2252 \pm 0.0009. \quad (11.8)$$

The latest determination from hyperon decays can be found in Ref. 19. The authors focus on the analysis of the vector form factor, protected from first order $SU(3)$ breaking effects by the Ademollo-Gatto theorem [20], and treat the ratio between the axial and vector form factors g_1/f_1 as experimental input, thus avoiding first order $SU(3)$ breaking effects in the axial-vector contribution. They find $|V_{us}| = 0.2250 \pm 0.0027$, although this does not include an estimate of the theoretical uncertainty due to second-order $SU(3)$ breaking, contrary to Eq. (11.8). Concerning hadronic τ decays to strange particles, the latest determinations based on LEP, BABAR, and Belle data yield $|V_{us}| = 0.2208 \pm 0.0039$ [21]. A measurement of the ratio of branching fractions $\mathcal{B}(\tau \rightarrow K\nu)/\mathcal{B}(\tau \rightarrow \pi\nu)$ by BABAR [22] combined with the above f_K/f_π value gives $|V_{us}| = 0.2255 \pm 0.0024$.

11.2.3. $|V_{cd}|$:

The magnitude of V_{cd} can be extracted from semileptonic charm decays if theoretical knowledge of the form factors is available. Three-flavor unquenched lattice QCD calculations for $D \rightarrow K\ell\nu$ and $D \rightarrow \pi\ell\nu$ have been published [23]. Using these estimates and the average of recent CLEO-c [24] and Belle [25] measurements of $D \rightarrow \pi\ell\nu$ decays, one obtains $|V_{cd}| = 0.229 \pm 0.006 \pm 0.024$, where the first uncertainty is experimental, and the second is from the theoretical uncertainty of the form factor.

This determination is not yet as precise as the one based on neutrino and antineutrino interactions. The difference of the ratio of double-muon to single-muon production by neutrino and antineutrino beams is proportional to the charm cross section off valence d quarks, and therefore to $|V_{cd}|^2$ times the average semileptonic branching ratio of charm mesons, \mathcal{B}_μ . The method was used first by CDHS [26] and then by CCFR [27,28] and CHARM II [29]. Averaging these results is complicated, not only because it requires assumptions about the scale of the QCD corrections, but also because \mathcal{B}_μ is an effective quantity, which depends on the specific neutrino beam characteristics. Given that no new experimental input is available, we quote the average provided in a previous review, $\mathcal{B}_\mu |V_{cd}|^2 = (0.463 \pm 0.034) \times 10^{-2}$ [30]. Analysis cuts make these experiments insensitive to neutrino energies smaller than 30 GeV. Thus, \mathcal{B}_μ should be computed using only neutrino interactions with visible energy larger than 30 GeV. An appraisal [31] based on charm-production fractions measured in neutrino interactions [32,33] gives $\mathcal{B}_\mu = 0.088 \pm 0.006$. Data from the CHORUS experiment [34] are sufficiently precise to extract \mathcal{B}_μ directly, by comparing the number of charm decays with a muon to the total number of charmed hadrons found in the nuclear emulsions. Requiring the visible energy to be larger than 30 GeV, CHORUS finds $\mathcal{B}_\mu = 0.085 \pm 0.009 \pm 0.006$. To extract $|V_{cd}|$, we use the average of these two determinations, $\mathcal{B}_\mu = 0.087 \pm 0.005$, and obtain

$$|V_{cd}| = 0.230 \pm 0.011. \quad (11.9)$$

11.2.4. $|V_{cs}|$:

The determination of $|V_{cs}|$ from neutrino and antineutrino scattering suffers from the uncertainty of the s -quark sea content. Measurements sensitive to $|V_{cs}|$ from on-shell W^\pm decays were performed at LEP-2. The branching ratios of the W depend on the six CKM matrix elements involving quarks with masses smaller than M_W . The W branching ratio to each lepton flavor is given by $1/\mathcal{B}(W \rightarrow \ell\bar{\nu}_\ell) = 3[1 + \sum_{u,c,d,s,b} |V_{ij}|^2 (1 + \alpha_s(m_W)/\pi)]$. The measurement assuming lepton universality, $\mathcal{B}(W \rightarrow \ell\bar{\nu}_\ell) = (10.83 \pm 0.07 \pm 0.07)\%$ [35], implies $\sum_{u,c,d,s,b} |V_{ij}|^2 = 2.002 \pm 0.027$. This is a precise test of unitarity, but only flavor-tagged W -decay measurements determine $|V_{cs}|$ directly. DELPHI measured tagged $W^+ \rightarrow c\bar{s}$ decays, obtaining $|V_{cs}| = 0.94^{+0.32}_{-0.26} \pm 0.13$ [36]. Hereafter, the first error is statistical and the second is systematic, unless mentioned otherwise.

The direct determination of $|V_{cs}|$ is possible from semileptonic D or leptonic D_s decays, using unquenched lattice QCD calculations of the semileptonic D form factor or the D_s decay constant. For muonic decays, the average of Belle [37], CLEO-c [38] and BABAR [39] gives $\mathcal{B}(D_s^+ \rightarrow \mu^+\nu) = (5.90 \pm 0.33) \times 10^{-3}$ [41]. For decays with τ leptons, the average of CLEO-c [38,42,43] and BABAR [39] gives $\mathcal{B}(D_s^+ \rightarrow \tau^+\nu) = (5.29 \pm 0.28) \times 10^{-2}$ [41]. From each of these values, determinations of $|V_{cs}|$ can be obtained by using the PDG values for the mass and lifetime of the D_s , the masses of the leptons, and $f_{D_s} = (248.6 \pm 3.0)$ MeV [44]. The average of these determinations gives $|V_{cs}| = 1.008 \pm 0.024$, where the error is dominated by the lattice QCD determination of f_{D_s} . In semileptonic D decays, unquenched lattice QCD calculations have predicted the normalization and the shape (dependence on the invariant mass of the lepton pair, q^2) of the form factors in $D \rightarrow K\ell\nu$ and $D \rightarrow \pi\ell\nu$ [23]. Using these theoretical results and the average of recent CLEO-c [24], Belle [25] and BABAR [45] measurements of $B \rightarrow K\ell\nu$ decays, one obtains $|V_{cs}| = 0.98 \pm 0.01 \pm 0.10$, where the first error is experimental and the second, which is dominant, is from the theoretical uncertainty of the form factor. Averaging the determinations from leptonic and semileptonic decays, we find

$$|V_{cs}| = 1.006 \pm 0.023. \quad (11.10)$$

11.2.5. $|V_{cb}|$:

This matrix element can be determined from exclusive and inclusive semileptonic decays of B mesons to charm. The inclusive determinations use the semileptonic decay rate measurement, together with the leptonic energy and the hadronic invariant-mass spectra. The theoretical foundation of the calculation is the operator product expansion [46,47]. It expresses the total rate and moments of differential energy and invariant-mass spectra as expansions in α_s , and inverse powers of the heavy quark mass. The dependence on m_b , m_c , and the parameters that occur at subleading order is different for different moments, and a large number of measured moments overconstrains all the parameters, and tests the consistency of the determination. The precise extraction of $|V_{cb}|$ requires using a ‘‘threshold’’ quark mass definition [48,49]. Inclusive measurements have been performed using B mesons from Z^0 decays at LEP, and at e^+e^- machines operated at the $\Upsilon(4S)$. At LEP, the large boost of B mesons from the Z^0 allows the determination of the moments throughout phase space, which is not possible otherwise, but the large statistics available at the B factories lead to more precise determinations. An average of the measurements and a compilation of the references are provided by Ref. [50]: $|V_{cb}| = (41.9 \pm 0.7) \times 10^{-3}$.

Exclusive determinations are based on semileptonic B decays to D and D^* . In the $m_{b,c} \gg \Lambda_{\text{QCD}}$ limit, all form factors are given by a single Isgur-Wise function [51], which depends on the product of the four-velocities of the B and $D^{(*)}$ mesons, $w = v \cdot v'$. Heavy quark symmetry determines the normalization of the rate at $w = 1$, the maximum momentum transfer to the leptons, and $|V_{cb}|$ is obtained from an extrapolation to $w = 1$. The exclusive determination, $|V_{cb}| = (39.6 \pm 0.9) \times 10^{-3}$ [50], is less precise than the inclusive one because of the theoretical uncertainty in the form factor and the experimental uncertainty in the rate near $w = 1$. The V_{cb} and V_{ub} minireview [50] quotes a combination with a scaled error as

$$|V_{cb}| = (40.9 \pm 1.1) \times 10^{-3}. \quad (11.11)$$

11.2.6. $|V_{ub}|$:

The determination of $|V_{ub}|$ from inclusive $B \rightarrow X_u \ell \bar{\nu}$ decay is complicated due to large $B \rightarrow X_c \ell \bar{\nu}$ backgrounds. In most regions of phase space where the charm background is kinematically forbidden, the hadronic physics enters via unknown nonperturbative functions, so-called shape functions. (In contrast, the nonperturbative physics for $|V_{cb}|$ is encoded in a few parameters.) At leading order in Λ_{QCD}/m_b , there is only one shape function, which can be extracted from the photon energy spectrum in $B \rightarrow X_s \gamma$ [52,53], and applied to several spectra in $B \rightarrow X_u \ell \bar{\nu}$. The subleading shape functions are modeled in the current determinations. Phase space cuts for which the rate has only subleading dependence on the shape function are also possible [54]. The measurements of both the hadronic and the leptonic systems are important for an optimal choice of phase space. A different approach is to make the measurements more inclusive by extending them deeper into the $B \rightarrow X_c \ell \bar{\nu}$ region, and thus reduce the theoretical uncertainties. Analyses of the electron-energy endpoint from CLEO [55], BABAR [56], and Belle [57] quote $B \rightarrow X_u e \bar{\nu}$ partial rates for $|\bar{p}_e| \geq 2.0 \text{ GeV}$ and 1.9 GeV , which are well below the charm endpoint. The large and pure $B\bar{B}$ samples at the B factories permit the selection of $B \rightarrow X_u \ell \bar{\nu}$ decays in events where the other B is fully reconstructed [58]. With this full-reconstruction tag method, the four-momenta of both the leptonic and the hadronic systems can be measured. It also gives access to a wider kinematic region because of improved signal purity. Ref. 50 quotes an inclusive average as $|V_{ub}| = (4.41 \pm 0.15^{+0.15}_{-0.19}) \times 10^{-3}$.

To extract $|V_{ub}|$ from an exclusive channel, the form factors have to be known. Experimentally, better signal-to-background ratios are offset by smaller yields. The $B \rightarrow \pi \ell \bar{\nu}$ branching ratio is now known to 5%. Unquenched lattice QCD calculations of the $B \rightarrow \pi \ell \bar{\nu}$ form factor are available [59,60] for the high q^2 region ($q^2 > 16$ or 18 GeV^2). A simultaneous fit to the experimental partial rates and lattice points versus q^2 yields $|V_{ub}| = (3.23 \pm 0.31) \times 10^{-3}$ [60]. Light-cone QCD sum rules are applicable for $q^2 < 14 \text{ GeV}^2$ [61] and yield similar results.

The theoretical uncertainties in extracting $|V_{ub}|$ from inclusive and exclusive decays are different. A combination of the determinations is quoted by Ref. [50] as

$$|V_{ub}| = (4.15 \pm 0.49) \times 10^{-3}. \quad (11.12)$$

A determination of $|V_{ub}|$ not included in this average is obtained from $\mathcal{B}(B \rightarrow \tau \bar{\nu}) = (1.67 \pm 0.30) \times 10^{-4}$ [40]. Using $f_B = (190.6 \pm 4.6) \text{ MeV}$ [44], we find $|V_{ub}| = (5.10 \pm 0.47) \times 10^{-3}$. This decay rate is sensitive, for example, to tree-level charged Higgs contributions, and is higher than other $|V_{ub}|$ determinations or the SM fit value.

11.2.7. $|V_{td}|$ and $|V_{ts}|$:

The CKM elements $|V_{td}|$ and $|V_{ts}|$ are not likely to be precisely measurable in tree-level processes involving top quarks, so one has to rely on determinations from B - \bar{B} oscillations mediated by box diagrams with top quarks, or loop-mediated rare K and B decays. Theoretical uncertainties in hadronic effects limit the accuracy of the current determinations. These can be reduced by taking ratios of processes that are equal in the flavor $SU(3)$ limit to determine $|V_{td}/V_{ts}|$.

The mass difference of the two neutral B meson mass eigenstates is very well measured, $\Delta m_d = (0.507 \pm 0.004) \text{ ps}^{-1}$ [62]. In the B_s^0 system, the average of the CDF [63] and recent LHCb [64] measurements yields $\Delta m_s = (17.719 \pm 0.043) \text{ ps}^{-1}$. Using the unquenched lattice QCD calculations [44], $f_{B_d} \sqrt{\hat{B}_{B_d}} = (211 \pm 12) \text{ MeV}$, $f_{B_s} \sqrt{\hat{B}_{B_s}} = (248 \pm 15) \text{ MeV}$, and assuming $|V_{tb}| = 1$, one finds

$$|V_{td}| = (8.4 \pm 0.6) \times 10^{-3}, \quad |V_{ts}| = (42.9 \pm 2.6) \times 10^{-3}. \quad (11.13)$$

The uncertainties are dominated by lattice QCD. Several uncertainties are reduced in the calculation of the ratio $\xi = (f_{B_s} \sqrt{\hat{B}_{B_s}})/(f_{B_d} \sqrt{\hat{B}_{B_d}}) = 1.237 \pm 0.032$ [44], and therefore the constraint on $|V_{td}/V_{ts}|$ from $\Delta m_d/\Delta m_s$ is more reliable theoretically. These provide a new, theoretically clean, and significantly improved constraint

$$|V_{td}/V_{ts}| = 0.211 \pm 0.001 \pm 0.006. \quad (11.14)$$

The inclusive branching ratio $\mathcal{B}(B \rightarrow X_s \gamma) = (3.55 \pm 0.26) \times 10^{-4}$ extrapolated to $E_\gamma > E_0 = 1.6 \text{ GeV}$ [65] is also sensitive to $V_{tb} V_{ts}^*$. In addition to t -quark penguins, a large part of the sensitivity comes from charm contributions proportional to $V_{cb} V_{cs}^*$ via the application of 3×3 CKM unitarity (which is used here; any CKM determination from loop processes necessarily assumes the SM). With the NNLO calculation of $\mathcal{B}(B \rightarrow X_s \gamma)_{E_\gamma > E_0}/\mathcal{B}(B \rightarrow X_c e \bar{\nu})$ [66], we obtain $|V_{ts}/V_{cb}| = 1.04 \pm 0.05$. The same CKM elements also determine the $B_s \rightarrow \mu^+ \mu^-$ decay rate in the SM, and with the bounds approaching the SM level [67], this mode can soon provide a strong constraint.

A complementary determination of $|V_{td}/V_{ts}|$ is possible from the ratio of $B \rightarrow \rho \gamma$ and $K^* \gamma$ rates. The ratio of the neutral modes is theoretically cleaner than that of the charged ones, because the poorly known spectator-interaction contribution is expected to be smaller (W -exchange vs. weak annihilation). For now, because of low statistics we average the charged and neutral rates assuming the isospin symmetry and heavy quark limit motivated relation, $|V_{td}/V_{ts}|^2/\xi_\gamma^2 = [\Gamma(B^+ \rightarrow \rho^+ \gamma) + 2\Gamma(B^0 \rightarrow \rho^0 \gamma)]/[\Gamma(B^+ \rightarrow K^{*+} \gamma) + \Gamma(B^0 \rightarrow K^{*0} \gamma)] = (3.19 \pm 0.46)\%$ [65]. Here ξ_γ contains the poorly known hadronic physics. Using $\xi_\gamma = 1.2 \pm 0.2$ [68], and combining the experimental and theoretical errors in quadrature, gives $|V_{td}/V_{ts}| = 0.21 \pm 0.04$.

A theoretically clean determination of $|V_{td} V_{ts}^*|$ is possible from $K^+ \rightarrow \pi^+ \nu \bar{\nu}$ decay [69]. Experimentally, only seven events have been observed [70] and the rate is consistent with the SM with large uncertainties. Much more data are needed for a precision measurement.

11.2.8. $|V_{tb}|$:

The determination of $|V_{tb}|$ from top decays uses the ratio of branching fractions $R = \mathcal{B}(t \rightarrow Wb)/\mathcal{B}(t \rightarrow Wq) = |V_{tb}|^2/(\sum_q |V_{tq}|^2) = |V_{tb}|^2$, where $q = b, s, d$. The CDF and DØ measurements performed on data collected during Run II of the Tevatron give $|V_{tb}| > 0.78$ [71] and $0.99 > |V_{tb}| > 0.90$ [72], respectively, at 95% CL. CMS recently measured the same quantity at 7 TeV and gives $|V_{tb}| > 0.92$ [73] at 95% CL. The direct determination of $|V_{tb}|$ without assuming unitarity is possible from the single top-quark-production cross section. The $(2.71^{+0.44}_{-0.43}) \text{ pb}$ average cross section measured by DØ [74] and CDF [75,76] implies $|V_{tb}| = 0.87 \pm 0.07$. The recent CMS measurement, $(83.6 \pm 29.8) \text{ pb}$ [77] at 7 TeV, implies $|V_{tb}| = 1.14 \pm 0.22$. The average of above gives

$$|V_{tb}| = 0.89 \pm 0.07. \quad (11.15)$$

An attempt at constraining $|V_{tb}|$ from the precision electroweak data was made in Ref. 78. The result, mostly driven by the top-loop contributions to $\Gamma(Z \rightarrow b\bar{b})$, gives $|V_{tb}| = 0.77^{+0.18}_{-0.24}$.

11.3. Phases of CKM elements

As can be seen from Fig. 11.1, the angles of the unitarity triangle are

$$\begin{aligned} \beta &= \phi_1 = \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right), \\ \alpha &= \phi_2 = \arg\left(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right), \\ \gamma &= \phi_3 = \arg\left(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right). \end{aligned} \quad (11.16)$$

Since CP violation involves phases of CKM elements, many measurements of CP -violating observables can be used to constrain these angles and the $\bar{\rho}, \bar{\eta}$ parameters.

11.3.1. ϵ and ϵ' :

The measurement of CP violation in K^0 - \bar{K}^0 mixing, $|\epsilon| = (2.233 \pm 0.015) \times 10^{-3}$ [79], provides important information about the CKM matrix. In the SM, in the basis where $V_{ud}V_{us}^*$ is real [80]

$$\begin{aligned} |\epsilon| &= \frac{G_F^2 f_K^2 m_K m_W^2}{12\sqrt{2}\pi^2 \Delta m_K} \hat{B}_K \left\{ \eta_1 S(x_c) \text{Im}[(V_{cs}V_{cd}^*)^2] \right. \\ &\quad \left. + \eta_2 S(x_t) \text{Im}[(V_{ts}V_{td}^*)^2] + 2\eta_3 S(x_c, x_t) \text{Im}(V_{cs}V_{cd}^*V_{ts}V_{td}^*) \right\}, \end{aligned} \quad (11.17)$$

where S is an Inami-Lim function [81], $x_q = m_q^2/m_W^2$, and η_i are perturbative QCD corrections. The constraint from ϵ in the $\bar{\rho}, \bar{\eta}$ plane is bounded by approximate hyperbolas. The dominant uncertainties are due to the bag parameter, for which we use $\hat{B}_K = 0.7674 \pm 0.0099$ from lattice QCD [44], and the parametric uncertainty proportional to $\sigma(A^4)$ from $(V_{ts}V_{td}^*)^2$, which is approximately $\sigma(|V_{cb}|^4)$.

The measurement of $6 \operatorname{Re}(\epsilon'/\epsilon) = 1 - |\eta_{00}/\eta_{+-}|^2$, where η_{00} and η_{+-} are the CP -violating amplitude ratios of K_S^0 and K_L^0 decays to two pions, provides a qualitative test of the CKM mechanism. Its nonzero experimental average, $\operatorname{Re}(\epsilon'/\epsilon) = (1.67 \pm 0.23) \times 10^{-3}$ [79], demonstrates the existence of direct CP violation, a prediction of the KM ansatz. While $\operatorname{Re}(\epsilon'/\epsilon) \propto \operatorname{Im}(V_{td}V_{ts}^*)$, this quantity cannot easily be used to extract CKM parameters, because the electromagnetic penguin contributions tend to cancel the gluonic penguins for large m_t [82], thereby significantly increasing the hadronic uncertainties. Most estimates [83–86] agree with the observed value, indicating that $\bar{\eta}$ is positive. Progress in lattice QCD, in particular finite-volume calculations [87,88], may eventually provide a determination of the $K \rightarrow \pi\pi$ matrix elements.

11.3.2. β / ϕ_1 :

11.3.2.1. Charmonium modes:

CP -violation measurements in B -meson decays provide direct information on the angles of the unitarity triangle, shown in Fig. 11.1. These overconstraining measurements serve to improve the determination of the CKM elements, or to reveal effects beyond the SM.

The time-dependent CP asymmetry of neutral B decays to a final state f common to B^0 and \bar{B}^0 is given by [89,90]

$$A_f = \frac{\Gamma(\bar{B}^0(t) \rightarrow f) - \Gamma(B^0(t) \rightarrow f)}{\Gamma(\bar{B}^0(t) \rightarrow f) + \Gamma(B^0(t) \rightarrow f)} = S_f \sin(\Delta m_d t) - C_f \cos(\Delta m_d t), \quad (11.18)$$

where

$$S_f = \frac{2 \operatorname{Im} \lambda_f}{1 + |\lambda_f|^2}, \quad C_f = \frac{1 - |\lambda_f|^2}{1 + |\lambda_f|^2}, \quad \lambda_f = \frac{q \bar{A}_f}{p A_f}. \quad (11.19)$$

Here, q/p describes B^0 - \bar{B}^0 mixing and, to a good approximation in the SM, $q/p = V_{tb}^* V_{td} / V_{ub} V_{ud}^* = e^{-2i\beta + \mathcal{O}(\lambda^4)}$ in the usual phase convention. A_f (\bar{A}_f) is the amplitude of the $B^0 \rightarrow f$ ($\bar{B}^0 \rightarrow f$) decay. If f is a CP eigenstate, and amplitudes with one CKM phase dominate the decay, then $|A_f| = |\bar{A}_f|$, $C_f = 0$, and $S_f = \sin(\arg \lambda_f) = \eta_f \sin 2\phi$, where η_f is the CP eigenvalue of f and 2ϕ is the phase difference between the $B^0 \rightarrow f$ and $B^0 \rightarrow \bar{B}^0 \rightarrow f$ decay paths. A contribution of another amplitude to the decay with a different CKM phase makes the value of S_f sensitive to relative strong interaction phases between the decay amplitudes (it also makes $C_f \neq 0$ possible).

The $b \rightarrow c\bar{c}s$ decays to CP eigenstates ($B^0 \rightarrow$ charmonium $K_{S,L}^0$) are the theoretically cleanest examples, measuring $S_f = -\eta_f \sin 2\beta$. The $b \rightarrow sq\bar{q}$ penguin amplitudes have dominantly the same weak phase as the $b \rightarrow c\bar{c}s$ tree amplitude. Since only λ^2 -suppressed penguin amplitudes introduce a new CP -violating phase, amplitudes with a single weak phase dominate, and we expect $|\bar{A}_{\psi K} / A_{\psi K} - 1| < 0.01$. The e^+e^- asymmetric-energy B -factory experiments, BABAR [92] and Belle [93], provide precise measurements. The world average is [94]

$$\sin 2\beta = 0.679 \pm 0.020. \quad (11.20)$$

This measurement has a four-fold ambiguity in β , which can be resolved by a global fit as mentioned in Sec. 11.4. Experimentally, the two-fold ambiguity $\beta \rightarrow \pi/2 - \beta$ (but not $\beta \rightarrow \pi + \beta$) can be resolved by a time-dependent angular analysis of $B^0 \rightarrow J/\psi K^{*0}$ [95,96], or a time-dependent Dalitz plot analysis of $B^0 \rightarrow \bar{D}^0 h^0$ ($h^0 = \pi^0, \eta, \omega$) with $\bar{D}^0 \rightarrow K_S^0 \pi^+ \pi^-$ [97,98]. These results indicate that negative $\cos 2\beta$ solutions are very unlikely, in agreement with the global CKM fit result.

The $b \rightarrow c\bar{c}d$ mediated transitions, such as $B^0 \rightarrow J/\psi \pi^0$ and $B^0 \rightarrow D^{(*)+} D^{(*)-}$, also measure approximately $\sin 2\beta$. However,

the dominant component of the $b \rightarrow d$ penguin amplitude has a different CKM phase ($V_{tb}^* V_{td}$) than the tree amplitude ($V_{cb}^* V_{cd}$), and its magnitudes are of the same order in λ . Therefore, the effect of penguins could be large, resulting in $S_f \neq -\eta_f \sin 2\beta$ and $C_f \neq 0$. These decay modes have also been measured by BABAR and Belle. The world averages [94], $S_{J/\psi \pi^0} = -0.93 \pm 0.15$, $S_{D^+ D^-} = -0.96 \pm 0.19$, and $S_{D^{*+} D^{*-}} = -0.77 \pm 0.14$ ($\eta_f = +1$ for these modes), are consistent with $\sin 2\beta$ obtained from $B^0 \rightarrow$ charmonium K^0 decays, and the C_f 's are consistent with zero, although the uncertainties are sizable.

The $b \rightarrow c\bar{u}d$ decays, $B^0 \rightarrow \bar{D}^0 h^0$ with $\bar{D}^0 \rightarrow CP$ eigenstates, have no penguin contributions and provide theoretically clean $\sin 2\beta$ measurements. BABAR measured $S_{D^{(*)} h^0} = -0.56 \pm 0.25$ [91].

11.3.2.2. Penguin-dominated modes:

The $b \rightarrow s\bar{q}q$ penguin-dominated decays have the same CKM phase as the $b \rightarrow c\bar{c}s$ tree level decays, up to corrections suppressed by λ^2 , since $V_{tb}^* V_{ts} = -V_{cb}^* V_{cs} [1 + \mathcal{O}(\lambda^2)]$. Therefore, decays such as $B^0 \rightarrow \phi K^0$ and $\eta' K^0$ provide $\sin 2\beta$ measurements in the SM. Any new physics contribution to the amplitude with a different weak phase would give rise to $S_f \neq -\eta_f \sin 2\beta$, and possibly $C_f \neq 0$. Therefore, the main interest in these modes is not simply to measure $\sin 2\beta$, but to search for new physics. Measurements of many other decay modes in this category, such as $B \rightarrow \pi^0 K_S^0$, $K_S^0 K_S^0 K_S^0$, etc., have also been performed by BABAR and Belle. The results and their uncertainties are summarized in Fig. 12.3 and Table 12.1 of Ref. 90.

11.3.3. α / ϕ_2 :

Since α is the phase between $V_{tb}^* V_{td}$ and $V_{ub}^* V_{ud}$, only time-dependent CP asymmetries in $b \rightarrow u\bar{u}d$ decay dominated modes can directly measure $\sin 2\alpha$, in contrast to $\sin 2\beta$, where several different transitions can be used. Since $b \rightarrow d$ penguin amplitudes have a different CKM phase than $b \rightarrow u\bar{u}d$ tree amplitudes, and their magnitudes are of the same order in λ , the penguin contribution can be sizable, which makes the determination of α complicated. To date, α has been measured in $B \rightarrow \pi\pi$, $\rho\pi$ and $\rho\rho$ decay modes.

11.3.3.1. $B \rightarrow \pi\pi$:

It is now experimentally well established that there is a sizable contribution of $b \rightarrow d$ penguin amplitudes in $B \rightarrow \pi\pi$ decays. Thus, $S_{\pi^+ \pi^-}$ in the time-dependent $B^0 \rightarrow \pi^+ \pi^-$ analysis does not measure $\sin 2\alpha$, but

$$S_{\pi^+ \pi^-} = \sqrt{1 - C_{\pi^+ \pi^-}^2} \sin(2\alpha + 2\Delta\alpha), \quad (11.21)$$

where $2\Delta\alpha$ is the phase difference between $e^{2i\gamma} \bar{A}_{\pi^+ \pi^-}$ and $A_{\pi^+ \pi^-}$. The value of $\Delta\alpha$, hence α , can be extracted using the isospin relation among the amplitudes of $B^0 \rightarrow \pi^+ \pi^-$, $B^0 \rightarrow \pi^0 \pi^0$, and $B^+ \rightarrow \pi^+ \pi^0$ decays [99],

$$\frac{1}{\sqrt{2}} A_{\pi^+ \pi^-} + A_{\pi^0 \pi^0} - A_{\pi^+ \pi^0} = 0, \quad (11.22)$$

and a similar expression for the $\bar{A}_{\pi\pi}$'s. This method utilizes the fact that a pair of pions from $B \rightarrow \pi\pi$ decay must be in a zero angular momentum state, and, because of Bose statistics, they must have even isospin. Consequently, $\pi^0 \pi^{\pm}$ is in a pure isospin-2 state, while the penguin amplitudes only contribute to the isospin-0 final state. The latter does not hold for the electroweak penguin amplitudes, but their effect is expected to be small. The isospin analysis uses the world averages [94,100] $S_{\pi^+ \pi^-} = -0.65 \pm 0.07$, $C_{\pi^+ \pi^-} = -0.38 \pm 0.06$, the branching fractions of all three modes, and the direct CP asymmetry $C_{\pi^0 \pi^0} = -0.43_{-0.24}^{+0.25}$. This analysis leads to 16 mirror solutions for $0 \leq \alpha < 2\pi$. Because of this, and the sizable experimental error of the $B^0 \rightarrow \pi^0 \pi^0$ rate and CP asymmetry, only a loose constraint on α can be obtained at present [101], $0^\circ < \alpha < 7^\circ$, $81^\circ < \alpha < 103^\circ$, $121^\circ < \alpha < 150^\circ$, and $166^\circ < \alpha < 180^\circ$ at 68% CL.

11.3.3.2. $B \rightarrow \rho\rho$:

The decay $B^0 \rightarrow \rho^+\rho^-$ contains two vector mesons in the final state, which in general is a mixture of CP -even and CP -odd components. Therefore, it was thought that extracting α from this mode would be complicated.

However, the longitudinal polarization fractions (f_L) in $B^+ \rightarrow \rho^+\rho^0$ and $B^0 \rightarrow \rho^+\rho^-$ decays were measured to be close to unity [102], which implies that the final states are almost purely CP -even. Furthermore, $\mathcal{B}(B^0 \rightarrow \rho^0\rho^0) = (0.73_{-0.28}^{+0.27}) \times 10^{-6}$ is much smaller than $\mathcal{B}(B^0 \rightarrow \rho^+\rho^-) = (24.2_{-3.2}^{+3.1}) \times 10^{-6}$ and $\mathcal{B}(B^+ \rightarrow \rho^+\rho^0) = (24.0_{-2.0}^{+1.9}) \times 10^{-6}$ [40], which implies that the effect of the penguin diagrams is small. The isospin analysis using the world averages, $S_{\rho^+\rho^-} = -0.05 \pm 0.17$ and $C_{\rho^+\rho^-} = -0.06 \pm 0.13$ [40], together with the time-dependent CP asymmetry, $S_{\rho^0\rho^0} = -0.3 \pm 0.7$ and $C_{\rho^0\rho^0} = -0.2 \pm 0.9$ [103], and the above-mentioned branching fractions, gives $\alpha = (89.9 \pm 5.4)^\circ$ [101], with a mirror solution at $3\pi/2 - \alpha$. A possible small violation of Eq. (11.22) due to the finite width of the ρ [104] is neglected.

11.3.3.3. $B \rightarrow \rho\pi$:

The final state in $B^0 \rightarrow \rho^+\pi^-$ decay is not a CP eigenstate, but this decay proceeds via the same quark-level diagrams as $B^0 \rightarrow \pi^+\pi^-$, and both B^0 and \bar{B}^0 can decay to $\rho^+\pi^-$. Consequently, mixing-induced CP violations can occur in four decay amplitudes, $B^0 \rightarrow \rho^\pm\pi^\mp$ and $\bar{B}^0 \rightarrow \rho^\pm\pi^\mp$. The time-dependent Dalitz plot analysis of $B^0 \rightarrow \pi^+\pi^-\pi^0$ decays permits the extraction of α with a single discrete ambiguity, $\alpha \rightarrow \alpha + \pi$, since one knows the variation of the strong phases in the interference regions of the $\rho^+\pi^-$, $\rho^-\pi^+$, and $\rho^0\pi^0$ amplitudes in the Dalitz plot [105]. The combination of Belle [106] and BABAR [107] measurements gives $\alpha = (120_{-7}^{+11})^\circ$ [101]. This constraint is still moderate, and there are also solutions around 30° and 90° within 2σ significance level.

Combining the above-mentioned three decay modes [101], α is constrained as

$$\alpha = (89.0_{-4.2}^{+4.4})^\circ. \quad (11.23)$$

A different statistical approach [108] gives similar constraint from the combination of these measurements.

11.3.4. γ / ϕ_3 :

By virtue of Eq. (11.16), γ does not depend on CKM elements involving the top quark, so it can be measured in tree-level B decays. This is an important distinction from the measurements of α and β , and implies that the measurements of γ are unlikely to be affected by physics beyond the SM.

11.3.4.1. $B^\pm \rightarrow DK^\pm$:

The interference of $B^- \rightarrow D^0K^-$ ($b \rightarrow c\bar{u}s$) and $B^- \rightarrow \bar{D}^0K^-$ ($b \rightarrow \bar{u}cs$) transitions can be studied in final states accessible in both D^0 and \bar{D}^0 decays [89]. In principle, it is possible to extract the B and D decay amplitudes, the relative strong phases, and the weak phase γ from the data.

A practical complication is that the precision depends sensitively on the ratio of the interfering amplitudes

$$r_B = \left| \frac{A(B^- \rightarrow \bar{D}^0K^-)}{A(B^- \rightarrow D^0K^-)} \right|, \quad (11.24)$$

which is around 0.1–0.2. The original GLW method [109,110] considers D decays to CP eigenstates, such as $B^\pm \rightarrow D_{CP}^{(*)}(\rightarrow \pi^+\pi^-)K^\pm$. To alleviate the smallness of r_B and make the interfering amplitudes (which are products of the B and D decay amplitudes) comparable in magnitude, the ADS method [111] considers final states where Cabibbo-allowed \bar{D}^0 and doubly-Cabibbo-suppressed D^0 decays interfere. Extensive measurements have been made by the B factories [112,113], CDF [114] and LHCb [115] using both methods.

It was realized that both D^0 and \bar{D}^0 have large branching fractions to certain three-body final states, such as $K_S\pi^+\pi^-$, and the analysis can be optimized by studying the Dalitz plot dependence of the interferences [116,117]. The best present determination of γ comes from this method. Belle [118] and BABAR [119] obtained

$\gamma = (78_{-12}^{+11} \pm 4 \pm 9)^\circ$ and $\gamma = (68 \pm 14 \pm 4 \pm 3)^\circ$, respectively, where the last uncertainty is due to the D -decay modeling. The error is sensitive to the central value of the amplitude ratio r_B (and r_B^* for the D^*K mode), for which Belle found somewhat larger central values than BABAR. The same values of $r_B^{(*)}$ enter the ADS analyses, and the data can be combined to fit for $r_B^{(*)}$ and γ . The $D^0\bar{D}^0$ mixing has been neglected in all measurements, but its effect on γ is far below the present experimental accuracy [120], unless $D^0\bar{D}^0$ mixing is due to CP -violating new physics, in which case it can be included in the analysis [121].

Combining the GLW, ADS, and Dalitz analyses [101], γ is constrained as

$$\gamma = (68_{-11}^{+10})^\circ. \quad (11.25)$$

Similar results are found in Ref. [108].

11.3.4.2. $B^0 \rightarrow D^{(*)}\pi^\mp$:

The interference of $b \rightarrow u$ and $b \rightarrow c$ transitions can be studied in $\bar{B}^0 \rightarrow D^{(*)}\pi^-$ ($b \rightarrow c\bar{u}d$) and $\bar{B}^0 \rightarrow B^0 \rightarrow D^{(*)}\pi^-$ ($\bar{b} \rightarrow \bar{u}c\bar{d}$) decays and their CP conjugates, since both B^0 and \bar{B}^0 decay to $D^{(*)}\pi^\mp$ (or $D^\pm\rho^\mp$, etc.). Since there are only tree and no penguin contributions to these decays, in principle, it is possible to extract from the four time-dependent rates the magnitudes of the two hadronic amplitudes, their relative strong phase, and the weak phase between the two decay paths, which is $2\beta + \gamma$.

A complication is that the ratio of the interfering amplitudes is very small, $r_{D\pi} = A(B^0 \rightarrow D^+\pi^-)/A(\bar{B}^0 \rightarrow D^+\pi^-) = \mathcal{O}(0.01)$ (and similarly for $r_{D^*\pi}$ and $r_{D\rho}$), and therefore it has not been possible to measure it. To obtain $2\beta + \gamma$, $SU(3)$ flavor symmetry and dynamical assumptions have been used to relate $A(\bar{B}^0 \rightarrow D^-\pi^+)$ to $A(\bar{B}^0 \rightarrow D_s^-\pi^+)$, so this measurement is not model-independent at present. Combining the $D^\pm\pi^\mp$, $D^*\pi^\mp$ and $D^\pm\rho^\mp$ measurements [122] gives $\sin(2\beta + \gamma) > 0.68$ at 68% CL [101], consistent with the previously discussed results for β and γ . The amplitude ratio is much larger in the analogous $B_s^0 \rightarrow D_s^\pm K^\mp$ decays, so it will be possible at LHCb to measure it and model-independently extract $\gamma - 2\beta_s$ [123] (where $\beta_s = \arg(-V_{ts}V_{tb}^*/V_{cs}V_{cb}^*)$ is related to the phase of B_s mixing).

11.4. Global fit in the Standard Model

Using the independently measured CKM elements mentioned in the previous sections, the unitarity of the CKM matrix can be checked. We obtain $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9999 \pm 0.0006$ (1st row), $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 1.067 \pm 0.047$ (2nd row), $|V_{ud}|^2 + |V_{cd}|^2 + |V_{td}|^2 = 1.002 \pm 0.005$ (1st column), and $|V_{us}|^2 + |V_{cs}|^2 + |V_{ts}|^2 = 1.065 \pm 0.046$ (2nd column), respectively. The uncertainties in the second row and column are dominated by that of $|V_{cs}|$. For the second row, a more stringent check is obtained from the measurement of $\sum_{u,c,d,s,b} |V_{ij}|^2$ in Sec. 11.2.4 minus the sum in the first row above: $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 1.002 \pm 0.027$. These provide strong tests of the unitarity of the CKM matrix. The sum of the three angles of the unitarity triangle, $\alpha + \beta + \gamma = (178_{-12}^{+11})^\circ$, is also consistent with the SM expectation.

The CKM matrix elements can be most precisely determined by a global fit that uses all available measurements and imposes the SM constraints (*i.e.*, three generation unitarity). The fit must also use theory predictions for hadronic matrix elements, which sometimes have significant uncertainties. There are several approaches to combining the experimental data. CKMfitter [6,101] and Ref. 124 (which develops [125,126] further) use frequentist statistics, while UTfit [108,127] uses a Bayesian approach. These approaches provide similar results.

The constraints implied by the unitarity of the three generation CKM matrix significantly reduce the allowed range of some of the CKM elements. The fit for the Wolfenstein parameters defined in Eq. (11.4) gives

$$\begin{aligned} \lambda &= 0.22535 \pm 0.00065, & A &= 0.811_{-0.012}^{+0.022}, \\ \bar{\rho} &= 0.131_{-0.013}^{+0.026}, & \bar{\eta} &= 0.345_{-0.014}^{+0.013}. \end{aligned} \quad (11.26)$$

Figure 11.2: Constraints on the $\bar{\rho}, \bar{\eta}$ plane. The shaded areas have 95% CL.

These values are obtained using the method of Refs. [6,101]. Using the prescription of Refs. [108,127] gives $\lambda = 0.22535 \pm 0.00065$, $A = 0.817 \pm 0.015$, $\bar{\rho} = 0.136 \pm 0.018$, $\bar{\eta} = 0.348 \pm 0.014$ [128]. The fit results for the magnitudes of all nine CKM elements are

$$V_{\text{CKM}} = \begin{pmatrix} 0.97427 \pm 0.00015 & 0.22534 \pm 0.00065 & 0.00351^{+0.00015}_{-0.00014} \\ 0.22520 \pm 0.00065 & 0.97344 \pm 0.00016 & 0.0412^{+0.0011}_{-0.0005} \\ 0.00867^{+0.00029}_{-0.00031} & 0.0404^{+0.0011}_{-0.0005} & 0.999146^{+0.000021}_{-0.000046} \end{pmatrix}, \quad (11.27)$$

and the Jarlskog invariant is $J = (2.96^{+0.20}_{-0.16}) \times 10^{-5}$.

Figure 11.2 illustrates the constraints on the $\bar{\rho}, \bar{\eta}$ plane from various measurements and the global fit result. The shaded 95% CL regions all overlap consistently around the global fit region. This consistency gets noticeably worse if $B \rightarrow \tau \bar{\nu}$ is included in the fit.

11.5. Implications beyond the SM

The effects in B , K , and D decays and mixings due to high-scale physics (W , Z , t , h in the SM, and new physics particles) can be parameterized by operators made of SM fields, obeying the $SU(3) \times SU(2) \times U(1)$ gauge symmetry. The beyond SM (BSM) contributions to the coefficients of these operators are suppressed by powers of the scale of new physics. At lowest order, there are of order a hundred flavor-changing operators of dimension-6, and the observable effects of BSM interactions are encoded in their coefficients. In the SM, these coefficients are determined by just the four CKM parameters, and the W , Z , and quark masses. For example, Δm_d , $\Gamma(B \rightarrow \rho \gamma)$, and $\Gamma(B \rightarrow X_d \ell^+ \ell^-)$ are all proportional to $|V_{td} V_{tb}^*|^2$ in the SM, however, they may receive unrelated contributions from new physics. The new physics contributions may or may not obey the SM relations. (For example, the flavor sector of the MSSM contains 69 CP -conserving parameters and 41 CP -violating phases, *i.e.*, 40 new ones [129]). Thus, similar to the measurements of $\sin 2\beta$ in tree- and loop-dominated decay modes, overconstraining measurements of the magnitudes and phases of flavor-changing neutral-current amplitudes give good sensitivity to new physics.

To illustrate the level of suppression required for BSM contributions, consider a class of models in which the unitarity of the CKM matrix is maintained, and the dominant effect of new physics is to modify the neutral meson mixing amplitudes [130] by $(z_{ij}/\Lambda^2)(\bar{q}_i \gamma^\mu P_L q_j)^2$ (for recent reviews, see [131,132]). It is only known since the measurements of γ and α that the SM gives the leading contribution to $B^0 - \bar{B}^0$ mixing [6,133]. Nevertheless, new physics with a generic weak phase may still contribute to neutral meson mixings at a significant fraction of the SM [134,127]. The existing data imply that $\Lambda/|z_{ij}|^{1/2}$ has to

exceed about 10^4 TeV for $K^0 - \bar{K}^0$ mixing, 10^3 TeV for $D^0 - \bar{D}^0$ mixing, 500 TeV for $B^0 - \bar{B}^0$ mixing, and 100 TeV for $B_s^0 - \bar{B}_s^0$ mixing [127,132]. (Some other operators are even better constrained [127].) The constraints are the strongest in the kaon sector, because the CKM suppression is the most severe. Thus, if there is new physics at the TeV scale, $|z_{ij}| \ll 1$ is required. Even if $|z_{ij}|$ are suppressed by a loop factor and $|V_{ti}^* V_{tj}|^2$ (in the down quark sector), similar to the SM, one expects percent-level effects, which may be observable in forthcoming flavor physics experiments. To constrain such extensions of the SM, many measurements irrelevant for the SM-CKM fit, such as the CP asymmetry in semileptonic $B_{d,s}^0$ decays, $A_{\text{SL}}^{d,s}$, are important [135]. A D^0 measurement sensitive to the approximate linear combination $0.6A_{\text{SL}}^d + 0.4A_{\text{SL}}^s$ shows a 3.9σ hint of a deviation from the SM [136].

Many key measurements which are sensitive to BSM flavor physics are not useful to think about in terms of constraining the unitarity triangle in Fig. 11.1. For example, besides the angles in Eq. (11.16), a key quantity in the B_s system is $\beta_s = \arg(-V_{ts} V_{tb}^* / V_{cs} V_{cb}^*)$, which is the small, λ^2 -suppressed, angle of a “squashed” unitarity triangle, obtained by taking the scalar product of the second and third columns. This angle can be measured via time-dependent CP violation in $B_s^0 \rightarrow J/\psi \phi$, similar to β in $B^0 \rightarrow J/\psi K^0$. Since the $J/\psi \phi$ final state is not a CP eigenstate, an angular analysis of the decay products is needed to separate the CP -even and CP -odd components, which give opposite asymmetries. In the SM, the asymmetry for the CP -even part is $2\beta_s$ (sometimes the notation $\phi_s = -2\beta_s$ plus a possible BSM contribution to the B_s mixing phase is used). Checking if the data agrees with the SM prediction, $\beta_s = 0.018 \pm 0.001$ [101], is another sensitive test of the SM. After the first CP -asymmetry measurements of $B_s^0 \rightarrow J/\psi \phi$ hinted at a possible large deviation from the SM, the latest Tevatron results [137] are consistent with the SM, within the sizable uncertainties. So is the much more precise LHCb measurement obtained from 1 fb^{-1} data, including the $J/\psi \pi \pi$ mode, yielding $\beta_s = 0.001 \pm 0.044$ [138]. This uncertainty is still more than twice the SM central value and 40 times the SM uncertainty; thus a lot will be learned from higher precision measurements in the future.

In the kaon sector, the two measured CP -violating observables ϵ and ϵ' are tiny, so models in which all sources of CP violation are small were viable before the B -factory measurements. Since the measurement of $\sin 2\beta$, we know that CP violation can be an $\mathcal{O}(1)$ effect, and only flavor mixing is suppressed between the three quark generations. Thus, many models with spontaneous CP violation are excluded. In the kaon sector, a very clean test of the SM will come from measurements of $K^+ \rightarrow \pi^+ \nu \bar{\nu}$ and $K_L^0 \rightarrow \pi^0 \nu \bar{\nu}$. These loop-induced rare decays are sensitive to new physics, and will allow a determination of β independent of its value measured in B decays [139].

The CKM elements are fundamental parameters, so they should be measured as precisely as possible. The overconstraining measurements of CP asymmetries, mixing, semileptonic, and rare decays have started to severely constrain the magnitudes and phases of possible new physics contributions to flavor-changing interactions. When new particles are observed at the LHC, it will be important to know the flavor parameters as precisely as possible to understand the underlying physics.

12. *CP VIOLATION IN MESON DECAYS*

Revised May 2012 by D. Kirkby (UC Irvine) and Y. Nir (Weizmann Institute).

The *CP* transformation combines charge conjugation *C* with parity *P*. Under *C*, particles and antiparticles are interchanged, by conjugating all internal quantum numbers, *e.g.*, $Q \rightarrow -Q$ for electromagnetic charge. Under *P*, the handedness of space is reversed, $\vec{x} \rightarrow -\vec{x}$. Thus, for example, a left-handed electron e_L^- is transformed under *CP* into a right-handed positron, e_R^+ .

If *CP* were an exact symmetry, the laws of Nature would be the same for matter and for antimatter. We observe that most phenomena are *C*- and *P*-symmetric, and therefore, also *CP*-symmetric. In particular, these symmetries are respected by the gravitational, electromagnetic, and strong interactions. The weak interactions, on the other hand, violate *C* and *P* in the strongest possible way. For example, the charged *W* bosons couple to left-handed electrons, e_L^- , and to their *CP*-conjugate right-handed positrons, e_R^+ , but to neither their *C*-conjugate left-handed positrons, e_L^+ , nor their *P*-conjugate right-handed electrons, e_R^- . While weak interactions violate *C* and *P* separately, *CP* is still preserved in most weak interaction processes. The *CP* symmetry is, however, violated in certain rare processes, as discovered in neutral *K* decays in 1964 [1], and observed in recent years in *B* decays. A K_L meson decays more often to $\pi^- e^+ \bar{\nu}_e$ than to $\pi^+ e^- \nu_e$, thus allowing electrons and positrons to be unambiguously distinguished, but the decay-rate asymmetry is only at the 0.003 level. The *CP*-violating effects observed in *B* decays are larger: the *CP* asymmetry in B^0/\bar{B}^0 meson decays to *CP* eigenstates like $J/\psi K_S$ is about 0.7 [2,3]. These effects are related to $K^0 - \bar{K}^0$ and $B^0 - \bar{B}^0$ mixing, but *CP* violation arising solely from decay amplitudes has also been observed, first in $K \rightarrow \pi\pi$ decays [4–6], and more recently in various neutral *B* [7,8] and charged *B* [9–11] decays. Evidence for *CP* violation in the decay amplitude at a level higher than 3σ (but still lower than 5σ) has also been achieved in neutral *D* [12] and B_s [13] decays. *CP* violation has not yet been observed in the lepton sector.

In addition to parity and to continuous Lorentz transformations, there is one other spacetime operation that could be a symmetry of the interactions: time reversal *T*, $t \rightarrow -t$. Violations of *T* symmetry have been observed in neutral *K* decays [14], and are expected as a corollary of *CP* violation if the combined *CPT* transformation is a fundamental symmetry of Nature [15]. All observations indicate that *CPT* is indeed a symmetry of Nature. Furthermore, one cannot build a Lorentz-invariant quantum field theory with a Hermitian Hamiltonian that violates *CPT*. (At several points in our discussion, we avoid assumptions about *CPT*, in order to identify cases where evidence for *CP* violation relies on assumptions about *CPT*.)

Within the Standard Model, *CP* symmetry is broken by complex phases in the Yukawa couplings (that is, the couplings of the Higgs scalar to quarks). When all manipulations to remove unphysical phases in this model are exhausted, one finds that there is a single *CP*-violating parameter [16]. In the basis of mass eigenstates, this single phase appears in the 3×3 unitary matrix that gives the *W*-boson couplings to an up-type antiquark and a down-type quark. (If the Standard Model is supplemented with Majorana mass terms for the neutrinos, the analogous mixing matrix for leptons has three *CP*-violating phases.) The beautifully consistent and economical Standard-Model description of *CP* violation in terms of Yukawa couplings, known as the Kobayashi-Maskawa (KM) mechanism [16], agrees with all measurements to date. (The measurement of the dimuon asymmetry in semi-leptonic *b*-hadron decays deviates from the Standard Model prediction by 3.9σ [17]. Pending confirmation, we do not discuss it further in this review.) Furthermore, one can fit the data allowing new physics contributions to loop processes to compete with, or even dominate over, the Standard Model ones [18,19]. Such an analysis provides a model-independent proof that the KM phase is different from zero, and that the matrix of three-generation quark mixing is the dominant source of *CP* violation in meson decays.

The current level of experimental accuracy and the theoretical uncertainties involved in the interpretation of the various observations leave room, however, for additional subdominant sources of *CP* violation from new physics. Indeed, almost all extensions of the

Standard Model imply that there are such additional sources. Moreover, *CP* violation is a necessary condition for baryogenesis, the process of dynamically generating the matter-antimatter asymmetry of the Universe [20]. Despite the phenomenological success of the KM mechanism, it fails (by several orders of magnitude) to accommodate the observed asymmetry [21]. This discrepancy strongly suggests that Nature provides additional sources of *CP* violation beyond the KM mechanism. (The evidence for neutrino masses implies that *CP* can be violated also in the lepton sector. This situation makes leptogenesis [22], a scenario where *CP*-violating phases in the Yukawa couplings of the neutrinos play a crucial role in the generation of the baryon asymmetry, a very attractive possibility.) The expectation of new sources motivates the large ongoing experimental effort to find deviations from the predictions of the KM mechanism.

CP violation can be experimentally searched for in a variety of processes, such as meson decays, electric dipole moments of neutrons, electrons and nuclei, and neutrino oscillations. Meson decays probe flavor-changing *CP* violation. The search for electric dipole moments may find (or constrain) sources of *CP* violation that, unlike the KM phase, are not related to flavor-changing couplings. Future searches for *CP* violation in neutrino oscillations might provide further input on leptogenesis.

The present measurements of *CP* asymmetries provide some of the strongest constraints on the weak couplings of quarks. Future measurements of *CP* violation in *K*, *D*, *B*, and B_s meson decays will provide additional constraints on the flavor parameters of the Standard Model, and can probe new physics. In this review, we give the formalism and basic physics that are relevant to present and near future measurements of *CP* violation in meson decays.

Before going into details, we list here the observables where *CP* violation has been observed at a level above 5σ [23–25]:

- Indirect *CP* violation in $K \rightarrow \pi\pi$ and $K \rightarrow \pi\ell\nu$ decays, and in the $K_L \rightarrow \pi^+ \pi^- e^+ e^-$ decay, is given by

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}. \quad (12.1)$$

- Direct *CP* violation in $K \rightarrow \pi\pi$ decays is given by

$$\text{Re}(\epsilon'/\epsilon) = (1.65 \pm 0.26) \times 10^{-3}. \quad (12.2)$$

- *CP* violation in the interference of mixing and decay in the tree-dominated $b \rightarrow c\bar{c}s$ transitions, such as $B \rightarrow \psi K^0$, is given by (we use K^0 throughout to denote results that combine K_S and K_L modes, but use the sign appropriate to K_S):

$$S_{\psi K^0} = +0.679 \pm 0.020. \quad (12.3)$$

- *CP* violation in the interference of mixing and decay in various modes related to $b \rightarrow q\bar{q}s$ (penguin) transitions is given by

$$S_{\eta' K^0} = +0.59 \pm 0.07, \quad (12.4)$$

$$S_{\phi K^0} = +0.74_{-0.13}^{+0.11}, \quad (12.5)$$

$$S_{f_0 K^0} = +0.69_{-0.12}^{+0.10}, \quad (12.6)$$

$$S_{K^+ K^- K_S} = +0.68_{-0.10}^{+0.09}, \quad (12.7)$$

- *CP* violation in the interference of mixing and decay in the $B \rightarrow \pi^+ \pi^-$ mode is given by

$$S_{\pi^+ \pi^-} = -0.65 \pm 0.07. \quad (12.8)$$

- Direct *CP* violation in the $B \rightarrow \pi^+ \pi^-$ mode is given by

$$C_{\pi^+ \pi^-} = -0.36 \pm 0.06. \quad (12.9)$$

- *CP* violation in the interference of mixing and decay in various modes related to $b \rightarrow c\bar{c}d$ transitions is given by

$$S_{\psi \pi^0} = -0.93 \pm 0.15, \quad (12.10)$$

$$S_{D^+ D^-} = -0.98 \pm 0.17. \quad (12.11)$$

$$S_{D^{*+} D^{*-}} = -0.77 \pm 0.10. \quad (12.12)$$

- Direct CP violation in the $\overline{B}^0 \rightarrow K^- \pi^+$ mode is given by

$$\mathcal{A}_{K^\mp \pi^\pm} = -0.087 \pm 0.008. \quad (12.13)$$

- Direct CP violation in $B^\pm \rightarrow D_+ K^\pm$ decays (D_+ is the CP -even neutral D state) is given by

$$\mathcal{A}_{D_+ K^\pm} = +0.19 \pm 0.03. \quad (12.14)$$

12.1. Formalism

The phenomenology of CP violation is superficially different in K , D , B , and B_s decays. This is primarily because each of these systems is governed by a different balance between decay rates, oscillations, and lifetime splitting. However, the underlying mechanisms of CP violation are identical for all pseudoscalar mesons.

In this section, we present a general formalism for, and classification of, CP violation in the decay of a pseudoscalar meson M that might be a charged or neutral K , D , B , or B_s meson. Subsequent sections describe the CP -violating phenomenology, approximations, and alternative formalisms that are specific to each system.

12.1.1. Charged- and neutral-meson decays: We define decay amplitudes of M (which could be charged or neutral) and its CP conjugate \overline{M} to a multi-particle final state f and its CP conjugate \overline{f} as

$$\begin{aligned} A_f &= \langle f | \mathcal{H} | M \rangle, & \overline{A}_f &= \langle f | \mathcal{H} | \overline{M} \rangle, \\ A_{\overline{f}} &= \langle \overline{f} | \mathcal{H} | M \rangle, & \overline{A}_{\overline{f}} &= \langle \overline{f} | \mathcal{H} | \overline{M} \rangle, \end{aligned} \quad (12.15)$$

where \mathcal{H} is the Hamiltonian governing weak interactions. The action of CP on these states introduces phases ξ_M and ξ_f that depend on their flavor content, according to

$$CP|M\rangle = e^{+i\xi_M} |\overline{M}\rangle, \quad CP|f\rangle = e^{+i\xi_f} |\overline{f}\rangle, \quad (12.16)$$

with

$$CP|\overline{M}\rangle = e^{-i\xi_M} |M\rangle, \quad CP|\overline{f}\rangle = e^{-i\xi_f} |f\rangle \quad (12.17)$$

so that $(CP)^2 = 1$. The phases ξ_M and ξ_f are arbitrary and unphysical because of the flavor symmetry of the strong interaction. If CP is conserved by the dynamics, $[CP, \mathcal{H}] = 0$, then A_f and $\overline{A}_{\overline{f}}$ have the same magnitude and an arbitrary unphysical relative phase

$$\overline{A}_{\overline{f}} = e^{i(\xi_f - \xi_M)} A_f. \quad (12.18)$$

12.1.2. Neutral-meson mixing: A state that is initially a superposition of M^0 and \overline{M}^0 , say

$$|\psi(0)\rangle = a(0)|M^0\rangle + b(0)|\overline{M}^0\rangle, \quad (12.19)$$

will evolve in time acquiring components that describe all possible decay final states $\{f_1, f_2, \dots\}$, that is,

$$|\psi(t)\rangle = a(t)|M^0\rangle + b(t)|\overline{M}^0\rangle + c_1(t)|f_1\rangle + c_2(t)|f_2\rangle + \dots \quad (12.20)$$

If we are interested in computing only the values of $a(t)$ and $b(t)$ (and not the values of all $c_i(t)$), and if the times t in which we are interested are much larger than the typical strong interaction scale, then we can use a much simplified formalism [26]. The simplified time evolution is determined by a 2×2 effective Hamiltonian \mathbf{H} that is not Hermitian, since otherwise the mesons would only oscillate and not decay. Any complex matrix, such as \mathbf{H} , can be written in terms of Hermitian matrices \mathbf{M} and $\mathbf{\Gamma}$ as

$$\mathbf{H} = \mathbf{M} - \frac{i}{2} \mathbf{\Gamma}. \quad (12.21)$$

\mathbf{M} and $\mathbf{\Gamma}$ are associated with $(M^0, \overline{M}^0) \leftrightarrow (M^0, \overline{M}^0)$ transitions via off-shell (dispersive), and on-shell (absorptive) intermediate states, respectively. Diagonal elements of \mathbf{M} and $\mathbf{\Gamma}$ are associated with

the flavor-conserving transitions $M^0 \rightarrow M^0$ and $\overline{M}^0 \rightarrow \overline{M}^0$, while off-diagonal elements are associated with flavor-changing transitions $M^0 \leftrightarrow \overline{M}^0$.

The eigenvectors of \mathbf{H} have well-defined masses and decay widths. To specify the components of the strong interaction eigenstates, M^0 and \overline{M}^0 , in the light (M_L) and heavy (M_H) mass eigenstates, we introduce three complex parameters: p , q , and, for the case that both CP and CPT are violated in mixing, z :

$$\begin{aligned} |M_L\rangle &\propto p\sqrt{1-z}|M^0\rangle + q\sqrt{1+z}|\overline{M}^0\rangle \\ |M_H\rangle &\propto p\sqrt{1+z}|M^0\rangle - q\sqrt{1-z}|\overline{M}^0\rangle, \end{aligned} \quad (12.22)$$

with the normalization $|q|^2 + |p|^2 = 1$ when $z = 0$. (Another possible choice, which is in standard usage for K mesons, defines the mass eigenstates according to their lifetimes: K_S for the short-lived and K_L for the long-lived state. The K_L is experimentally found to be the heavier state.)

The real and imaginary parts of the eigenvalues $\omega_{L,H}$ corresponding to $|M_{L,H}\rangle$ represent their masses and decay widths, respectively. The mass and width splittings are

$$\begin{aligned} \Delta m &\equiv m_H - m_L = \mathcal{R}e(\omega_H - \omega_L), \\ \Delta\Gamma &\equiv \Gamma_H - \Gamma_L = -2\mathcal{I}m(\omega_H - \omega_L). \end{aligned} \quad (12.23)$$

Note that here Δm is positive by definition, while the sign of $\Delta\Gamma$ is to be experimentally determined. The sign of $\Delta\Gamma$ has not yet been established for the B mesons, while $\Delta\Gamma < 0$ is established for K and B_s mesons and $\Delta\Gamma > 0$ is established for D mesons. The Standard Model predicts $\Delta\Gamma < 0$ also for B mesons (for this reason, $\Delta\Gamma = \Gamma_L - \Gamma_H$, which is still a signed quantity, is often used in the B and B_s literature and is the convention used in the PDG experimental summaries).

Solving the eigenvalue problem for \mathbf{H} yields

$$\left(\frac{q}{p}\right)^2 = \frac{\mathbf{M}_{12}^* - (i/2)\mathbf{\Gamma}_{12}^*}{\mathbf{M}_{12} - (i/2)\mathbf{\Gamma}_{12}} \quad (12.24)$$

and

$$z \equiv \frac{\delta m - (i/2)\delta\Gamma}{\Delta m - (i/2)\Delta\Gamma}, \quad (12.25)$$

where

$$\delta m \equiv \mathbf{M}_{11} - \mathbf{M}_{22}, \quad \delta\Gamma \equiv \mathbf{\Gamma}_{11} - \mathbf{\Gamma}_{22} \quad (12.26)$$

are the differences in effective mass and decay-rate expectation values for the strong interaction states M^0 and \overline{M}^0 .

If either CP or CPT is a symmetry of \mathbf{H} (independently of whether T is conserved or violated), then the values of δm and $\delta\Gamma$ are both zero, and hence $z = 0$. We also find that

$$\omega_H - \omega_L = 2\sqrt{\left(\mathbf{M}_{12} - \frac{i}{2}\mathbf{\Gamma}_{12}\right)\left(\mathbf{M}_{12}^* - \frac{i}{2}\mathbf{\Gamma}_{12}^*\right)}. \quad (12.27)$$

If either CP or T is a symmetry of \mathbf{H} (independently of whether CPT is conserved or violated), then $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is real, leading to

$$\left(\frac{q}{p}\right)^2 = e^{2i\xi_M} \Rightarrow \left|\frac{q}{p}\right| = 1, \quad (12.28)$$

where ξ_M is the arbitrary unphysical phase introduced in Eq. (12.17). If, and only if, CP is a symmetry of \mathbf{H} (independently of CPT and T), then both of the above conditions hold, with the result that the mass eigenstates are orthogonal

$$\langle M_H | M_L \rangle = |p|^2 - |q|^2 = 0. \quad (12.29)$$

12.1.3. *CP-violating observables* : All *CP*-violating observables in M and \bar{M} decays to final states f and \bar{f} can be expressed in terms of phase-convention-independent combinations of A_f , \bar{A}_f , $A_{\bar{f}}$, and $\bar{A}_{\bar{f}}$, together with, for neutral-meson decays only, q/p . *CP* violation in charged-meson decays depends only on the combination $|\bar{A}_{\bar{f}}/A_f|$, while *CP* violation in neutral-meson decays is complicated by $M^0 \leftrightarrow \bar{M}^0$ oscillations, and depends, additionally, on $|q/p|$ and on $\lambda_f \equiv (q/p)(\bar{A}_f/A_f)$.

The decay rates of the two neutral K mass eigenstates, K_S and K_L , are different enough ($\Gamma_S/\Gamma_L \sim 500$) that one can, in most cases, actually study their decays independently. For neutral D , B , and B_s mesons, however, values of $\Delta\Gamma/\Gamma$ (where $\Gamma \equiv (\Gamma_H + \Gamma_L)/2$) are relatively small, and so both mass eigenstates must be considered in their evolution. We denote the state of an initially pure $|M^0\rangle$ or $|\bar{M}^0\rangle$ after an elapsed proper time t as $|M_{\text{phys}}^0(t)\rangle$ or $|\bar{M}_{\text{phys}}^0(t)\rangle$, respectively. Using the effective Hamiltonian approximation, but not assuming *CPT* is a good symmetry, we obtain

$$\begin{aligned} |M_{\text{phys}}^0(t)\rangle &= (g_+(t) + z g_-(t)) |M^0\rangle - \sqrt{1-z^2} \frac{q}{p} g_-(t) |\bar{M}^0\rangle, \\ |\bar{M}_{\text{phys}}^0(t)\rangle &= (g_+(t) - z g_-(t)) |\bar{M}^0\rangle - \sqrt{1-z^2} \frac{p}{q} g_-(t) |M^0\rangle, \end{aligned} \quad (12.30)$$

where

$$g_{\pm}(t) \equiv \frac{1}{2} \left(e^{-im_H t - \frac{1}{2}\Gamma_H t} \pm e^{-im_L t - \frac{1}{2}\Gamma_L t} \right) \quad (12.31)$$

and $z = 0$ if either *CPT* or *CP* is conserved.

Defining $x \equiv \Delta m/\Gamma$ and $y \equiv \Delta\Gamma/(2\Gamma)$, and assuming $z = 0$, one obtains the following time-dependent decay rates:

$$\begin{aligned} \frac{d\Gamma[M_{\text{phys}}^0(t) \rightarrow f]/dt}{e^{-\Gamma t} \mathcal{N}_f} &= \\ & \left(|A_f|^2 + |(q/p)\bar{A}_f|^2 \right) \cosh(y\Gamma t) + \left(|A_f|^2 - |(q/p)\bar{A}_f|^2 \right) \cos(x\Gamma t) \\ & + 2 \operatorname{Re}((q/p)A_f^* \bar{A}_f) \sinh(y\Gamma t) - 2 \operatorname{Im}((q/p)A_f^* \bar{A}_f) \sin(x\Gamma t), \end{aligned} \quad (12.32)$$

$$\begin{aligned} \frac{d\Gamma[\bar{M}_{\text{phys}}^0(t) \rightarrow f]/dt}{e^{-\Gamma t} \mathcal{N}_f} &= \\ & \left(|(p/q)A_f|^2 + |\bar{A}_f|^2 \right) \cosh(y\Gamma t) - \left(|(p/q)A_f|^2 - |\bar{A}_f|^2 \right) \cos(x\Gamma t) \\ & + 2 \operatorname{Re}((p/q)A_f \bar{A}_f^*) \sinh(y\Gamma t) - 2 \operatorname{Im}((p/q)A_f \bar{A}_f^*) \sin(x\Gamma t), \end{aligned} \quad (12.33)$$

where \mathcal{N}_f is a common, time-independent, normalization factor. Decay rates to the *CP*-conjugate final state \bar{f} are obtained analogously, with $\mathcal{N}_f = \mathcal{N}_{\bar{f}}$ and the substitutions $A_f \rightarrow A_{\bar{f}}$ and $\bar{A}_f \rightarrow \bar{A}_{\bar{f}}$ in Eqs. (12.32, 12.33). Terms proportional to $|A_f|^2$ or $|\bar{A}_f|^2$ are associated with decays that occur without any net $M \leftrightarrow \bar{M}$ oscillation, while terms proportional to $|(q/p)\bar{A}_f|^2$ or $|(p/q)A_f|^2$ are associated with decays following a net oscillation. The $\sinh(y\Gamma t)$ and $\sin(x\Gamma t)$ terms of Eqs. (12.32, 12.33) are associated with the interference between these two cases. Note that, in multi-body decays, amplitudes are functions of phase-space variables. Interference may be present in some regions but not others, and is strongly influenced by resonant substructure.

When neutral pseudoscalar mesons are produced coherently in pairs from the decay of a vector resonance, $V \rightarrow M^0 \bar{M}^0$ (for example, $\Upsilon(4S) \rightarrow B^0 \bar{B}^0$ or $\phi \rightarrow K^0 \bar{K}^0$), the time-dependence of their subsequent decays to final states f_1 and f_2 has a similar form to Eqs. (12.32, 12.33):

$$\begin{aligned} \frac{d\Gamma[V_{\text{phys}}(t_1, t_2) \rightarrow f_1 f_2]/d(\Delta t)}{e^{-\Gamma|\Delta t|} \mathcal{N}_{f_1 f_2}} &= \\ & \left(|a_+|^2 + |a_-|^2 \right) \cosh(y\Gamma\Delta t) + \left(|a_+|^2 - |a_-|^2 \right) \cos(x\Gamma\Delta t) \\ & - 2 \operatorname{Re}(a_+^* a_-) \sinh(y\Gamma\Delta t) + 2 \operatorname{Im}(a_+^* a_-) \sin(x\Gamma\Delta t), \end{aligned} \quad (12.34)$$

where $\Delta t \equiv t_2 - t_1$ is the difference in the production times, t_1 and t_2 , of f_1 and f_2 , respectively, and the dependence on the average decay time and on decay angles has been integrated out. The coefficients in Eq. (12.34) are determined by the amplitudes for no net oscillation from $t_1 \rightarrow t_2$, $\bar{A}_{f_1} A_{f_2}$, and $A_{f_1} \bar{A}_{f_2}$, and for a net oscillation, $(q/p)\bar{A}_{f_1} \bar{A}_{f_2}$ and $(p/q)A_{f_1} A_{f_2}$, via

$$\begin{aligned} a_+ &\equiv \bar{A}_{f_1} A_{f_2} - A_{f_1} \bar{A}_{f_2}, \\ a_- &\equiv -\sqrt{1-z^2} \left(\frac{q}{p} \bar{A}_{f_1} \bar{A}_{f_2} - \frac{p}{q} A_{f_1} A_{f_2} \right) + z (\bar{A}_{f_1} A_{f_2} + A_{f_1} \bar{A}_{f_2}). \end{aligned} \quad (12.35)$$

Assuming *CPT* conservation, $z = 0$, and identifying $\Delta t \rightarrow t$ and $f_2 \rightarrow f$, we find that Eqs. (12.34) and (12.35) reduce to Eq. (12.32) with $A_{f_1} = 0$, $\bar{A}_{f_1} = 1$, or to Eq. (12.33) with $\bar{A}_{f_1} = 0$, $A_{f_1} = 1$. Indeed, such a situation plays an important role in experiments. Final states f_1 with $A_{f_1} = 0$ or $\bar{A}_{f_1} = 0$ are called tagging states, because they identify the decaying pseudoscalar meson as, respectively, \bar{M}^0 or M^0 . Before one of M^0 or \bar{M}^0 decays, they evolve in phase, so that there is always one M^0 and one \bar{M}^0 present. A tagging decay of one meson sets the clock for the time evolution of the other: it starts at t_1 as purely M^0 or \bar{M}^0 , with time evolution that depends only on $t_2 - t_1$.

When f_1 is a state that both M^0 and \bar{M}^0 can decay into, then Eq. (12.34) contains interference terms proportional to $A_{f_1} \bar{A}_{f_1} \neq 0$ that are not present in Eqs. (12.32, 12.33). Even when f_1 is dominantly produced by M^0 decays rather than \bar{M}^0 decays, or vice versa, $A_{f_1} \bar{A}_{f_1}$ can be non-zero owing to doubly-CKM-suppressed decays (with amplitudes suppressed by at least two powers of λ relative to the dominant amplitude, in the language of Section 12.3), and these terms should be considered for precision studies of *CP* violation in coherent $V \rightarrow M^0 \bar{M}^0$ decays [27].

12.1.4. *Classification of CP-violating effects* : We distinguish three types of *CP*-violating effects in meson decays:

I. *CP* violation in decay is defined by

$$|\bar{A}_{\bar{f}}/A_f| \neq 1. \quad (12.36)$$

In charged meson decays, where mixing effects are absent, this is the only possible source of *CP* asymmetries:

$$A_{f\pm} \equiv \frac{\Gamma(M^- \rightarrow f^-) - \Gamma(M^+ \rightarrow f^+)}{\Gamma(M^- \rightarrow f^-) + \Gamma(M^+ \rightarrow f^+)} = \frac{|\bar{A}_{f-}/A_{f+}|^2 - 1}{|\bar{A}_{f-}/A_{f+}|^2 + 1}. \quad (12.37)$$

II. *CP* (and *T*) violation in mixing is defined by

$$|q/p| \neq 1. \quad (12.38)$$

In charged-current semileptonic neutral meson decays $M, \bar{M} \rightarrow \ell^\pm X$ (taking $|A_{\ell^+ X}| = |\bar{A}_{\ell^- X}|$ and $A_{\ell^- X} = \bar{A}_{\ell^+ X} = 0$, as is the case in the Standard Model, to lowest order in G_F , and in most of its reasonable extensions), this is the only source of *CP* violation, and can be measured via the asymmetry of “wrong-sign” decays induced by oscillations:

$$\begin{aligned} A_{\text{SL}}(t) &\equiv \frac{d\Gamma/dt[\bar{M}_{\text{phys}}^0(t) \rightarrow \ell^+ X] - d\Gamma/dt[M_{\text{phys}}^0(t) \rightarrow \ell^- X]}{d\Gamma/dt[\bar{M}_{\text{phys}}^0(t) \rightarrow \ell^+ X] + d\Gamma/dt[M_{\text{phys}}^0(t) \rightarrow \ell^- X]} \\ &= \frac{1 - |q/p|^4}{1 + |q/p|^4}. \end{aligned} \quad (12.39)$$

Note that this asymmetry of time-dependent decay rates is actually time-independent.

III. *CP* violation in interference between a decay without mixing, $M^0 \rightarrow f$, and a decay with mixing, $M^0 \rightarrow \bar{M}^0 \rightarrow f$ (such an effect occurs only in decays to final states that are common to M^0 and \bar{M}^0 , including all *CP* eigenstates), is defined by

$$\operatorname{Im}(\lambda_f) \neq 0, \quad (12.40)$$

with

$$\lambda_f \equiv \frac{q \bar{A}_f}{p A_f}. \quad (12.41)$$

This form of CP violation can be observed, for example, using the asymmetry of neutral meson decays into final CP eigenstates f_{CP}

$$\mathcal{A}_{f_{CP}}(t) \equiv \frac{d\Gamma/dt[\bar{M}_{\text{phys}}^0(t) \rightarrow f_{CP}] - d\Gamma/dt[M_{\text{phys}}^0(t) \rightarrow f_{CP}]}{d\Gamma/dt[\bar{M}_{\text{phys}}^0(t) \rightarrow f_{CP}] + d\Gamma/dt[M_{\text{phys}}^0(t) \rightarrow f_{CP}]}. \quad (12.42)$$

If $\Delta\Gamma = 0$ and $|q/p| = 1$, as expected to a good approximation for B_d mesons, but not for K and B_s mesons, then $\mathcal{A}_{f_{CP}}$ has a particularly simple form (see Eq. (12.86), below). If, in addition, the decay amplitudes fulfill $|\bar{A}_{f_{CP}}| = |A_{f_{CP}}|$, the interference between decays with and without mixing is the only source of the asymmetry and $\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_{f_{CP}}) \sin(x\Gamma t)$.

Examples of these three types of CP violation will be given in Sections 12.4, 12.5, and 12.6.

12.2. Theoretical Interpretation: General Considerations

Consider the $M \rightarrow f$ decay amplitude A_f , and the CP conjugate process, $\bar{M} \rightarrow \bar{f}$, with decay amplitude $\bar{A}_{\bar{f}}$. There are two types of phases that may appear in these decay amplitudes. Complex parameters in any Lagrangian term that contributes to the amplitude will appear in complex conjugate form in the CP -conjugate amplitude. Thus, their phases appear in A_f and $\bar{A}_{\bar{f}}$ with opposite signs. In the Standard Model, these phases occur only in the couplings of the W^\pm bosons, and hence, are often called ‘‘weak phases.’’ The weak phase of any single term is convention-dependent. However, the difference between the weak phases in two different terms in A_f is convention-independent. A second type of phase can appear in scattering or decay amplitudes, even when the Lagrangian is real. Their origin is the possible contribution from intermediate on-shell states in the decay process. Since these phases are generated by CP -invariant interactions, they are the same in A_f and $\bar{A}_{\bar{f}}$. Usually the dominant rescattering is due to strong interactions; hence the designation ‘‘strong phases’’ for the phase shifts so induced. Again, only the relative strong phases between different terms in the amplitude are physically meaningful.

The ‘weak’ and ‘strong’ phases discussed here appear in addition to the ‘spurious’ CP -transformation phases of Eq. (12.18). Those spurious phases are due to an arbitrary choice of phase convention, and do not originate from any dynamics or induce any CP violation. For simplicity, we set them to zero from here on.

It is useful to write each contribution a_i to A_f in three parts: its magnitude $|a_i|$, its weak phase ϕ_i , and its strong phase δ_i . If, for example, there are two such contributions, $A_f = a_1 + a_2$, we have

$$\begin{aligned} A_f &= |a_1|e^{i(\delta_1+\phi_1)} + |a_2|e^{i(\delta_2+\phi_2)}, \\ \bar{A}_{\bar{f}} &= |a_1|e^{i(\delta_1-\phi_1)} + |a_2|e^{i(\delta_2-\phi_2)}. \end{aligned} \quad (12.43)$$

Similarly, for neutral meson decays, it is useful to write

$$\mathbf{M}_{12} = |\mathbf{M}_{12}|e^{i\phi_M}, \quad \mathbf{\Gamma}_{12} = |\mathbf{\Gamma}_{12}|e^{i\phi_\Gamma}. \quad (12.44)$$

Each of the phases appearing in Eqs. (12.43, 12.44) is convention-dependent, but combinations such as $\delta_1 - \delta_2$, $\phi_1 - \phi_2$, $\phi_M - \phi_\Gamma$, and $\phi_M + \phi_1 - \bar{\phi}_1$ (where $\bar{\phi}_1$ is a weak phase contributing to $\bar{A}_{\bar{f}}$) are physical.

It is now straightforward to evaluate the various asymmetries in terms of the theoretical parameters introduced here. We will do so with approximations that are often relevant to the most interesting measured asymmetries.

1. The CP asymmetry in charged meson decays [Eq. (12.37)] is given by

$$\mathcal{A}_{f^\pm} = -\frac{2|a_1 a_2| \sin(\delta_2 - \delta_1) \sin(\phi_2 - \phi_1)}{|a_1|^2 + |a_2|^2 + 2|a_1 a_2| \cos(\delta_2 - \delta_1) \cos(\phi_2 - \phi_1)}. \quad (12.45)$$

The quantity of most interest to theory is the weak phase difference $\phi_2 - \phi_1$. Its extraction from the asymmetry requires, however, that the amplitude ratio $|a_2/a_1|$ and the strong phase difference $\delta_2 - \delta_1$ are known. Both quantities depend on non-perturbative hadronic parameters that are difficult to calculate.

2. In the approximation that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| \ll 1$ (valid for B and B_s mesons), the CP asymmetry in semileptonic neutral-meson decays [Eq. (12.39)] is given by

$$\mathcal{A}_{\text{SL}} = -\left| \frac{\mathbf{\Gamma}_{12}}{\mathbf{M}_{12}} \right| \sin(\phi_M - \phi_\Gamma). \quad (12.46)$$

The quantity of most interest to theory is the weak phase $\phi_M - \phi_\Gamma$. Its extraction from the asymmetry requires, however, that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}|$ is known. This quantity depends on long-distance physics that is difficult to calculate.

3. In the approximations that only a single weak phase contributes to decay, $A_f = |a_f|e^{i(\delta_f+\phi_f)}$, and that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| = 0$, we obtain $|\lambda_f| = 1$, and the CP asymmetries in decays to a final CP eigenstate f [Eq. (12.42)] with eigenvalue $\eta_f = \pm 1$ are given by

$$\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_f) \sin(\Delta mt) \quad \text{with} \quad \mathcal{I}m(\lambda_f) = \eta_f \sin(\phi_M + 2\phi_f). \quad (12.47)$$

Note that the phase so measured is purely a weak phase, and no hadronic parameters are involved in the extraction of its value from $\mathcal{I}m(\lambda_f)$.

The discussion above allows us to introduce another classification of CP -violating effects:

1. *Indirect CP violation* is consistent with taking $\phi_M \neq 0$ and setting all other CP violating phases to zero. CP violation in mixing (type II) belongs to this class.
2. *Direct CP violation* cannot be accounted for by just $\phi_M \neq 0$. CP violation in decay (type I) belongs to this class.

As concerns type III CP violation, observing $\eta_{f_1} \mathcal{I}m(\lambda_{f_1}) \neq \eta_{f_2} \mathcal{I}m(\lambda_{f_2})$ (for the same decaying meson and two different final CP eigenstates f_1 and f_2) would establish direct CP violation. The significance of this classification is related to theory. In superweak models [28], CP violation appears only in diagrams that contribute to \mathbf{M}_{12} , hence they predict that there is no direct CP violation. In most models and, in particular, in the Standard Model, CP violation is both direct and indirect. The experimental observation of $\epsilon' \neq 0$ (see Section 12.4) excluded the superweak scenario.

12.3. Theoretical Interpretation: The KM Mechanism

Of all the Standard Model quark parameters, only the Kobayashi-Maskawa (KM) phase is CP -violating. Having a single source of CP violation, the Standard Model is very predictive for CP asymmetries: some vanish, and those that do not are correlated.

To be precise, CP could be violated also by strong interactions. The experimental upper bound on the electric-dipole moment of the neutron implies, however, that θ_{QCD} , the non-perturbative parameter that determines the strength of this type of CP violation, is tiny, if not zero. (The smallness of θ_{QCD} constitutes a theoretical puzzle, known as ‘the strong CP problem.’) In particular, it is irrelevant to our discussion of meson decays.

The charged current interactions (that is, the W^\pm interactions) for quarks are given by

$$-\mathcal{L}_{W^\pm} = \frac{g}{\sqrt{2}} \bar{u}_{Li} \gamma^\mu (V_{\text{CKM}})_{ij} d_{Lj} W_\mu^\pm + \text{h.c.} \quad (12.48)$$

Here $i, j = 1, 2, 3$ are generation numbers. The Cabibbo-Kobayashi-Maskawa (CKM) mixing matrix for quarks is a 3×3 unitary matrix [29]. Ordering the quarks by their masses, *i.e.*, $(u_1, u_2, u_3) \rightarrow (u, c, t)$ and $(d_1, d_2, d_3) \rightarrow (d, s, b)$, the elements of V_{CKM} are written as follows:

$$V_{\text{CKM}} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix}. \quad (12.49)$$

While a general 3×3 unitary matrix depends on three real angles and six phases, the freedom to redefine the phases of the quark mass eigenstates can be used to remove five of the phases, leaving a single physical phase, the Kobayashi-Maskawa phase, that is responsible for all *CP* violation in meson decays in the Standard Model.

The fact that one can parametrize V_{CKM} by three real and only one imaginary physical parameters can be made manifest by choosing an explicit parametrization. The Wolfenstein parametrization [30,31] is particularly useful:

$$V_{\text{CKM}} = \begin{pmatrix} 1 - \frac{1}{2}\lambda^2 - \frac{1}{8}\lambda^4 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda + \frac{1}{2}A^2\lambda^5[1 - 2(\rho + i\eta)] & 1 - \frac{1}{2}\lambda^2 - \frac{1}{8}\lambda^4(1 + 4A^2) & A\lambda^2 \\ A\lambda^3[1 - (1 - \frac{1}{2}\lambda^2)(\rho + i\eta)] & -A\lambda^2 + \frac{1}{2}A\lambda^4[1 - 2(\rho + i\eta)] & 1 - \frac{1}{2}A^2\lambda^4 \end{pmatrix}. \quad (12.50)$$

Here $\lambda \approx 0.23$ (not to be confused with λ_f), the sine of the Cabibbo angle, plays the role of an expansion parameter, and η represents the *CP*-violating phase. Terms of $\mathcal{O}(\lambda^6)$ were neglected.

The unitarity of the CKM matrix, $(VV^\dagger)_{ij} = (V^\dagger V)_{ij} = \delta_{ij}$, leads to twelve distinct complex relations among the matrix elements. The six relations with $i \neq j$ can be represented geometrically as triangles in the complex plane. Two of these,

$$\begin{aligned} V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* &= 0 \\ V_{td}V_{ud}^* + V_{ts}V_{us}^* + V_{tb}V_{ub}^* &= 0, \end{aligned}$$

have terms of equal order, $\mathcal{O}(A\lambda^3)$, and so have corresponding triangles whose interior angles are all $\mathcal{O}(1)$ physical quantities that can be independently measured. The angles of the first triangle (see Fig. 12.1) are given by

$$\begin{aligned} \alpha \equiv \varphi_2 &\equiv \arg\left(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right) \simeq \arg\left(-\frac{1 - \rho - i\eta}{\rho + i\eta}\right), \\ \beta \equiv \varphi_1 &\equiv \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right) \simeq \arg\left(\frac{1}{1 - \rho - i\eta}\right), \\ \gamma \equiv \varphi_3 &\equiv \arg\left(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right) \simeq \arg(\rho + i\eta). \end{aligned} \quad (12.51)$$

The angles of the second triangle are equal to (α, β, γ) up to corrections of $\mathcal{O}(\lambda^2)$. The notations (α, β, γ) and $(\varphi_1, \varphi_2, \varphi_3)$ are both in common usage but, for convenience, we only use the first convention in the following.

Figure 12.1: Graphical representation of the unitarity constraint $V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0$ as a triangle in the complex plane.

Another relation that can be represented as a triangle,

$$V_{us}V_{ub}^* + V_{cs}V_{cb}^* + V_{ts}V_{tb}^* = 0, \quad (12.52)$$

and, in particular, its small angle, of $\mathcal{O}(\lambda^2)$,

$$\beta_s \equiv \arg\left(-\frac{V_{ts}V_{tb}^*}{V_{cs}V_{cb}^*}\right), \quad (12.53)$$

is convenient for analyzing *CP* violation in the B_s sector.

All unitarity triangles have the same area, commonly denoted by $J/2$ [32]. If *CP* is violated, J is different from zero and can be taken as the single *CP*-violating parameter. In the Wolfenstein parametrization of Eq. (12.50), $J \simeq \lambda^6 A^2 \eta$.

12.4. *K* Decays

CP violation was discovered in $K \rightarrow \pi\pi$ decays in 1964 [1]. The same mode provided the first evidence for direct *CP* violation [4–6].

The decay amplitudes actually measured in neutral K decays refer to the mass eigenstates K_L and K_S , rather than to the K and \bar{K} states referred to in Eq. (12.15). The final $\pi^+\pi^-$ and $\pi^0\pi^0$ states are *CP*-even. In the *CP* limit, $K_S(K_L)$ would be *CP*-even (odd), and therefore would (would not) decay to two pions. We define *CP*-violating amplitude ratios for two-pion final states,

$$\eta_{00} \equiv \frac{\langle \pi^0\pi^0 | \mathcal{H} | K_L \rangle}{\langle \pi^0\pi^0 | \mathcal{H} | K_S \rangle}, \quad \eta_{+-} \equiv \frac{\langle \pi^+\pi^- | \mathcal{H} | K_L \rangle}{\langle \pi^+\pi^- | \mathcal{H} | K_S \rangle}. \quad (12.54)$$

Another important observable is the asymmetry of time-integrated semileptonic decay rates:

$$\delta_L \equiv \frac{\Gamma(K_L \rightarrow \ell^+\nu_\ell\pi^-) - \Gamma(K_L \rightarrow \ell^-\bar{\nu}_\ell\pi^+)}{\Gamma(K_L \rightarrow \ell^+\nu_\ell\pi^-) + \Gamma(K_L \rightarrow \ell^-\bar{\nu}_\ell\pi^+)}. \quad (12.55)$$

CP violation has been observed as an appearance of K_L decays to two-pion final states [23],

$$|\eta_{00}| = (2.221 \pm 0.011) \times 10^{-3} \quad |\eta_{+-}| = (2.232 \pm 0.011) \times 10^{-3} \quad (12.56)$$

$$|\eta_{00}/\eta_{+-}| = 0.9951 \pm 0.0008, \quad (12.57)$$

where the phase ϕ_{ij} of the amplitude ratio η_{ij} has been determined both assuming *CPT* invariance:

$$\phi_{00} = (43.52 \pm 0.06)^\circ, \quad \phi_{+-} = (43.51 \pm 0.05)^\circ, \quad (12.58)$$

and without assuming *CPT* invariance:

$$\phi_{00} = (43.7 \pm 0.8)^\circ, \quad \phi_{+-} = (43.4 \pm 0.7)^\circ. \quad (12.59)$$

CP violation has also been observed in semileptonic K_L decays [23]

$$\delta_L = (3.32 \pm 0.06) \times 10^{-3}, \quad (12.60)$$

where δ_L is a weighted average of muon and electron measurements, as well as in K_L decays to $\pi^+\pi^-\gamma$ and $\pi^+\pi^-e^+e^-$ [23]. *CP* violation in $K \rightarrow 3\pi$ decays has not yet been observed [23,33].

Historically, *CP* violation in neutral K decays has been described in terms of parameters ϵ and ϵ' . The observables η_{00} , η_{+-} , and δ_L are related to these parameters, and to those of Section 12.1, by

$$\begin{aligned} \eta_{00} &= \frac{1 - \lambda_{\pi^0\pi^0}}{1 + \lambda_{\pi^0\pi^0}} = \epsilon - 2\epsilon', \\ \eta_{+-} &= \frac{1 - \lambda_{\pi^+\pi^-}}{1 + \lambda_{\pi^+\pi^-}} = \epsilon + \epsilon', \\ \delta_L &= \frac{1 - |q/p|^2}{1 + |q/p|^2} = \frac{2\mathcal{R}e(\epsilon)}{1 + |\epsilon|^2}, \end{aligned} \quad (12.61)$$

where, in the last line, we have assumed that $|A_{\ell^+\nu_\ell\pi^-}| = |\bar{A}_{\ell^-\bar{\nu}_\ell\pi^+}|$ and $|A_{\ell^-\bar{\nu}_\ell\pi^+}| = |\bar{A}_{\ell^+\nu_\ell\pi^-}| = 0$. (The convention-dependent parameter $\bar{\epsilon} \equiv (1 - q/p)/(1 + q/p)$, sometimes used in the literature, is, in general, different from ϵ but yields a similar expression, $\delta_L = 2\mathcal{R}e(\bar{\epsilon})/(1 + |\bar{\epsilon}|^2)$.) A fit to the $K \rightarrow \pi\pi$ data yields [23]

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3},$$

$$\mathcal{R}e(\epsilon'/\epsilon) = (1.65 \pm 0.26) \times 10^{-3}. \quad (12.62)$$

In discussing two-pion final states, it is useful to express the amplitudes $A_{\pi^0\pi^0}$ and $A_{\pi^+\pi^-}$ in terms of their isospin components via

$$\begin{aligned} A_{\pi^0\pi^0} &= \sqrt{\frac{1}{3}} |A_0| e^{i(\delta_0 + \phi_0)} - \sqrt{\frac{2}{3}} |A_2| e^{i(\delta_2 + \phi_2)}, \\ A_{\pi^+\pi^-} &= \sqrt{\frac{2}{3}} |A_0| e^{i(\delta_0 + \phi_0)} + \sqrt{\frac{1}{3}} |A_2| e^{i(\delta_2 + \phi_2)}, \end{aligned} \quad (12.63)$$

where we parameterize the amplitude $A_I(\bar{A}_I)$ for $K^0(\bar{K}^0)$ decay into two pions with total isospin $I = 0$ or 2 as

$$\begin{aligned} A_I &\equiv \langle (\pi\pi)_I | \mathcal{H} | K^0 \rangle = |A_I| e^{i(\delta_I + \phi_I)}, \\ \bar{A}_I &\equiv \langle (\pi\pi)_I | \mathcal{H} | \bar{K}^0 \rangle = |A_I| e^{i(\delta_I - \phi_I)}. \end{aligned} \quad (12.64)$$

The smallness of $|\eta_{00}|$ and $|\eta_{+-}|$ allows us to approximate

$$\epsilon \simeq \frac{1}{2}(1 - \lambda_{(\pi\pi)_{I=0}}), \quad \epsilon' \simeq \frac{1}{6}(\lambda_{\pi^0\pi^0} - \lambda_{\pi^+\pi^-}). \quad (12.65)$$

The parameter ϵ represents indirect CP violation, while ϵ' parameterizes direct CP violation: $\mathcal{R}e(\epsilon')$ measures CP violation in decay (type I), $\mathcal{R}e(\epsilon)$ measures CP violation in mixing (type II), and $\mathcal{I}m(\epsilon)$ and $\mathcal{I}m(\epsilon')$ measure the interference between decays with and without mixing (type III).

The following expressions for ϵ and ϵ' are useful for theoretical evaluations:

$$\epsilon \simeq \frac{e^{i\pi/4} \mathcal{I}m(\mathbf{M}_{12})}{\sqrt{2} \Delta m}, \quad \epsilon' \simeq \frac{i}{\sqrt{2}} \left| \frac{A_2}{A_0} \right| e^{i(\delta_2 - \delta_0)} \sin(\phi_2 - \phi_0). \quad (12.66)$$

The expression for ϵ is only valid in a phase convention where $\phi_2 = 0$, corresponding to a real $V_{ud}V_{us}^*$, and in the approximation that also $\phi_0 = 0$. The phase of ϵ , $\arg(\epsilon) \approx \arctan(-2\Delta m/\Delta\Gamma)$, is independent of the electroweak model and is experimentally determined to be about $\pi/4$. The calculation of ϵ benefits from the fact that $\mathcal{I}m(\mathbf{M}_{12})$ is dominated by short distance physics. Consequently, the main source of uncertainty in theoretical interpretations of ϵ are the values of matrix elements, such as $\langle K^0 | (\bar{s}d)_{V-A} (\bar{s}d)_{V-A} | \bar{K}^0 \rangle$. The expression for ϵ' is valid to first order in $|A_2/A_0| \sim 1/20$. The phase of ϵ' is experimentally determined, $\pi/2 + \delta_2 - \delta_0 \approx \pi/4$, and is independent of the electroweak model. Note that, accidentally, ϵ'/ϵ is real to a good approximation.

A future measurement of much interest is that of CP violation in the rare $K \rightarrow \pi\nu\bar{\nu}$ decays. The signal for CP violation is simply observing the $K_L \rightarrow \pi^0\nu\bar{\nu}$ decay. The effect here is that of interference between decays with and without mixing (type III) [34]:

$$\frac{\Gamma(K_L \rightarrow \pi^0\nu\bar{\nu})}{\Gamma(K^+ \rightarrow \pi^+\nu\bar{\nu})} = \frac{1}{2} \left[1 + |\lambda_{\pi\nu\bar{\nu}}|^2 - 2\mathcal{R}e(\lambda_{\pi\nu\bar{\nu}}) \right] \simeq 1 - \mathcal{R}e(\lambda_{\pi\nu\bar{\nu}}), \quad (12.67)$$

where in the last equation we neglect CP violation in decay and in mixing (expected, model-independently, to be of order 10^{-5} and 10^{-3} , respectively). Such a measurement would be experimentally very challenging and theoretically very rewarding [35]. Similar to the CP asymmetry in $B \rightarrow J/\psi K_S$, the CP violation in $K \rightarrow \pi\nu\bar{\nu}$ decay is predicted to be large (that is, the ratio in Eq. (12.67) is neither CKM- nor loop-suppressed) and can be very cleanly interpreted.

Within the Standard Model, the $K_L \rightarrow \pi^0\nu\bar{\nu}$ decay is dominated by an intermediate top quark contribution and, consequently, can be interpreted in terms of CKM parameters [36]. (For the charged mode, $K^+ \rightarrow \pi^+\nu\bar{\nu}$, the contribution from an intermediate charm quark is not negligible, and constitutes a source of hadronic uncertainty.) In particular, $\mathcal{B}(K_L \rightarrow \pi^0\nu\bar{\nu})$ provides a theoretically clean way to determine the Wolfenstein parameter η [37]:

$$\mathcal{B}(K_L \rightarrow \pi^0\nu\bar{\nu}) = \kappa_L [X(m_t^2/m_W^2)]^2 A^4 \eta^2, \quad (12.68)$$

where $\kappa_L \sim 2 \times 10^{-10}$ incorporates the value of the four-fermion matrix element which is deduced, using isospin relations, from $\mathcal{B}(K^+ \rightarrow \pi^0 e^+ \nu)$, and $X(m_t^2/m_W^2)$ is a known function of the top mass.

12.5. D Decays

Evidence for $D^0-\bar{D}^0$ mixing has been obtained in recent years [38–40]. The experimental constraints read [25,41] $x \equiv \Delta m/\Gamma = 0.0063 \pm 0.0019$ and $y \equiv \Delta\Gamma/(2\Gamma) = 0.0075 \pm 0.0012$. Long-distance contributions make it difficult to calculate the Standard Model prediction for the $D^0-\bar{D}^0$ mixing parameters. Therefore, the goal of the search for $D^0-\bar{D}^0$ mixing is not to constrain the CKM parameters, but rather to probe new physics. Here CP violation plays an important role. Within the Standard Model, the CP -violating effects are predicted to be small, since the mixing and the relevant decays are described, to an excellent approximation, by physics of the first two generations. The expectation is that the Standard Model size of CP violation in D decays is of $\mathcal{O}(10^{-3})$ or less, but theoretical work is ongoing to understand whether QCD effects can significantly enhance it. At present, the most sensitive searches involve the $D \rightarrow K^+K^-$, $D \rightarrow \pi^+\pi^-$ and $D \rightarrow K^\pm\pi^\mp$ modes.

The neutral D mesons decay via a singly-Cabibbo-suppressed transition to the CP eigenstates K^+K^- and $\pi^+\pi^-$. These decays are dominated by Standard-Model tree diagrams. Thus, we can write, for $f = K^+K^-$ or $\pi^+\pi^-$,

$$\begin{aligned} A_f &= A_f^T e^{+i\phi_f^T} \left[1 + r_f e^{i(\delta_f + \phi_f)} \right], \\ \bar{A}_f &= A_f^T e^{-i\phi_f^T} \left[1 + r_f e^{i(\delta_f - \phi_f)} \right], \end{aligned} \quad (12.69)$$

where $A_f^T e^{\pm i\phi_f^T}$ is the SM tree level contribution, ϕ_f^T and ϕ_f are weak, CP violating phases, δ_f is a strong phase, and r_f is the ratio between a subleading ($r_f \ll 1$) contribution with a weak phase different from ϕ_f^T and the SM tree level contribution. Neglecting r_f , λ_f is universal, and we can define a phase ϕ_D via

$$\lambda_f \equiv -|q/p| e^{i\phi_D}. \quad (12.70)$$

(In the limit of CP conservation, choosing $\phi_D = 0$ is equivalent to defining the mass eigenstates by their CP eigenvalue: $|D_\mp\rangle = p|D^0\rangle \pm q|\bar{D}^0\rangle$, with $D_-(D_+)$ being the CP -odd (CP -even) state; that is, the state that does not (does) decay into K^+K^- .)

We define the time integrated CP asymmetry for a final CP eigenstate f as follows:

$$a_f \equiv \frac{\int_0^\infty \Gamma(D_{\text{phys}}^0(t) \rightarrow f) dt - \int_0^\infty \Gamma(\bar{D}_{\text{phys}}^0(t) \rightarrow f) dt}{\int_0^\infty \Gamma(D_{\text{phys}}^0(t) \rightarrow f) dt + \int_0^\infty \Gamma(\bar{D}_{\text{phys}}^0(t) \rightarrow f) dt}. \quad (12.71)$$

(This expression corresponds to the D meson being tagged at production, hence the integration goes from 0 to $+\infty$; measurements are also possible with $\psi(3770) \rightarrow D\bar{D}$, in which case the integration goes from $-\infty$ to $+\infty$.) We take $x, y, r_f \ll 1$ and expand to leading order in these parameters. Then, we can separate the contribution to a_f to three parts [42],

$$a_f = a_f^d + a_f^m + a_f^i, \quad (12.72)$$

with the following underlying mechanisms:

1. a_f^d signals CP violation in decay (similar to Eq. (12.37)):

$$a_f^d = 2r_f \sin \phi_f \sin \delta_f. \quad (12.73)$$

2. a_f^m signals CP violation in mixing (similar to Eq. (12.46)). With our approximations, it is universal:

$$a_f^m = -\frac{y}{2} \left(\left| \frac{q}{p} \right| - \left| \frac{p}{q} \right| \right) \cos \phi_D. \quad (12.74)$$

3. a_f^i signals CP violation in the interference of mixing and decay (similar to Eq. (12.47)). With our approximations, it is universal:

$$a_f^i = \frac{x}{2} \left(\left| \frac{q}{p} \right| + \left| \frac{p}{q} \right| \right) \sin \phi_D. \quad (12.75)$$

One can isolate the effects of direct CP violation by taking the difference between the CP asymmetries in the K^+K^- and $\pi^+\pi^-$ modes:

$$\Delta a_{CP} \equiv a_{K^+K^-} - a_{\pi^+\pi^-} = a_{K^+K^-}^d - a_{\pi^+\pi^-}^d, \quad (12.76)$$

where we neglected a residual, experiment-dependent, contribution from indirect CP violation due to the fact that there is a time dependent acceptance function that can be different for the K^+K^- and $\pi^+\pi^-$ channels. Recently, evidence for such direct CP violation has been obtained [25]:

$$a_{K^+K^-}^d - a_{\pi^+\pi^-}^d = (-6.4 \pm 1.8) \times 10^{-3}. \quad (12.77)$$

One can also isolate the effects of indirect CP violation in the following way. Consider the time dependent decay rates in Eq. (12.32) and Eq. (12.33). The mixing processes modify the time dependence from a pure exponential. However, given the small values of x and y , the time dependences can be recast, to a good approximation, into purely exponential form, but with modified decay-rate parameters [43]:

$$\begin{aligned} \Gamma_{D^0 \rightarrow K^+K^-} &= \Gamma \times [1 + |q/p| (y \cos \phi_D - x \sin \phi_D)], \\ \Gamma_{\bar{D}^0 \rightarrow K^+K^-} &= \Gamma \times [1 + |p/q| (y \cos \phi_D + x \sin \phi_D)]. \end{aligned} \quad (12.78)$$

One can define CP -conserving and CP -violating combinations of these two observables (normalized to the true width Γ):

$$\begin{aligned} y_{CP} &\equiv \frac{\Gamma_{\bar{D}^0 \rightarrow K^+K^-} + \Gamma_{D^0 \rightarrow K^+K^-} - 1}{2\Gamma} \\ &= (y/2) (|q/p| + |p/q|) \cos \phi_D - (x/2) (|q/p| - |p/q|) \sin \phi_D, \\ A_\Gamma &\equiv \frac{\Gamma_{D^0 \rightarrow K^+K^-} - \Gamma_{\bar{D}^0 \rightarrow K^+K^-}}{2\Gamma} \\ &= -(a^m + a^i). \end{aligned} \quad (12.79)$$

In the limit of CP conservation (and, in particular, within the Standard Model), $y_{CP} = (\Gamma_+ - \Gamma_-)/2\Gamma$ (where $\Gamma_+(\Gamma_-)$ is the decay width of the CP -even (-odd) mass eigenstate) and $A_\Gamma = 0$. Indeed, present measurements imply that CP violation is small [25],

$$\begin{aligned} y_{CP} &= + (1.06 \pm 0.21) \times 10^{-2}, \\ A_\Gamma &= + (0.03 \pm 0.23) \times 10^{-2}. \end{aligned}$$

The $K^\pm\pi^\mp$ states are not CP eigenstates, but they are still common final states for D^0 and \bar{D}^0 decays. Since $D^0(\bar{D}^0) \rightarrow K^-\pi^+$ is a Cabibbo-favored (doubly-Cabibbo-suppressed) process, these processes are particularly sensitive to x and/or $y = \mathcal{O}(\lambda^2)$. Taking into account that $|\lambda_{K^-\pi^+}|, |\lambda_{K^+\pi^-}^{-1}| \ll 1$ and $x, y \ll 1$, assuming that there is no direct CP violation (these are Standard Model tree-level decays dominated by a single weak phase, and there is no contribution from penguin-like and chromomagnetic operators), and expanding the time-dependent rates for $xt, yt \lesssim \Gamma^{-1}$, one obtains

$$\begin{aligned} \Gamma[D_{\text{phys}}^0(t) \rightarrow K^+\pi^-] &= e^{-\Gamma t} |\bar{A}_{K^-\pi^+}|^2 \\ &\times \left[r_d^2 + r_d \left| \frac{q}{p} \right| (y' \cos \phi_D - x' \sin \phi_D) \Gamma t + \left| \frac{q}{p} \right|^2 \frac{y^2 + x^2}{4} (\Gamma t)^2 \right], \\ \Gamma[\bar{D}_{\text{phys}}^0(t) \rightarrow K^-\pi^+] &= e^{-\Gamma t} |\bar{A}_{K^-\pi^+}|^2 \\ &\times \left[r_d^2 + r_d \left| \frac{p}{q} \right| (y' \cos \phi_D + x' \sin \phi_D) \Gamma t + \left| \frac{p}{q} \right|^2 \frac{y^2 + x^2}{4} (\Gamma t)^2 \right], \end{aligned} \quad (12.80)$$

where

$$\begin{aligned} y' &\equiv y \cos \delta - x \sin \delta, \\ x' &\equiv x \cos \delta + y \sin \delta. \end{aligned} \quad (12.81)$$

The weak phase ϕ_D is the same as that of Eq. (12.70) (a consequence of neglecting direct CP violation), δ is a strong-phase difference for these processes, and $r_d = \mathcal{O}(\tan^2 \theta_c)$ is the amplitude ratio, $r_d = |\bar{A}_{K^-\pi^+}/A_{K^-\pi^+}| = |A_{K^+\pi^-}/\bar{A}_{K^+\pi^-}|$, that is, $\lambda_{K^-\pi^+} = r_d |q/p| e^{-i(\delta - \phi_D)}$ and $\lambda_{K^+\pi^-}^{-1} = r_d |p/q| e^{-i(\delta + \phi_D)}$. By fitting to the six coefficients of the various time-dependences, one can extract r_d , $|q/p|$, $(x^2 + y^2)$, $y' \cos \phi_D$, and $x' \sin \phi_D$. In particular, finding CP violation ($|q/p| \neq 1$ and/or $\sin \phi_D \neq 0$) at a level much higher than 10^{-3} would constitute evidence for new physics.

A fit to all data [25] yields no evidence for indirect CP violation:

$$\begin{aligned} 1 - |q/p| &= +0.12 \pm 0.17, \\ \phi_D &= -0.18 \pm 0.16. \end{aligned}$$

More details on various theoretical and experimental aspects of $D^0 - \bar{D}^0$ mixing can be found in Ref. [44].

12.6. B and B_s Decays

The upper bound on the CP asymmetry in semileptonic B decays [24] implies that CP violation in $B^0 - \bar{B}^0$ mixing is a small effect (we use $\mathcal{A}_{\text{SL}}/2 \approx 1 - |q/p|$, see Eq. (12.39)):

$$\mathcal{A}_{\text{SL}}^d = (-3.3 \pm 3.3) \times 10^{-3} \implies |q/p| = 1.0017 \pm 0.0017. \quad (12.82)$$

The Standard Model prediction is

$$\mathcal{A}_{\text{SL}}^d = \mathcal{O} \left[(m_c^2/m_t^2) \sin \beta \right] \lesssim 0.001. \quad (12.83)$$

In models where $\Gamma_{12}/\mathbf{M}_{12}$ is approximately real, such as the Standard Model, an upper bound on $\Delta\Gamma/\Delta m \approx \text{Re}(\Gamma_{12}/\mathbf{M}_{12})$ provides yet another upper bound on the deviation of $|q/p|$ from one. This constraint does not hold if $\Gamma_{12}/\mathbf{M}_{12}$ is approximately imaginary. (An alternative parameterization uses $q/p = (1 - \tilde{\epsilon}_B)/(1 + \tilde{\epsilon}_B)$, leading to $\mathcal{A}_{\text{SL}} \simeq 4\text{Re}(\tilde{\epsilon}_B)$.)

The small deviation (less than one percent) of $|q/p|$ from 1 implies that, at the present level of experimental precision, CP violation in B mixing is a negligible effect. Thus, for the purpose of analyzing CP asymmetries in hadronic B decays, we can use

$$\lambda_f = e^{-i\phi_{M(B)}} (\bar{A}_f/A_f), \quad (12.84)$$

where $\phi_{M(B)}$ refers to the phase of \mathbf{M}_{12} appearing in Eq. (12.44) that is appropriate for $B^0 - \bar{B}^0$ oscillations. Within the Standard Model, the corresponding phase factor is given by

$$e^{-i\phi_{M(B)}} = (V_{tb}^* V_{td}) / (V_{cb} V_{cd}^*). \quad (12.85)$$

Some of the most interesting decays involve final states that are common to B^0 and \bar{B}^0 [45,46]. It is convenient to rewrite Eq. (12.42) for B decays as [47–49]

$$\begin{aligned} A_f(t) &= S_f \sin(\Delta m t) - C_f \cos(\Delta m t), \\ S_f &\equiv \frac{2\text{Im}(\lambda_f)}{1 + |\lambda_f|^2}, \quad C_f \equiv \frac{1 - |\lambda_f|^2}{1 + |\lambda_f|^2}, \end{aligned} \quad (12.86)$$

where we assume that $\Delta\Gamma = 0$ and $|q/p| = 1$. An alternative notation in use is $A_f \equiv -C_f$, but this A_f should not be confused with the A_f of Eq. (12.15).

A large class of interesting processes proceed via quark transitions of the form $\bar{b} \rightarrow \bar{q}q\bar{q}'$ with $q' = s$ or d . For $q = c$ or u , there are contributions from both tree (t) and penguin (p^{qu} , where $q_u = u, c, t$ is the quark in the loop) diagrams (see Fig. 12.2) which carry different weak phases:

$$A_f = (V_{qb}^* V_{qq'}) t_f + \sum_{q_u=u,c,t} (V_{qub}^* V_{quq'}) p_f^{q_u}. \quad (12.87)$$

(The distinction between tree and penguin contributions is a heuristic one; the separation by the operator that enters is more precise. For a detailed discussion of the more complete operator product approach, which also includes higher order QCD corrections, see, for example, Ref. [50].) Using CKM unitarity, these decay amplitudes can always be written in terms of just two CKM combinations. For example, for $f = \pi\pi$, which proceeds via $\bar{b} \rightarrow \bar{u}u\bar{d}$ transition, we can write

$$A_{\pi\pi} = (V_{ub}^*V_{ud})T_{\pi\pi} + (V_{tb}^*V_{td})P_{\pi\pi}^t, \quad (12.88)$$

where $T_{\pi\pi} = t_{\pi\pi} + p_{\pi\pi}^u - p_{\pi\pi}^c$ and $P_{\pi\pi}^t = p_{\pi\pi}^t - p_{\pi\pi}^c$. *CP*-violating phases in Eq. (12.88) appear only in the CKM elements, so that

$$\frac{\bar{A}_{\pi\pi}}{A_{\pi\pi}} = \frac{(V_{ub}V_{ud}^*)T_{\pi\pi} + (V_{tb}V_{td}^*)P_{\pi\pi}^t}{(V_{ub}^*V_{ud})T_{\pi\pi} + (V_{tb}^*V_{td})P_{\pi\pi}^t}. \quad (12.89)$$

For $f = J/\psi K$, which proceeds via $\bar{b} \rightarrow \bar{c}c\bar{s}$ transition, we can write

$$A_{\psi K} = (V_{cb}^*V_{cs})T_{\psi K} + (V_{ub}^*V_{us})P_{\psi K}^u, \quad (12.90)$$

where $T_{\psi K} = t_{\psi K} + p_{\psi K}^c - p_{\psi K}^t$ and $P_{\psi K}^u = p_{\psi K}^u - p_{\psi K}^t$. A subtlety arises in this decay that is related to the fact that B^0 decays into a final $J/\psi K^0$ state while \bar{B}^0 decays into a final $J/\psi \bar{K}^0$ state. A common final state, *e.g.*, $J/\psi K_S$, is reached only via $K^0 - \bar{K}^0$ mixing. Consequently, the phase factor (defined in Eq. (12.44)) corresponding to neutral K mixing, $e^{-i\phi_{M(K)}} = (V_{cd}^*V_{cs})/(V_{cd}V_{cs}^*)$, plays a role:

$$\frac{\bar{A}_{\psi K_S}}{A_{\psi K_S}} = -\frac{(V_{cb}V_{cs}^*)T_{\psi K} + (V_{ub}V_{us}^*)P_{\psi K}^u}{(V_{cb}^*V_{cs})T_{\psi K} + (V_{ub}^*V_{us})P_{\psi K}^u} \times \frac{V_{cd}^*V_{cs}}{V_{cd}V_{cs}^*}. \quad (12.91)$$

For $q = s$ or d , there are only penguin contributions to A_f , that is, $t_f = 0$ in Eq. (12.87). (The tree $\bar{b} \rightarrow \bar{u}u\bar{q}$ transition followed by $\bar{u}u \rightarrow \bar{q}q$ rescattering is included below in the P^u terms.) Again, CKM unitarity allows us to write A_f in terms of two CKM combinations. For example, for $f = \phi K_S$, which proceeds via $\bar{b} \rightarrow \bar{s}s\bar{s}$ transition, we can write

$$\frac{\bar{A}_{\phi K_S}}{A_{\phi K_S}} = -\frac{(V_{cb}V_{cs}^*)P_{\phi K}^c + (V_{ub}V_{us}^*)P_{\phi K}^u}{(V_{cb}^*V_{cs})P_{\phi K}^c + (V_{ub}^*V_{us})P_{\phi K}^u} \times \frac{V_{cd}^*V_{cs}}{V_{cd}V_{cs}^*}, \quad (12.92)$$

where $P_{\phi K}^c = p_{\phi K}^c - p_{\phi K}^t$ and $P_{\phi K}^u = p_{\phi K}^u - p_{\phi K}^t$.

Since the amplitude A_f involves two different weak phases, the corresponding decays can exhibit both *CP* violation in the interference of decays with and without mixing, $S_f \neq 0$, and *CP* violation in decays, $C_f \neq 0$. (At the present level of experimental precision, the contribution to C_f from *CP* violation in mixing is negligible, see Eq. (12.82).) If the contribution from a second weak phase is suppressed, then the interpretation of S_f in terms of Lagrangian *CP*-violating parameters is clean, while C_f is small. If such a second contribution is not suppressed, S_f depends on hadronic parameters and, if the relevant strong phase is large, C_f is large.

A summary of $\bar{b} \rightarrow \bar{q}q\bar{q}'$ modes with $q' = s$ or d is given in Table 12.1. The $\bar{b} \rightarrow \bar{d}d\bar{q}$ transitions lead to final states that are similar to the $\bar{b} \rightarrow \bar{u}u\bar{q}$ transitions and have similar phase dependence. Final states that consist of two-vector mesons ($\psi\phi$ and $\phi\phi$) are not *CP* eigenstates, and angular analysis is needed to separate the *CP*-even from the *CP*-odd contributions.

The cleanliness of the theoretical interpretation of S_f can be assessed from the information in the last column of Table 12.1. In case of small uncertainties, the expression for S_f in terms of CKM phases can be deduced from the fourth column of Table 12.1 in combination with Eq. (12.85) (and, for $b \rightarrow \bar{q}q\bar{s}$ decays, the example in Eq. (12.91)). Here we consider several interesting examples.

For $B \rightarrow J/\psi K_S$ and other $\bar{b} \rightarrow \bar{c}c\bar{s}$ processes, we can neglect the P^u contribution to A_f , in the Standard Model, to an approximation that is better than one percent:

$$\lambda_{\psi K_S} = -e^{-2i\beta} \Rightarrow S_{\psi K_S} = \sin 2\beta, \quad C_{\psi K_S} = 0. \quad (12.93)$$

Figure 12.2: Feynman diagrams for (a) tree and (b) penguin amplitudes contributing to $B^0 \rightarrow f$ or $B_s \rightarrow f$ via a $\bar{b} \rightarrow \bar{q}q\bar{q}'$ quark-level process.

Table 12.1: Summary of $\bar{b} \rightarrow \bar{q}q\bar{q}'$ modes with $q' = s$ or d . The second and third columns give examples of final hadronic states. The fourth column gives the CKM dependence of the amplitude A_f , using the notation of Eqs. (12.88, 12.90, 12.92), with the dominant term first and the subdominant second. The suppression factor of the second term compared to the first is given in the last column. “Loop” refers to a penguin versus tree-suppression factor (it is mode-dependent and roughly $\mathcal{O}(0.2 - 0.3)$) and $\lambda = 0.23$ is the expansion parameter of Eq. (12.50).

$\bar{b} \rightarrow \bar{q}q\bar{q}'$	$B^0 \rightarrow f$	$B_s \rightarrow f$	CKM dependence of A_f	Suppression
$\bar{b} \rightarrow \bar{c}c\bar{s}$	ψK_S	$\psi\phi$	$(V_{cb}^*V_{cs})T + (V_{ub}^*V_{us})P^u$	loop $\times \lambda^2$
$\bar{b} \rightarrow \bar{s}s\bar{s}$	ϕK_S	$\phi\phi$	$(V_{cb}^*V_{cs})P^c + (V_{ub}^*V_{us})P^u$	λ^2
$\bar{b} \rightarrow \bar{u}u\bar{s}$	$\pi^0 K_S$	$K^+ K^-$	$(V_{cb}^*V_{cs})P^c + (V_{ub}^*V_{us})T$	λ^2/loop
$\bar{b} \rightarrow \bar{c}c\bar{d}$	$D^+ D^-$	ψK_S	$(V_{cb}^*V_{cd})T + (V_{tb}^*V_{td})P^t$	loop
$\bar{b} \rightarrow \bar{s}s\bar{d}$	$K_S K_S$	ϕK_S	$(V_{tb}^*V_{td})P^t + (V_{cb}^*V_{cd})P^c$	$\lesssim 1$
$\bar{b} \rightarrow \bar{u}u\bar{d}$	$\pi^+ \pi^-$	$\rho^0 K_S$	$(V_{ub}^*V_{ud})T + (V_{tb}^*V_{td})P^t$	loop

In the presence of new physics, A_f is still likely to be dominated by the T term, but the mixing amplitude might be modified. We learn that, model-independently, $C_f \approx 0$ while S_f cleanly determines the mixing phase ($\phi_M - 2\arg(V_{cb}V_{cd}^*)$). The experimental measurement [25], $S_{\psi K} = 0.665 \pm 0.022$, gave the first precision test of the Kobayashi-Maskawa mechanism, and its consistency with the predictions for $\sin 2\beta$ makes it very likely that this mechanism is indeed the dominant source of *CP* violation in meson decays.

For $B \rightarrow \phi K_S$ and other $\bar{b} \rightarrow \bar{s}s\bar{s}$ processes (as well as some $\bar{b} \rightarrow \bar{u}u\bar{s}$ processes), we can neglect the subdominant contributions, in the Standard Model, to an approximation that is good on the order of

a few percent:

$$\lambda_{\phi K_S} = -e^{-2i\beta} \Rightarrow S_{\phi K_S} = \sin 2\beta, \quad C_{\phi K_S} = 0. \quad (12.94)$$

In the presence of new physics, both A_f and M_{12} can get contributions that are comparable in size to those of the Standard Model and carry new weak phases. Such a situation gives several interesting consequences for penguin-dominated $b \rightarrow q\bar{q}s$ decays ($q = u, d, s$) to a final state f :

1. The value of $-\eta_f S_f$ may be different from $S_{\psi K_S}$ by more than a few percent, where η_f is the CP eigenvalue of the final state.
2. The values of $\eta_f S_f$ for different final states f may be different from each other by more than a few percent (for example, $S_{\phi K_S} \neq S_{\eta' K_S}$).
3. The value of C_f may be different from zero by more than a few percent.

While a clear interpretation of such signals in terms of Lagrangian parameters will be difficult because, under these circumstances, hadronic parameters do play a role, any of the above three options will clearly signal new physics. Fig. 12.3 summarizes the present experimental results: none of the possible signatures listed above is unambiguously established, but there is definitely still room for new physics.

Figure 12.3: Summary of the results [25] of time-dependent analyses of $b \rightarrow q\bar{q}s$ decays, which are potentially sensitive to new physics.

For $B \rightarrow \pi\pi$ and other $\bar{b} \rightarrow \bar{u}d$ processes, the penguin-to-tree ratio can be estimated using $SU(3)$ relations and experimental data on related $B \rightarrow K\pi$ decays. The result is that the suppression is on the order of 0.2–0.3 and so cannot be neglected. The expressions for $S_{\pi\pi}$ and $C_{\pi\pi}$ to leading order in $R_{PT} \equiv (|V_{tb}V_{td}| P_{\pi\pi}^t)/(|V_{ub}V_{ud}| T_{\pi\pi})$ are:

$$\lambda_{\pi\pi} = e^{2i\alpha} \left[(1 - R_{PT}e^{-i\alpha}) / (1 - R_{PT}e^{+i\alpha}) \right] \Rightarrow$$

$$S_{\pi\pi} \approx \sin 2\alpha + 2 \operatorname{Re}(R_{PT}) \cos 2\alpha \sin \alpha, \quad C_{\pi\pi} \approx 2 \operatorname{Im}(R_{PT}) \sin \alpha. \quad (12.95)$$

Note that R_{PT} is mode-dependent and, in particular, could be different for $\pi^+\pi^-$ and $\pi^0\pi^0$. If strong phases can be neglected, then R_{PT} is real, resulting in $C_{\pi\pi} = 0$. The size of $C_{\pi\pi}$ is an indicator of how large the strong phase is. The present experimental range is

$C_{\pi\pi} = -0.38 \pm 0.06$ [25]. As concerns $S_{\pi\pi}$, it is clear from Eq. (12.95) that the relative size or strong phase of the penguin contribution must be known to extract α . This is the problem of penguin pollution.

The cleanest solution involves isospin relations among the $B \rightarrow \pi\pi$ amplitudes [51]:

$$\frac{1}{\sqrt{2}} A_{\pi^+\pi^-} + A_{\pi^0\pi^0} = A_{\pi^+\pi^0}. \quad (12.96)$$

The method exploits the fact that the penguin contribution to $P_{\pi\pi}^t$ is pure $\Delta I = \frac{1}{2}$ (this is not true for the electroweak penguins which, however, are expected to be small), while the tree contribution to $T_{\pi\pi}$ contains pieces which are both $\Delta I = \frac{1}{2}$ and $\Delta I = \frac{3}{2}$. A simple geometric construction then allows one to find R_{PT} and extract α cleanly from $S_{\pi^+\pi^-}$. The key experimental difficulty is that one must measure accurately the separate rates for $B^0, \bar{B}^0 \rightarrow \pi^0\pi^0$.

CP asymmetries in $B \rightarrow \rho\pi$ and $B \rightarrow \rho\rho$ can also be used to determine α . In particular, the $B \rightarrow \rho\rho$ measurements are presently very significant in constraining α . The extraction proceeds via isospin analysis similar to that of $B \rightarrow \pi\pi$. There are, however, several important differences. First, due to the finite width of the ρ mesons, a final $(\rho\rho)_{I=1}$ state is possible [52]. The effect is, however, small, on the order of $(\Gamma_\rho/m_\rho)^2 \sim 0.04$. Second, due to the presence of three helicity states for the two-vector mesons, angular analysis is needed to separate the CP -even and CP -odd components. The theoretical expectation is, however, that the CP -odd component is small. This expectation is supported by experiments which find that the $\rho^+\rho^-$ and $\rho^\pm\rho^0$ modes are dominantly longitudinally polarized. Third, an important advantage of the $\rho\rho$ modes is that the penguin contribution is expected to be small due to different hadronic dynamics. This expectation is confirmed by the smallness of $\mathcal{B}(B^0 \rightarrow \rho^0\rho^0) = (0.73 \pm 0.28) \times 10^{-6}$ compared to $\mathcal{B}(B^0 \rightarrow \rho^+\rho^-) = (24.2 \pm 3.1) \times 10^{-6}$. Thus, $S_{\rho^+\rho^-}$ is not far from $\sin 2\alpha$. Finally, both $S_{\rho^0\rho^0}$ and $C_{\rho^0\rho^0}$ are experimentally accessible, which may allow a precision determination of α . The consistency between the range of α determined by the $B \rightarrow \pi\pi, \rho\pi, \rho\rho$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides further support to the Kobayashi-Maskawa mechanism.

An interesting class of decay modes is that of the tree level decays $B^\pm \rightarrow D^{(*)0}K^\pm$. These decays provide golden methods for a clean determination of the angle γ [53–56]. The method uses the decays $B^+ \rightarrow D^0K^+$, which proceeds via the quark transition $\bar{b} \rightarrow \bar{u}c\bar{s}$, and $B^+ \rightarrow \bar{D}^0K^+$, which proceeds via the quark transition $\bar{b} \rightarrow \bar{c}u\bar{s}$, with the D^0 and \bar{D}^0 decaying into a common final state. The decays into common final states, such as $(\pi^0 K_S) D K^+$, involve interference effects between the two amplitudes, with sensitivity to the relative phase, $\delta + \gamma$ (δ is the relevant strong phase). The CP -conjugate processes are sensitive to $\delta - \gamma$. Measurements of branching ratios and CP asymmetries allow an extraction of γ and δ from amplitude triangle relations. The extraction suffers from discrete ambiguities but involves no hadronic uncertainties. However, the smallness of the CKM-suppressed $b \rightarrow u$ transitions makes it difficult at present to use the simplest methods [53–55] to determine γ . These difficulties are overcome (and the discrete ambiguities are removed) by performing a Dalitz plot analysis for multi-body D decays [56]. The consistency between the range of γ determined by the $B \rightarrow DK$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides further support to the Kobayashi-Maskawa mechanism.

The upper bound on the CP asymmetry in semileptonic B_s decays [25] implies that CP violation in $B_s - \bar{B}_s$ mixing is a small effect:

$$\mathcal{A}_{SL}^s = (-10.5 \pm 6.4) \times 10^{-3} \Rightarrow |q/p| = 1.0052 \pm 0.0032. \quad (12.97)$$

Neglecting the deviation of $|q/p|$ from 1, implies that we can use

$$\lambda_f = e^{-i\phi_M(B_s)} (\bar{A}_f/A_f). \quad (12.98)$$

Within the Standard Model,

$$e^{-i\phi_M(B_s)} = (V_{tb}^* V_{ts}) / (V_{tb} V_{ts}^*). \quad (12.99)$$

Note that $\Delta\Gamma/\Gamma = 0.15 \pm 0.02$ [25] and therefore y should not be put to zero in Eqs. (12.32, 12.33). However, $|q/p| = 1$ is expected to hold to an even better approximation than for B mesons. The $B_s \rightarrow J/\psi\phi$ decay proceeds via the $b \rightarrow c\bar{c}s$ transition. The CP asymmetry in this mode thus determines (with angular analysis to disentangle the CP -even and CP -odd components of the final state) $\sin 2\beta_s$, where β_s is defined in Eq. (12.53). The combination of CDF, D0 and LHCb measurements yields [25]

$$\beta_s = 0.07^{+0.06}_{-0.08}, \quad (12.100)$$

consistent with the Standard Model prediction, $\beta_s = 0.018 \pm 0.001$ [18].

12.7. Summary and Outlook

CP violation has been experimentally established in K and B meson decays. A full list of CP asymmetries that have been measured at a level higher than 5σ is given in the introduction to this review. In Section 12.1.4 we introduced three types of CP -violating effects. Examples of these three types include the following:

1. All three types of CP violation have been observed in $K \rightarrow \pi\pi$ decays:

$$\text{Re}(\epsilon') = \frac{1}{6} \left(\left| \frac{\bar{A}_{\pi^0\pi^0}}{A_{\pi^0\pi^0}} \right| - \left| \frac{\bar{A}_{\pi^+\pi^-}}{A_{\pi^+\pi^-}} \right| \right) = (2.5 \pm 0.4) \times 10^{-6} \quad (\text{I})$$

$$\text{Re}(\epsilon) = \frac{1}{2} \left(1 - \left| \frac{q}{p} \right| \right) = (1.66 \pm 0.02) \times 10^{-3} \quad (\text{II})$$

$$\text{Im}(\epsilon) = -\frac{1}{2} \text{Im}(\lambda_{(\pi\pi)_{I=0}}) = (1.57 \pm 0.02) \times 10^{-3}. \quad (\text{III}) \quad (12.101)$$

2. Direct CP violation has been observed in, for example, the $B^0 \rightarrow K^+\pi^-$ decays, while CP violation in interference of decays with and without mixing has been observed in, for example, the $B \rightarrow J/\psi K_S$ decay:

$$A_{K^+\pi^-} = \frac{|\bar{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 - 1}{|\bar{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 + 1} = -0.087 \pm 0.008 \quad (\text{I})$$

$$S_{\psi K} = \text{Im}(\lambda_{\psi K}) = +0.679 \pm 0.020. \quad (\text{II}) \quad (12.102)$$

Based on Standard Model predictions, further observation of CP violation in D , B and B_s decays seems promising for the near future, at both LHCb and a possible higher-luminosity asymmetric-energy B factory [58]. Observables that are subject to clean theoretical interpretation, such as $S_{\psi K_S}$, $\mathcal{B}(K_L \rightarrow \pi^0 \nu \bar{\nu})$ and CP violation in $B \rightarrow DK$ decays, are of particular value for constraining the values of the CKM parameters and probing the flavor sector of extensions to the Standard Model. Other probes of CP violation now being pursued experimentally include the electric dipole moments of the neutron and electron, and the decays of tau leptons. Additional processes that are likely to play an important role in future CP studies include top-quark production and decay, and neutrino oscillations.

All measurements of CP violation to date are consistent with the predictions of the Kobayashi-Maskawa mechanism of the Standard Model. Actually, it is now established that the KM mechanism plays a major role in the CP violation measured in meson decays. However, a dynamically-generated matter-antimatter asymmetry of the universe requires additional sources of CP violation, and such sources are naturally generated by extensions to the Standard Model. New sources might eventually reveal themselves as small deviations from the predictions of the KM mechanism in meson decay rates, or else might not be observable in meson decays at all, but observable with future probes such as neutrino oscillations or electric dipole moments. We cannot guarantee that new sources of CP violation will ever be found experimentally, but the fundamental nature of CP violation demands a vigorous effort.

A number of excellent reviews of CP violation are available [59–67], where the interested reader may find a detailed discussion of the various topics that are briefly reviewed here.

We thank Tim Gershon for significant contributions to the 2012 update.

13. NEUTRINO MASS, MIXING, AND OSCILLATIONS

Updated May 2012 by K. Nakamura (Kavli IPMU (WPI), U. Tokyo, KEK) and S.T. Petcov (SISSA/INFN Trieste, Kavli IPMU (WPI), U. Tokyo, Bulgarian Academy of Sciences).

The experiments with solar, atmospheric, reactor and accelerator neutrinos have provided compelling evidences for oscillations of neutrinos caused by nonzero neutrino masses and neutrino mixing. The data imply the existence of 3-neutrino mixing in vacuum. We review the theory of neutrino oscillations, the phenomenology of neutrino mixing, the problem of the nature - Dirac or Majorana, of massive neutrinos, the issue of CP violation in the lepton sector, and the current data on the neutrino masses and mixing parameters. The open questions and the main goals of future research in the field of neutrino mixing and oscillations are outlined.

13.1. Introduction: Massive neutrinos and neutrino mixing

It is a well-established experimental fact that the neutrinos and antineutrinos which take part in the standard charged current (CC) and neutral current (NC) weak interaction are of three varieties (types) or flavours: electron, ν_e and $\bar{\nu}_e$, muon, ν_μ and $\bar{\nu}_\mu$, and tauon, ν_τ and $\bar{\nu}_\tau$. The notion of neutrino type or flavour is dynamical: ν_e is the neutrino which is produced with e^+ , or produces an e^- in CC weak interaction processes; ν_μ is the neutrino which is produced with μ^+ , or produces μ^- , etc. The flavour of a given neutrino is Lorentz invariant. Among the three different flavour neutrinos and antineutrinos, no two are identical. Correspondingly, the states which describe different flavour neutrinos must be orthogonal (within the precision of the current data): $\langle \nu_l | \nu_l \rangle = \delta_{ll}$, $\langle \bar{\nu}_l | \bar{\nu}_l \rangle = \delta_{ll}$, $\langle \bar{\nu}_l | \nu_l \rangle = 0$.

It is also well-known from the existing data (all neutrino experiments were done so far with relativistic neutrinos or antineutrinos), that the flavour neutrinos ν_l (antineutrinos $\bar{\nu}_l$), are always produced in weak interaction processes in a state that is predominantly left-handed (LH) (right-handed (RH)). To account for this fact, ν_l and $\bar{\nu}_l$ are described in the Standard Model (SM) by a chiral LH flavour neutrino field $\nu_{lL}(x)$, $l = e, \mu, \tau$. For massless ν_l , the state of ν_l ($\bar{\nu}_l$) which the field $\nu_{lL}(x)$ annihilates (creates) is with helicity (-1/2) (helicity +1/2). If ν_l has a non-zero mass $m(\nu_l)$, the state of ν_l ($\bar{\nu}_l$) is a linear superposition of the helicity (-1/2) and (+1/2) states, but the helicity +1/2 state (helicity (-1/2) state) enters into the superposition with a coefficient $\propto m(\nu_l)/E$, E being the neutrino energy, and thus is strongly suppressed. Together with the LH charged lepton field $l_L(x)$, $\nu_{lL}(x)$ forms an $SU(2)_L$ doublet. In the absence of neutrino mixing and zero neutrino masses, $\nu_{lL}(x)$ and $l_L(x)$ can be assigned one unit of the additive lepton charge L_l and the three charges L_l , $l = e, \mu, \tau$, are conserved by the weak interaction.

At present there is no compelling evidence for the existence of states of relativistic neutrinos (antineutrinos), which are predominantly right-handed, ν_R (left-handed, $\bar{\nu}_L$). If RH neutrinos and LH antineutrinos exist, their interaction with matter should be much weaker than the weak interaction of the flavour LH neutrinos ν_l and RH antineutrinos $\bar{\nu}_l$, i.e., ν_R ($\bar{\nu}_L$) should be “sterile” or “inert” neutrinos (antineutrinos) [1]. In the formalism of the Standard Model, the sterile ν_R and $\bar{\nu}_L$ can be described by $SU(2)_L$ singlet RH neutrino fields $\nu_{lR}(x)$. In this case, ν_{lR} and $\bar{\nu}_L$ will have no gauge interactions, i.e., will not couple to the weak W^\pm and Z^0 bosons. If present in an extension of the Standard Model, the RH neutrinos can play a crucial role i) in the generation of neutrino masses and mixing, ii) in understanding the remarkable disparity between the magnitudes of neutrino masses and the masses of the charged leptons and quarks, and iii) in the generation of the observed matter-antimatter asymmetry of the Universe (via the leptogenesis mechanism [2]). In this scenario which is based on the see-saw theory [3], there is a link between the generation of neutrino masses and the generation of the baryon asymmetry of the Universe. The simplest hypothesis (based on symmetry considerations) is that to each LH flavour neutrino field $\nu_{lL}(x)$ there corresponds a RH neutrino field $\nu_{lR}(x)$, $l = e, \mu, \tau$, although schemes with less (more) than three RH neutrinos are also being considered.

The experiments with solar, atmospheric and reactor neutrinos [4–16] have provided compelling evidences for the existence of neutrino oscillations [17,18], transitions in flight between the different flavour neutrinos ν_e, ν_μ, ν_τ (antineutrinos $\bar{\nu}_e, \bar{\nu}_\mu, \bar{\nu}_\tau$), caused by nonzero neutrino masses and neutrino mixing.

The existence of flavour neutrino oscillations implies that if a neutrino of a given flavour, say ν_μ , with energy E is produced in some weak interaction process, at a sufficiently large distance L from the ν_μ source the probability to find a neutrino of a different flavour, say ν_τ , $P(\nu_\mu \rightarrow \nu_\tau; E, L)$, is different from zero. $P(\nu_\mu \rightarrow \nu_\tau; E, L)$ is called the $\nu_\mu \rightarrow \nu_\tau$ oscillation or transition probability. If $P(\nu_\mu \rightarrow \nu_\tau; E, L) \neq 0$, the probability that ν_μ will not change into a neutrino of a different flavour, i.e., the “ ν_μ survival probability” $P(\nu_\mu \rightarrow \nu_\mu; E, L)$, will be smaller than one. If only muon neutrinos ν_μ are detected in a given experiment and they take part in oscillations, one would observe a “disappearance” of muon neutrinos on the way from the ν_μ source to the detector. Disappearance of the solar ν_e , reactor $\bar{\nu}_e$ and of atmospheric ν_μ and $\bar{\nu}_\mu$ due to the oscillations have been observed respectively, in the solar neutrino [4–12], KamLAND [15,16] and Super-Kamokande [13,14] experiments. Strong evidences for disappearance of muon neutrinos due to oscillations were obtained also in the long-baseline accelerator neutrino experiments K2K [19] and MINOS [20,21]. As a consequence of the results of the experiments quoted above the existence of oscillations or transitions of the solar ν_e , atmospheric ν_μ and $\bar{\nu}_\mu$, accelerator ν_μ (at $L \sim 250$ km and $L \sim 730$ km) and reactor $\bar{\nu}_e$ (at $L \sim 180$ km), driven by nonzero neutrino masses and neutrino mixing, was firmly established. There are strong indications that the solar ν_e transitions are affected by the solar matter [22,23]. In June of 2011, the T2K [24] Collaboration reported indication of $\nu_\mu \rightarrow \nu_e$ oscillations, i.e., “appearance” of ν_e in a beam of ν_μ at a significance of 2.5σ . Also MINOS [25] Collaboration obtained data consistent with $\nu_\mu \rightarrow \nu_e$ oscillations. In March and April, 2012, the Daya Bay [26] and RENO [27] experiments reported strong evidence for reactor $\bar{\nu}_e$ disappearance respectively at $L \sim 1.65$ km and $L \sim 1.38$ km and with statistical significance of 5.2σ and 4.9σ .

Oscillations of neutrinos are a consequence of the presence of flavour neutrino mixing, or lepton mixing, in vacuum. In the formalism of local quantum field theory, used to construct the Standard Model, this means that the LH flavour neutrino fields $\nu_{lL}(x)$, which enter into the expression for the lepton current in the CC weak interaction Lagrangian, are linear combinations of the fields of three (or more) neutrinos ν_j , having masses $m_j \neq 0$:

$$\nu_{lL}(x) = \sum_j U_{lj} \nu_{jL}(x), \quad l = e, \mu, \tau, \quad (13.1)$$

where $\nu_{jL}(x)$ is the LH component of the field of ν_j possessing a mass m_j and U is a unitary matrix - the neutrino mixing matrix [1,17,18]. The matrix U is often called the Pontecorvo-Maki-Nakagawa-Sakata (PMNS) or Maki-Nakagawa-Sakata (MNS) mixing matrix. Obviously, Eq. (13.1) implies that the individual lepton charges L_l , $l = e, \mu, \tau$, are not conserved.

All existing neutrino oscillation data, except for the LSND [28] and the MiniBooNE [29] results (see below), can be described assuming 3-flavour neutrino mixing in vacuum. The data on the invisible decay width of the Z^0 -boson is compatible with only 3 light flavour neutrinos coupled to Z^0 [30]. The number of massive neutrinos ν_j , n , can, in general, be bigger than 3, $n > 3$, if, for instance, there exist sterile neutrinos and they mix with the flavour neutrinos. It follows from the existing data that at least 3 of the neutrinos ν_j , say ν_1, ν_2, ν_3 , must be light, $m_{1,2,3} \lesssim 1$ eV, and must have different masses, $m_1 \neq m_2 \neq m_3$.

The short-baseline accelerator experiment LSND [28] observed a possible indication of $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillations. Performing a $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillation search, the MiniBooNE Collaboration reported a 1.5σ excess of $\bar{\nu}_e$ events [29], which is marginally consistent with the LSND indication of $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillations. However, in the MiniBooNE experiment no indications of $\nu_\mu \rightarrow \nu_e$ oscillations were found so far [31]. Interpreting the LSND [28] and the MiniBooNE [29,31] results in terms of neutrino oscillations requires the introduction of at least two more light neutrinos with masses in the 1 eV range [32], and thus of two sterile neutrino fields which mix with the ν_e and ν_μ fields.

However, further experimental investigations are definitely needed since the excess of $\bar{\nu}_e$ events observed in the MiniBooNE experiment has a relatively low statistical significance.

Hints (at $\sim 2.5\sigma$) for existence of additional light neutrinos beyond the three firmly established were obtained in the re-analysis [33] of the old short baseline (SBL) reactor $\bar{\nu}_e$ oscillation data using the results of a new and very detailed calculation of the reactor $\bar{\nu}_e$ fluxes [34]. The latter were found in Ref. 34 to be by approximately 3% larger than the fluxes calculated in Ref. 35 and widely used in the interpretation of the results of the SBL reactor $\bar{\nu}_e$ oscillation experiments. It should be added that the results for the reactor $\bar{\nu}_e$ fluxes have an uncertainty associated, *e.g.*, with the weak magnetism term contribution to the corresponding β -decay rates, which can be larger than the 3% difference between the “old” and “new” fluxes [36].

On the basis of the preceding discussion we can conclude that at present there are no compelling experimental evidences for the existence of more than 3 light neutrinos.

Being electrically neutral, the neutrinos with definite mass ν_j can be Dirac fermions or Majorana particles [37,38]. The first possibility is realised when there exists a lepton charge carried by the neutrinos ν_j , which is conserved by the particle interactions. This could be, *e.g.*, the total lepton charge $L = L_e + L_\mu + L_\tau$: $L(\nu_j) = 1$, $j = 1, 2, 3$. In this case the neutrino ν_j has a distinctive antiparticle $\bar{\nu}_j$: $\bar{\nu}_j$ differs from ν_j by the value of the lepton charge L it carries, $L(\bar{\nu}_j) = -1$. The massive neutrinos ν_j can be Majorana particles if no lepton charge is conserved (see, *e.g.*, Ref. 39). A massive Majorana particle χ_j is identical with its antiparticle $\bar{\chi}_j$: $\chi_j \equiv \bar{\chi}_j$. On the basis of the existing neutrino data it is impossible to determine whether the massive neutrinos are Dirac or Majorana fermions.

In the case of n neutrino flavours and n massive neutrinos, the $n \times n$ unitary neutrino mixing matrix U can be parametrised by $n(n-1)/2$ Euler angles and $n(n+1)/2$ phases. If the massive neutrinos ν_j are Dirac particles, only $(n-1)(n-2)/2$ phases are physical and can be responsible for CP violation in the lepton sector. In this respect the neutrino (lepton) mixing with Dirac massive neutrinos is similar to the quark mixing. For $n = 3$ there is just one CP violating phase in U , which is usually called “the Dirac CP violating phase.” CP invariance holds if (in a certain standard convention) U is real, $U^* = U$.

If, however, the massive neutrinos are Majorana fermions, $\nu_j \equiv \chi_j$, the neutrino mixing matrix U contains $n(n-1)/2$ CP violation phases [40,41], *i.e.*, by $(n-1)$ phases more than in the Dirac neutrino case: in contrast to Dirac fields, the massive Majorana neutrino fields cannot “absorb” phases. In this case U can be cast in the form [40]

$$U = V P \quad (13.2)$$

where the matrix V contains the $(n-1)(n-2)/2$ Dirac CP violation phases, while P is a diagonal matrix with the additional $(n-1)$ Majorana CP violation phases $\alpha_{21}, \alpha_{31}, \dots, \alpha_{n1}$,

$$P = \text{diag} \left(1, e^{i\frac{\alpha_{21}}{2}}, e^{i\frac{\alpha_{31}}{2}}, \dots, e^{i\frac{\alpha_{n1}}{2}} \right). \quad (13.3)$$

The Majorana phases will conserve CP if [42] $\alpha_{j1} = \pi q_j$, $q_j = 0, 1, 2$, $j = 2, 3, \dots, n$. In this case $\exp[i(\alpha_{j1} - \alpha_{k1})] = \pm 1$ has a simple physical interpretation: this is the relative CP-parity of Majorana neutrinos χ_j and χ_k . The condition of CP invariance of the leptonic CC weak interaction in the case of mixing and massive Majorana neutrinos reads [39]:

$$U_{lj}^* = U_{lj} \rho_j, \quad \rho_j = \frac{1}{i} \eta_{CP}(\chi_j) = \pm 1, \quad (13.4)$$

where $\eta_{CP}(\chi_j) = i\rho_j = \pm i$ is the CP parity of the Majorana neutrino χ_j [42]. Thus, if CP invariance holds, the elements of U are either real or purely imaginary.

In the case of $n = 3$ there are altogether 3 CP violation phases - one Dirac and two Majorana. Even in the mixing involving only 2 massive Majorana neutrinos there is one physical CP violation Majorana phase. In contrast, the CC weak interaction is automatically CP-invariant in the case of mixing of two massive Dirac neutrinos or of two quarks.

13.2. Neutrino oscillations in vacuum

Neutrino oscillations are a quantum mechanical consequence of the existence of nonzero neutrino masses and neutrino (lepton) mixing, Eq. (13.1), and of the relatively small splitting between the neutrino masses. The neutrino mixing and oscillation phenomena are analogous to the $K^0 - \bar{K}^0$ and $B^0 - \bar{B}^0$ mixing and oscillations.

In what follows we will present a simplified version of the derivation of the expressions for the neutrino and antineutrino oscillation probabilities. The complete derivation would require the use of the wave packet formalism for the evolution of the massive neutrino states, or, alternatively, of the field-theoretical approach, in which one takes into account the processes of production, propagation and detection of neutrinos [43].

Suppose the flavour neutrino ν_l is produced in a CC weak interaction process and after a time T it is observed by a neutrino detector, located at a distance L from the neutrino source and capable of detecting also neutrinos $\nu_{l'}$, $l' \neq l$. We will consider the evolution of the neutrino state $|\nu_l\rangle$ in the frame in which the detector is at rest (laboratory frame). The oscillation probability, as we will see, is a Lorentz invariant quantity. If lepton mixing, Eq. (13.1), takes place and the masses m_j of all neutrinos ν_j are sufficiently small, the state of the neutrino ν_l , $|\nu_l\rangle$, will be a coherent superposition of the states $|\nu_j\rangle$ of neutrinos ν_j :

$$|\nu_l\rangle = \sum_j U_{lj}^* |\nu_j; \vec{p}_j\rangle, \quad l = e, \mu, \tau, \quad (13.5)$$

where U is the neutrino mixing matrix and \vec{p}_j is the 4-momentum of ν_j [44].

We will consider the case of relativistic neutrinos ν_j , which corresponds to the conditions in both past and currently planned future neutrino oscillation experiments [46]. In this case the state $|\nu_j; \vec{p}_j\rangle$ practically coincides with the helicity (-1) state $|\nu_j, L; \vec{p}_j\rangle$ of the neutrino ν_j , the admixture of the helicity (+1) state $|\nu_j, R; \vec{p}_j\rangle$ in $|\nu_j; \vec{p}_j\rangle$ being suppressed due to the factor $\sim m_j/E_j$, where E_j is the energy of ν_j . If ν_j are Majorana particles, $\nu_j \equiv \chi_j$, due to the presence of the helicity (+1) state $|\chi_j, R; \vec{p}_j\rangle$ in $|\chi_j; \vec{p}_j\rangle$, the neutrino ν_l can produce an l^+ (instead of l^-) when it interacts with nucleons. The cross section of such a $|\Delta L_l| = 2$ process is suppressed by the factor $(m_j/E_j)^2$, which renders the process unobservable at present.

If the number n of massive neutrinos ν_j is bigger than 3 due to a mixing between the active flavour and sterile neutrinos, one will have additional relations similar to that in Eq. (13.5) for the state vectors of the (predominantly LH) sterile antineutrinos. In the case of just one RH sterile neutrino field $\nu_{sR}(x)$, for instance, we will have in addition to Eq. (13.5):

$$|\bar{\nu}_{sL}\rangle = \sum_{j=1}^4 U_{sj}^* |\nu_j; \vec{p}_j\rangle \cong \sum_{j=1}^4 U_{sj}^* |\nu_j, L; \vec{p}_j\rangle, \quad (13.6)$$

where the neutrino mixing matrix U is now a 4×4 unitary matrix.

For the state vector of RH flavour antineutrino $\bar{\nu}_l$, produced in a CC weak interaction process we similarly get:

$$|\bar{\nu}_l\rangle = \sum_j U_{lj} |\bar{\nu}_j; \vec{p}_j\rangle \cong \sum_{j=1}^4 U_{lj} |\bar{\nu}_j, R; \vec{p}_j\rangle, \quad l = e, \mu, \tau, \quad (13.7)$$

where $|\bar{\nu}_j, R; \vec{p}_j\rangle$ is the helicity (+1) state of the antineutrino $\bar{\nu}_j$ if ν_j are Dirac fermions, or the helicity (+1) state of the neutrino $\nu_j \equiv \bar{\nu}_j \equiv \chi_j$ if the massive neutrinos are Majorana particles. Thus, in the latter case we have in Eq. (13.7): $|\bar{\nu}_j; \vec{p}_j\rangle \cong |\nu_j, R; \vec{p}_j\rangle \equiv |\chi_j, R; \vec{p}_j\rangle$. The presence of the matrix U in Eq. (13.7) (and not of U^*) follows directly from Eq. (13.1).

We will assume in what follows that the spectrum of masses of neutrinos is not degenerate: $m_j \neq m_k$, $j \neq k$. Then the states $|\nu_j; \vec{p}_j\rangle$ in the linear superposition in the r.h.s. of Eq. (13.5) will have, in general, different energies and different momenta, independently of whether they are produced in a decay or interaction process: $\vec{p}_j \neq \vec{p}_k$, or $E_j \neq E_k$, $\mathbf{p}_j \neq \mathbf{p}_k$, $j \neq k$, where $E_j = \sqrt{p_j^2 + m_j^2}$, $p_j \equiv |\mathbf{p}_j|$.

The deviations of E_j and p_j from the values for a massless neutrino E and $p = E$ are proportional to m_j^2/E_0 , E_0 being a characteristic energy of the process, and are extremely small. In the case of $\pi^+ \rightarrow \mu^+ + \nu_\mu$ decay at rest, for instance, we have: $E_j = E + m_j^2/(2m_\pi)$, $p_j = E - \xi m_j^2/(2E)$, where $E = (m_\pi/2)(1 - m_\mu^2/m_\pi^2) \cong 30$ MeV, $\xi = (1 + m_\mu^2/m_\pi^2)/2 \cong 0.8$, and m_μ and m_π are the μ^+ and π^+ masses. Taking $m_j = 1$ eV we find: $E_j \cong E(1 + 1.2 \times 10^{-16})$ and $p_j \cong E(1 - 4.4 \times 10^{-16})$.

Suppose that the neutrinos are observed via a CC weak interaction process and that in the detector's rest frame they are detected after time T after emission, after traveling a distance L . Then the amplitude of the probability that neutrino $\nu_{l'}$ will be observed if neutrino ν_l was produced by the neutrino source can be written as [43,45,47]:

$$A(\nu_l \rightarrow \nu_{l'}) = \sum_j U_{lj} D_j U_{j l'}^\dagger, \quad l, l' = e, \mu, \tau, \quad (13.8)$$

where $D_j = D_j(p_j; L, T)$ describes the propagation of ν_j between the source and the detector, U_{jl}^\dagger and U_{lj} are the amplitudes to find ν_j in the initial and in the final flavour neutrino state, respectively. It follows from relativistic Quantum Mechanics considerations that [43,45]

$$D_j \equiv D_j(\vec{p}_j; L, T) = e^{-i\vec{p}_j(x_f - x_0)} = e^{-i(E_j T - p_j L)}, \quad p_j \equiv |\vec{p}_j|, \quad (13.9)$$

where [48] x_0 and x_f are the space-time coordinates of the points of neutrino production and detection, $T = (t_f - t_0)$ and $L = \mathbf{k}(\mathbf{x}_f - \mathbf{x}_0)$, \mathbf{k} being the unit vector in the direction of neutrino momentum, $\vec{p}_j = \mathbf{k}p_j$. What is relevant for the calculation of the probability $P(\nu_l \rightarrow \nu_{l'}) = |A(\nu_l \rightarrow \nu_{l'})|^2$ is the interference factor $D_j D_k^*$ which depends on the phase

$$\begin{aligned} \delta\varphi_{jk} &= (E_j - E_k)T - (p_j - p_k)L = (E_j - E_k) \left[T - \frac{E_j + E_k}{p_j + p_k} L \right] \\ &+ \frac{m_j^2 - m_k^2}{p_j + p_k} L. \end{aligned} \quad (13.10)$$

Some authors [49] have suggested that the distance traveled by the neutrinos L and the time interval T are related by $T = (E_j + E_k)L/(p_j + p_k) = L/\bar{v}$, $\bar{v} = (E_j/(E_j + E_k))v_j + (E_k/(E_j + E_k))v_k$ being the "average" velocity of ν_j and ν_k , where $v_{j,k} = p_{j,k}/E_{j,k}$. In this case the first term in the r.h.s. of Eq. (13.10) vanishes. The indicated relation has not emerged so far from any dynamical wave packet calculations. We arrive at the same conclusion concerning the term under discussion in Eq. (13.10) if one assumes [50] that $E_j = E_k = E_0$. Finally, it was proposed in Ref. 47 and Ref. 51 that the states of ν_j and $\bar{\nu}_j$ in Eq. (13.5) and Eq. (13.7) have the same 3-momentum, $p_j = p_k = p$. Under this condition the first term in the r.h.s. of Eq. (13.10) is negligible, being suppressed by the additional factor $(m_j^2 + m_k^2)/p^2$ since for relativistic neutrinos $L = T$ up to terms $\sim m_{j,k}^2/p^2$. We arrive at the same conclusion if $E_j \neq E_k$, $p_j \neq p_k$, $j \neq k$, and we take into account that neutrinos are relativistic and therefore, up to corrections $\sim m_{j,k}^2/E_{j,k}^2$, we have $L \cong T$ (see, e.g., C. Giunti quoted in Ref. 43).

Although the cases considered above are physically quite different, they lead to the same result for the phase difference $\delta\varphi_{jk}$. Thus, we have:

$$\delta\varphi_{jk} \cong \frac{m_j^2 - m_k^2}{2p} L = 2\pi \frac{L}{L_{jk}^v} \text{sgn}(m_j^2 - m_k^2), \quad (13.11)$$

where $p = (p_j + p_k)/2$ and

$$L_{jk}^v = 4\pi \frac{p}{|\Delta m_{jk}^2|} \cong 2.48 \text{ m} \frac{p[\text{MeV}]}{|\Delta m_{jk}^2|[\text{eV}^2]} \quad (13.12)$$

is the neutrino oscillation length associated with Δm_{jk}^2 . We can safely neglect the dependence of p_j and p_k on the masses m_j and m_k and

consider p to be the zero neutrino mass momentum, $p = E$. The phase difference $\delta\varphi_{jk}$, Eq. (13.11), is Lorentz-invariant.

Eq. (13.9) corresponds to a plane-wave description of the propagation of neutrinos ν_j . It accounts only for the movement of the center of the wave packet describing ν_j . In the wave packet treatment of the problem, the interference between the states of ν_j and ν_k is subject to a number of conditions [43], the localisation condition and the condition of overlapping of the wave packets of ν_j and ν_k at the detection point being the most important. For relativistic neutrinos, the localisation condition in space, for instance, reads: $\sigma_{xP}, \sigma_{xD} < L_{jk}^v/(2\pi)$, $\sigma_{xP(D)}$ being the spatial width of the production (detection) wave packet. Thus, the interference will not be suppressed if the spatial width of the neutrino wave packets determined by the neutrino production and detection processes is smaller than the corresponding oscillation length in vacuum. In order for the interference to be nonzero, the wave packets describing ν_j and ν_k should also overlap in the point of neutrino detection. This requires that the spatial separation between the two wave packets at the point of neutrinos detection, caused by the two wave packets having different group velocities $v_j \neq v_k$, satisfies $|(v_j - v_k)T| \ll \max(\sigma_{xP}, \sigma_{xD})$. If the interval of time T is not measured, T in the preceding condition must be replaced by the distance L between the neutrino source and the detector (for further discussion see, e.g., Refs. [43,45,47]).

For the $\nu_l \rightarrow \nu_{l'}$ and $\bar{\nu}_l \rightarrow \bar{\nu}_{l'}$ oscillation probabilities we get from Eq. (13.8), Eq. (13.9), and Eq. (13.11):

$$\begin{aligned} P(\nu_l \rightarrow \nu_{l'}) &= \sum_j |U_{lj}|^2 |U_{l'j}|^2 + 2 \sum_{j>k} |U_{lj} U_{l'j}^* U_{lk} U_{l'k}^*| \\ &\cos\left(\frac{\Delta m_{jk}^2}{2p} L - \phi_{l'l;jk}\right), \end{aligned} \quad (13.13)$$

$$\begin{aligned} P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'}) &= \sum_j |U_{l'j}|^2 |U_{lj}|^2 + 2 \sum_{j>k} |U_{l'j} U_{lj}^* U_{lk} U_{l'k}^*| \\ &\cos\left(\frac{\Delta m_{jk}^2}{2p} L + \phi_{l'l;jk}\right), \end{aligned} \quad (13.14)$$

where $l, l' = e, \mu, \tau$ and $\phi_{l'l;jk} = \arg(U_{lj} U_{l'j}^* U_{lk} U_{l'k}^*)$. It follows from Eq. (13.8) - Eq. (13.10) that in order for neutrino oscillations to occur, at least two neutrinos ν_j should not be degenerate in mass and lepton mixing should take place, $U \neq \mathbf{1}$. The neutrino oscillations effects can be large if we have

$$\frac{|\Delta m_{jk}^2|}{2p} L = 2\pi \frac{L}{L_{jk}^v} \gtrsim 1, \quad j \neq k. \quad (13.15)$$

at least for one Δm_{jk}^2 . This condition has a simple physical interpretation: the neutrino oscillation length L_{jk}^v should be of the order of, or smaller, than source-detector distance L , otherwise the oscillations will not have time to develop before neutrinos reach the detector.

We see from Eq. (13.13) and Eq. (13.14) that $P(\nu_l \rightarrow \nu_{l'}) = P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'})$, $l, l' = e, \mu, \tau$. This is a consequence of CPT invariance. The conditions of CP and T invariance read [40,52,53]: $P(\nu_l \rightarrow \nu_{l'}) = P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'})$, $l, l' = e, \mu, \tau$ (CP), $P(\nu_l \rightarrow \nu_{l'}) = P(\nu_{l'} \rightarrow \nu_l)$, $P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'}) = P(\bar{\nu}_{l'} \rightarrow \bar{\nu}_l)$, $l, l' = e, \mu, \tau$ (T). In the case of CPT invariance, which we will assume to hold throughout this article, we get for the survival probabilities: $P(\nu_l \rightarrow \nu_l) = P(\bar{\nu}_l \rightarrow \bar{\nu}_l)$, $l, l' = e, \mu, \tau$. Thus, the study of the "disappearance" of ν_l and $\bar{\nu}_l$, caused by oscillations in vacuum, cannot be used to test whether CP invariance holds in the lepton sector. It follows from Eq. (13.13) and Eq. (13.14) that we can have CP violation effects in neutrino oscillations only if $\phi_{l'l;jk} \neq \pi q$, $q = 0, 1, 2$, i.e., if $U_{lj} U_{l'j}^* U_{lk} U_{l'k}^*$, and therefore U itself, is not real. As a measure of CP and T violation in neutrino oscillations we can consider the asymmetries:

$$A_{\text{CP}}^{(l'l)} \equiv P(\nu_l \rightarrow \nu_{l'}) - P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'}), \quad A_{\text{T}}^{(l'l)} \equiv P(\nu_l \rightarrow \nu_{l'}) - P(\nu_{l'} \rightarrow \nu_l). \quad (13.16)$$

CPT invariance implies: $A_{\text{CP}}^{(l'l)} = -A_{\text{CP}}^{(l'l)}$, $A_{\text{T}}^{(l'l)} = P(\bar{\nu}_{l'} \rightarrow \bar{\nu}_l) - P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'}) = A_{\text{CP}}^{(l'l)}$. It follows further directly from Eq. (13.13) and Eq. (13.14) that

$$A_{\text{CP}}^{(l'l)} = 4 \sum_{j>k} \text{Im} \left(U_{l'j} U_{lj}^* U_{lk} U_{l'k}^* \right) \sin \frac{\Delta m_{jk}^2}{2p} L, \quad l, l' = e, \mu, \tau. \quad (13.17)$$

Eq. (13.2) and Eq. (13.13) - Eq. (13.14) imply that $P(\nu_l \rightarrow \nu_{l'})$ and $P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'})$ do not depend on the Majorana CP violation phases in the neutrino mixing matrix U [40]. Thus, the experiments investigating the $\nu_l \rightarrow \nu_{l'}$ and $\bar{\nu}_l \rightarrow \bar{\nu}_{l'}$ oscillations, $l, l' = e, \mu, \tau$, cannot provide information on the nature - Dirac or Majorana, of massive neutrinos. The same conclusions hold also when the $\nu_l \rightarrow \nu_{l'}$ and $\bar{\nu}_l \rightarrow \bar{\nu}_{l'}$ oscillations take place in matter [54]. In the case of $\nu_l \leftrightarrow \nu_{l'}$ and $\bar{\nu}_l \leftrightarrow \bar{\nu}_{l'}$ oscillations in vacuum, only the Dirac phase(s) in U can cause CP violating effects leading to $P(\nu_l \rightarrow \nu_{l'}) \neq P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'})$, $l \neq l'$.

In the case of 3-neutrino mixing all different $\text{Im}(U_{l'j} U_{lj}^* U_{lk} U_{l'k}^*) \neq 0$, $l' \neq l = e, \mu, \tau$, $j \neq k = 1, 2, 3$, coincide up to a sign as a consequence of the unitarity of U . Therefore one has [55]:

$$A_{\text{CP}}^{(\mu e)} = -A_{\text{CP}}^{(\tau e)} = A_{\text{CP}}^{(\tau \mu)} = 4 J_{\text{CP}} \left(\sin \frac{\Delta m_{32}^2}{2p} L + \sin \frac{\Delta m_{21}^2}{2p} L + \sin \frac{\Delta m_{13}^2}{2p} L \right) \quad (13.18)$$

where

$$J_{\text{CP}} = \text{Im} \left(U_{\mu 3} U_{e 3}^* U_{e 2} U_{\mu 2}^* \right), \quad (13.19)$$

Figure 13.1: The ν_e ($\bar{\nu}_e$) survival probability $P(\nu_e \rightarrow \nu_e) = P(\bar{\nu}_e \rightarrow \bar{\nu}_e)$, Eq. (13.30), as a function of the neutrino energy for $L = 180$ km, $\Delta m^2 = 7.0 \times 10^{-5}$ eV² and $\sin^2 2\theta = 0.84$ (from Ref. 62).

is the “rephasing invariant” associated with the Dirac CP violation phase in U . It is analogous to the rephasing invariant associated with the Dirac CP violating phase in the CKM quark mixing matrix [56]. It is clear from Eq. (13.18) that J_{CP} controls the magnitude of CP violation effects in neutrino oscillations in the case of 3-neutrino mixing. If $\sin(\Delta m_{ij}^2/(2p))L \cong 0$ for $(ij) = (32)$, or (21) , or (13) , we get $A_{\text{CP}}^{(l'l)} \cong 0$. Thus, if as a consequence of the production, propagation and/or detection of neutrinos, effectively oscillations due only to one non-zero neutrino mass squared difference take place, the CP violating effects will be strongly suppressed. In particular, we get $A_{\text{CP}}^{(l'l)} = 0$, unless all three $\Delta m_{ij}^2 \neq 0$, $(ij) = (32)$, (21) , (13) .

If the number of massive neutrinos n is equal to the number of neutrino flavours, $n = 3$, one has as a consequence of the unitarity of the neutrino mixing matrix: $\sum_{l'=e,\mu,\tau} P(\nu_l \rightarrow \nu_{l'}) = 1$, $l = e, \mu, \tau$, $\sum_{l=e,\mu,\tau} P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'}) = 1$, $l' = e, \mu, \tau$. Similar “probability conservation” equations hold for $P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'})$. If, however, the number of light massive neutrinos is bigger than the number of flavour

neutrinos as a consequence, *e.g.*, of a flavour neutrino - sterile neutrino mixing, we would have $\sum_{l'=e,\mu,\tau} P(\nu_l \rightarrow \nu_{l'}) = 1 - P(\nu_l \rightarrow \bar{\nu}_{sL})$, $l = e, \mu, \tau$, where we have assumed the existence of just one sterile neutrino. Obviously, in this case $\sum_{l'=e,\mu,\tau} P(\nu_l \rightarrow \nu_{l'}) < 1$ if $P(\nu_l \rightarrow \bar{\nu}_{sL}) \neq 0$. The former inequality is used in the searches for oscillations between active and sterile neutrinos.

Consider next neutrino oscillations in the case of one neutrino mass squared difference “dominance”: suppose that $|\Delta m_{j1}^2| \ll |\Delta m_{n1}^2|$, $j = 2, \dots, (n-1)$, $|\Delta m_{n1}^2| L/(2p) \gtrsim 1$ and $|\Delta m_{j1}^2| L/(2p) \ll 1$, so that $\exp[i(\Delta m_{j1}^2 L/(2p))] \cong 1$, $j = 2, \dots, (n-1)$. Under these conditions we obtain from Eq. (13.13) and Eq. (13.14), keeping only the oscillating terms involving Δm_{n1}^2 :

$$P(\nu_{l(l')} \rightarrow \nu_{l(l)}) \cong P(\bar{\nu}_{l(l')} \rightarrow \bar{\nu}_{l(l)}) \cong \delta_{ll'} - 2|U_{ln}|^2 \left[\delta_{ll'} - |U_{l'n}|^2 \right] \left(1 - \cos \frac{\Delta m_{n1}^2}{2p} L \right). \quad (13.20)$$

It follows from the neutrino oscillation data (Sections 13.4 and 13.5) that in the case of 3-neutrino mixing, one of the two independent neutrino mass squared differences, say Δm_{21}^2 , is much smaller in absolute value than the second one, Δm_{31}^2 : $|\Delta m_{21}^2| \ll |\Delta m_{31}^2|$. The data imply:

$$\begin{aligned} |\Delta m_{21}^2| &\cong 7.6 \times 10^{-5} \text{ eV}^2, \\ |\Delta m_{31}^2| &\cong 2.4 \times 10^{-3} \text{ eV}^2, \\ |\Delta m_{21}^2|/|\Delta m_{31}^2| &\cong 0.032. \end{aligned} \quad (13.21)$$

Neglecting the effects due to Δm_{21}^2 we get from Eq. (13.20) by setting $n = 3$ and choosing, *e.g.*, i) $l = l' = e$ and ii) $l = e(\mu)$, $l' = \mu(e)$ [57]:

$$P(\nu_e \rightarrow \nu_e) = P(\bar{\nu}_e \rightarrow \bar{\nu}_e) \cong 1 - 2|U_{e3}|^2 \left(1 - |U_{e3}|^2 \right) \left(1 - \cos \frac{\Delta m_{31}^2}{2p} L \right), \quad (13.22)$$

$$\begin{aligned} P(\nu_{\mu(e)} \rightarrow \nu_{e(\mu)}) &\cong 2|U_{\mu 3}|^2 |U_{e 3}|^2 \left(1 - \cos \frac{\Delta m_{31}^2}{2p} L \right) \\ &= \frac{|U_{\mu 3}|^2}{1 - |U_{e 3}|^2} P^{2\nu} \left(|U_{e 3}|^2, m_{31}^2 \right), \end{aligned} \quad (13.23)$$

Table 13.1: Sensitivity of different oscillation experiments.

Source	Type of ν	\bar{E} [MeV]	L [km]	$\min(\Delta m^2)$ [eV ²]
Reactor	$\bar{\nu}_e$	~ 1	1	$\sim 10^{-3}$
Reactor	$\bar{\nu}_e$	~ 1	100	$\sim 10^{-5}$

Atmospheric ν 's	$\nu_{\mu,e}, \bar{\nu}_{\mu,e}$	$\sim 10^3$	10^4	$\sim 10^{-4}$
Sun	ν_e	~ 1	1.5×10^8	$\sim 10^{-11}$

and $P(\bar{\nu}_{\mu(e)} \rightarrow \bar{\nu}_{e(\mu)}) = P(\nu_{\mu(e)} \rightarrow \nu_{e(\mu)})$. Here $P^{2\nu}(|U_{e3}|^2, m_{31}^2)$ is the probability of the 2-neutrino transition $\nu_e \rightarrow (s_{23}\nu_\mu + c_{23}\nu_\tau)$ due to Δm_{31}^2 and a mixing with angle θ_{13} , where

$$\begin{aligned} \sin^2 \theta_{13} &= |U_{e3}|^2, \quad s_{23}^2 \equiv \sin^2 \theta_{23} = \frac{|U_{\mu 3}|^2}{1 - |U_{e3}|^2}, \\ c_{23}^2 &\equiv \cos^2 \theta_{23} = \frac{|U_{\tau 3}|^2}{1 - |U_{e3}|^2}. \end{aligned} \quad (13.24)$$

Eq. (13.22) describes with a relatively high precision the oscillations of reactor $\bar{\nu}_e$ on a distance $L \sim 1$ km in the case of 3-neutrino mixing. It was used in the analysis of the data of the Chooz [58], Double Chooz [59], Daya Bay [26] and RENO [27] experiments. Eq. (13.20) with $n = 3$ and $l = l' = \mu$ describes with a relatively good precision the effects of oscillations of the accelerator ν_μ , seen in the K2K [19]

and MINOS [20,21] experiments. The $\nu_\mu \rightarrow \nu_\tau$ oscillations, which the OPERA experiment [60,61] is aiming to detect, can be described by Eq. (13.20) with $n = 3$ and $l = \mu, l' = \tau$. Finally, the probability Eq. (13.23) describes with a good precision the $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillations under the conditions of the K2K experiment.

In certain cases the dimensions of the neutrino source, ΔL , are not negligible in comparison with the oscillation length. Similarly, when analyzing neutrino oscillation data one has to include the energy resolution of the detector, ΔE , etc. in the analysis. As can be shown [39], if $2\pi\Delta L/L_{jk}^v \gg 1$, and/or $2\pi(L/L_{jk}^v)(\Delta E/E) \gg 1$, the oscillating terms in the neutrino oscillation probabilities will be strongly suppressed. In this case (as well as in the case of sufficiently large separation of the ν_j and ν_k wave packets at the detection point) the interference terms in $P(\nu_l \rightarrow \nu_{l'})$ and $P(\bar{\nu}_l \rightarrow \bar{\nu}_{l'})$ will be negligibly small and the neutrino flavour conversion will be determined by the average probabilities:

$$\bar{P}(\nu_l \rightarrow \nu_{l'}) = \bar{P}(\bar{\nu}_l \rightarrow \bar{\nu}_{l'}) \cong \sum_j |U_{l'j}|^2 |U_{lj}|^2. \quad (13.25)$$

Suppose next that in the case of 3-neutrino mixing, $|\Delta m_{21}^2| L/(2p) \sim 1$, while at the same time $|\Delta m_{31(32)}^2| L/(2p) \gg 1$, and the oscillations due to Δm_{31}^2 and Δm_{32}^2 are strongly suppressed (averaged out) due to integration over the region of neutrino production, the energy resolution function, etc. In this case we get for the ν_e and $\bar{\nu}_e$ survival probabilities:

$$P(\nu_e \rightarrow \nu_e) = P(\bar{\nu}_e \rightarrow \bar{\nu}_e) \cong |U_{e3}|^4 + (1 - |U_{e3}|^2)^2 P^{2\nu}(\nu_e \rightarrow \nu_e), \quad (13.26)$$

$$P^{2\nu}(\nu_e \rightarrow \nu_e) = P^{2\nu}(\bar{\nu}_e \rightarrow \bar{\nu}_e) \equiv P_{ee}^{2\nu}(\theta_{12}, \Delta m_{21}^2) = 1 - \frac{1}{2} \sin^2 2\theta_{12} \left(1 - \cos \frac{\Delta m_{21}^2 L}{2p} \right) \quad (13.27)$$

being the ν_e and $\bar{\nu}_e$ survival probability in the case of 2-neutrino oscillations “driven” by the angle θ_{12} and Δm_{21}^2 , with θ_{12} determined by

$$\cos^2 \theta_{12} = \frac{|U_{e1}|^2}{1 - |U_{e3}|^2}, \quad \sin^2 \theta_{12} = \frac{|U_{e2}|^2}{1 - |U_{e3}|^2}. \quad (13.28)$$

Eq. (13.26) with $P^{2\nu}(\bar{\nu}_e \rightarrow \bar{\nu}_e)$ given by Eq. (13.27) describes the effects of neutrino oscillations of reactor $\bar{\nu}_e$ observed by the KamLAND experiment.

In the case of 3-neutrino mixing with $0 < \Delta m_{21}^2 < |\Delta m_{31(32)}^2|$ and $|U_{e3}|^2 = |\sin \theta_{13}|^2 \ll 1$ (see Section 13.6), one can identify Δm_{21}^2 and θ_{12} as the neutrino mass squared difference and mixing angle responsible for the solar ν_e oscillations, and Δm_{31}^2 and θ_{23} as those associated with the dominant atmospheric ν_μ and $\bar{\nu}_\mu$ oscillations. Thus, θ_{12} and θ_{23} are often called “solar” and “atmospheric” neutrino mixing angles and denoted as $\theta_{12} = \theta_\odot$ and $\theta_{23} = \theta_A$ (or θ_{atm}), while Δm_{21}^2 and Δm_{31}^2 are often referred to as the “solar” and “atmospheric” neutrino mass squared differences and denoted as $\Delta m_{21}^2 \equiv \Delta m_\odot^2$ and $\Delta m_{31}^2 \equiv \Delta m_A^2$ (or Δm_{atm}^2).

The data of ν -oscillations experiments is often analyzed assuming 2-neutrino mixing:

$$|\nu_l\rangle = |\nu_1\rangle \cos \theta + |\nu_2\rangle \sin \theta, \quad |\nu_x\rangle = -|\nu_1\rangle \sin \theta + |\nu_2\rangle \cos \theta, \quad (13.29)$$

where θ is the neutrino mixing angle in vacuum and ν_x is another flavour neutrino or sterile (anti-) neutrino, $x = l' \neq l$ or $\nu_x \equiv \bar{\nu}_{sL}$. In this case we have [51]:

$$P^{2\nu}(\nu_l \rightarrow \nu_l) = 1 - \frac{1}{2} \sin^2 2\theta \left(1 - \cos 2\pi \frac{L}{L^v} \right), \quad P^{2\nu}(\nu_l \rightarrow \nu_x) = 1 - P^{2\nu}(\nu_l \rightarrow \nu_l), \quad (13.30)$$

where $L^v = 4\pi p/\Delta m^2$, $\Delta m^2 = m_2^2 - m_1^2 > 0$. Combining the CPT invariance constraints with the probability conservation one obtains: $P(\nu_l \rightarrow \nu_x) = P(\bar{\nu}_l \rightarrow \bar{\nu}_x) = P(\nu_x \rightarrow \nu_l) = P(\bar{\nu}_x \rightarrow \bar{\nu}_l)$.

These equalities and Eq. (13.30) with $l = \mu$ and $x = \tau$ were used, for instance, in the analysis of the Super-K atmospheric neutrino data [13], in which the first compelling evidence for oscillations of neutrinos was obtained. The probability $P^{2\nu}(\nu_l \rightarrow \nu_x)$, Eq. (13.30), depends on two factors: on $(1 - \cos 2\pi L/L^v)$, which exhibits oscillatory dependence on the distance L and on the neutrino energy $p = E$ (hence the name “neutrino oscillations”), and on $\sin^2 2\theta$, which determines the amplitude of the oscillations. In order to have $P^{2\nu}(\nu_l \rightarrow \nu_x) \cong 1$, two conditions have to be fulfilled: one should have $\sin^2 2\theta \cong 1$ and $L^v \lesssim 2\pi L$ with $\cos 2\pi L/L^v \cong -1$. If $L^v \gg 2\pi L$, the oscillations do not have enough time to develop on the way to the neutrino detector and $P(\nu_l \rightarrow \nu_x) \cong 0$. This is illustrated in Fig. 1 showing the dependence of the probability $P^{2\nu}(\nu_e \rightarrow \nu_e) = P^{2\nu}(\bar{\nu}_e \rightarrow \bar{\nu}_e)$ on the neutrino energy.

A given experiment searching for neutrino oscillations is specified, in particular, by the average energy of the neutrinos being studied, \bar{E} , and by the source-detector distance L . The requirement $L_{jk}^v \lesssim 2\pi L$ determines the minimal value of a generic neutrino mass squared difference $\Delta m^2 > 0$, to which the experiment is sensitive (figure of merit of the experiment): $\min(\Delta m^2) \sim 2\bar{E}/L$. Because of the interference nature of neutrino oscillations, experiments can probe, in general, rather small values of Δm^2 (see, e.g., Ref. 47). Values of $\min(\Delta m^2)$, characterizing qualitatively the sensitivity of different experiments are given in Table 1. They correspond to the reactor experiments Chooz ($L \sim 1$ km) and KamLAND ($L \sim 100$ km), to accelerator experiments - past ($L \sim 1$ km), recent, current and future (K2K, MINOS, OPERA, T2K, NOVA [63]), $L \sim (300 \div 1000)$ km), to the Super-Kamiokande experiment studying atmospheric neutrino oscillations, and to the solar neutrino experiments.

13.3. Matter effects in neutrino oscillations

The presence of matter can change drastically the pattern of neutrino oscillations: neutrinos can interact with the particles forming the matter. Accordingly, the Hamiltonian of the neutrino system in matter H_m , differs from the Hamiltonian in vacuum H_0 , $H_m = H_0 + H_{\text{int}}$, where H_{int} describes the interaction of neutrinos with the particles of matter. When, for instance, ν_e and ν_μ propagate in matter, they can scatter (due to H_{int}) on the electrons (e^-), protons (p) and neutrons (n) present in matter. The incoherent elastic and the quasi-elastic scattering, in which the states of the initial particles change in the process (destroying the coherence between the neutrino states), are not of interest - they have a negligible effect on the solar neutrino propagation in the Sun and on the solar, atmospheric and reactor neutrino propagation in the Earth [64]: even in the center of the Sun, where the matter density is relatively high (~ 150 g/cm³), a ν_e with energy of 1 MeV has a mean free path with respect to the indicated scattering processes $\sim 10^{10}$ km. We recall that the solar radius is much smaller: $R_\odot = 6.96 \times 10^5$ km. The oscillating ν_e and ν_μ can scatter also elastically in the forward direction on the e^- , p and n , with the momenta and the spin states of the particles remaining unchanged. In such a process the coherence of the neutrino states is preserved.

The ν_e and ν_μ coherent elastic scattering on the particles of matter generates nontrivial indices of refraction of the ν_e and ν_μ in matter [22]: $\kappa(\nu_e) \neq 1$, $\kappa(\nu_\mu) \neq 1$. Most importantly, we have $\kappa(\nu_e) \neq \kappa(\nu_\mu)$. The difference $\kappa(\nu_e) - \kappa(\nu_\mu)$ is determined essentially by the difference of the real parts of the forward $\nu_e - e^-$ and $\nu_\mu - e^-$ elastic scattering amplitudes [22] $\text{Re}[F_{\nu_e e^-}(0)] - \text{Re}[F_{\nu_\mu e^-}(0)]$: due to the flavour symmetry of the neutrino - quark (neutrino - nucleon) neutral current interaction, the forward $\nu_e - p, n$ and $\nu_\mu - p, n$ elastic scattering amplitudes are equal and therefore do not contribute to the difference of interest [65]. The imaginary parts of the forward scattering amplitudes (responsible, in particular, for decoherence effects) are proportional to the corresponding total scattering cross-sections and in the case of interest are negligible in comparison with the real parts. The real parts of the amplitudes $F_{\nu_e e^-}(0)$ and $F_{\nu_\mu e^-}(0)$ can be calculated in the Standard Model. To leading order in the Fermi constant G_F , only the term in $F_{\nu_e e^-}(0)$ due to the diagram with exchange of a virtual W^\pm -boson contributes to $F_{\nu_e e^-}(0) - F_{\nu_\mu e^-}(0)$. One finds the following result

for $\kappa(\nu_e) - \kappa(\nu_\mu)$ in the rest frame of the scatters [22,67,68]:

$$\begin{aligned}\kappa(\nu_e) - \kappa(\nu_\mu) &= \frac{2\pi}{p^2} \left(\text{Re} [F_{\nu_e e^-}(0)] - \text{Re} [F_{\nu_\mu e^-}(0)] \right) \\ &= -\frac{1}{p} \sqrt{2} G_F N_e, \end{aligned} \quad (13.31)$$

where N_e is the electron number density in matter. Given $\kappa(\nu_e) - \kappa(\nu_\mu)$, the system of evolution equations describing the $\nu_e \leftrightarrow \nu_\mu$ oscillations in matter reads [22]:

$$i \frac{d}{dt} \begin{pmatrix} A_e(t, t_0) \\ A_\mu(t, t_0) \end{pmatrix} = \begin{pmatrix} -\epsilon(t) & \epsilon' \\ \epsilon' & \epsilon(t) \end{pmatrix} \begin{pmatrix} A_e(t, t_0) \\ A_\mu(t, t_0) \end{pmatrix} \quad (13.32)$$

where $A_e(t, t_0)$ ($A_\mu(t, t_0)$) is the amplitude of the probability to find ν_e (ν_μ) at time t of the evolution of the system if at time $t_0 \leq t$ the neutrino ν_e or ν_μ has been produced and

$$\epsilon(t) = \frac{1}{2} \left[\frac{\Delta m^2}{2E} \cos 2\theta - \sqrt{2} G_F N_e(t) \right], \quad \epsilon' = \frac{\Delta m^2}{4E} \sin 2\theta. \quad (13.33)$$

The term $\sqrt{2} G_F N_e(t)$ in $\epsilon(t)$ accounts for the effects of matter on neutrino oscillations. The system of evolution equations describing the oscillations of antineutrinos $\bar{\nu}_e \leftrightarrow \bar{\nu}_\mu$ in matter has exactly the same form except for the matter term in $\epsilon(t)$ which changes sign. The effect of matter in neutrino oscillations is usually called the Mikheyev, Smirnov, Wolfenstein (or MSW) effect.

Consider first the case of $\nu_e \leftrightarrow \nu_\mu$ oscillations in matter with constant density: $N_e(t) = N_e = \text{const.}$ Due to the interaction term H_{int} in H_m , the eigenstates of the Hamiltonian of the neutrino system in vacuum, $|\nu_{1,2}\rangle$ are not eigenstates of H_m . For the eigenstates $|\nu_{1,2}^m\rangle$ of H_m , which diagonalize the evolution matrix in the r.h.s. of the system Eq. (13.32) we have:

$$|\nu_e\rangle = |\nu_1^m\rangle \cos \theta_m + |\nu_2^m\rangle \sin \theta_m, \quad |\nu_\mu\rangle = -|\nu_1^m\rangle \sin \theta_m + |\nu_2^m\rangle \cos \theta_m. \quad (13.34)$$

Here θ_m is the neutrino mixing angle in matter [22],

$$\sin 2\theta_m = \frac{\tan 2\theta}{\sqrt{\left(1 - \frac{N_e}{N_e^{res}}\right)^2 + \tan^2 2\theta}}, \quad \cos 2\theta_m = \frac{1 - N_e/N_e^{res}}{\sqrt{\left(1 - \frac{N_e}{N_e^{res}}\right)^2 + \tan^2 2\theta}}, \quad (13.35)$$

where the quantity

$$N_e^{res} = \frac{\Delta m^2 \cos 2\theta}{2E\sqrt{2}G_F} \cong 6.56 \times 10^6 \frac{\Delta m^2 [\text{eV}^2]}{E [\text{MeV}]} \cos 2\theta \text{ cm}^{-3} N_A, \quad (13.36)$$

is called (for $\Delta m^2 \cos 2\theta > 0$) “resonance density” [23,67], N_A being Avogadro’s number. The “adiabatic” states $|\nu_{1,2}^m\rangle$ have energies $E_{1,2}^m$ whose difference is given by

$$E_2^m - E_1^m = \frac{\Delta m^2}{2E} \left(\left(1 - \frac{N_e}{N_e^{res}}\right)^2 \cos^2 2\theta + \sin^2 2\theta \right)^{\frac{1}{2}} \equiv \frac{\Delta m^2}{2E}. \quad (13.37)$$

The probability of $\nu_e \rightarrow \nu_\mu$ transition in matter with $N_e = \text{const.}$ has the form [22,67]

$$\begin{aligned} P_m^{2\nu}(\nu_e \rightarrow \nu_\mu) &= |A_\mu(t)|^2 = \frac{1}{2} \sin^2 2\theta_m \left[1 - \cos 2\pi \frac{L}{L_m} \right] \\ L_m &= 2\pi / (E_2^m - E_1^m), \end{aligned} \quad (13.38)$$

where L_m is the oscillation length in matter. As Eq. (13.35) indicates, the dependence of $\sin^2 2\theta_m$ on N_e has a resonance character [23]. Indeed, if $\Delta m^2 \cos 2\theta > 0$, for any $\sin^2 2\theta \neq 0$ there exists a value of N_e given by N_e^{res} , such that when $N_e = N_e^{res}$ we have $\sin^2 2\theta_m = 1$ independently of the value of $\sin^2 2\theta < 1$. This implies that the presence of matter can lead to a strong enhancement of the oscillation probability $P_m^{2\nu}(\nu_e \rightarrow \nu_\mu)$ even when the $\nu_e \leftrightarrow \nu_\mu$ oscillations in vacuum are suppressed due to a small value of $\sin^2 2\theta$. For obvious reasons

$$N_e = N_e^{res} \equiv \frac{\Delta m^2 \cos 2\theta}{2E\sqrt{2}G_F}, \quad (13.39)$$

is called the “resonance condition” [23,67], while the energy at which Eq. (13.39) holds for given N_e and $\Delta m^2 \cos 2\theta$, is referred to as the “resonance energy”, E^{res} . The oscillation length at resonance is given by [23] $L_m^{res} = L^v / \sin 2\theta$, while the width in N_e of the resonance at half height reads $\Delta N_e^{res} = 2N_e^{res} \tan 2\theta$. Thus, if the mixing angle in vacuum is small, the resonance is narrow, $\Delta N_e^{res} \ll N_e^{res}$, and $L_m^{res} \gg L^v$. The energy difference $E_2^m - E_1^m$ has a minimum at the resonance: $(E_2^m - E_1^m)^{res} = \min (E_2^m - E_1^m) = (\Delta m^2 / (2E)) \sin 2\theta$.

It is instructive to consider two limiting cases. If $N_e \ll N_e^{res}$, we have from Eq. (13.35) and Eq. (13.37), $\theta_m \cong \theta$, $L_m \cong L^v$ and neutrinos oscillate practically as in vacuum. In the limit $N_e \gg N_e^{res}$, $N_e^{res} \tan^2 2\theta$, one finds $\theta_m \cong \pi/2$ ($\cos 2\theta_m \cong -1$) and the presence of matter suppresses the $\nu_e \leftrightarrow \nu_\mu$ oscillations. In this case $|\nu_e\rangle \cong |\nu_2^m\rangle$, $|\nu_\mu\rangle = -|\nu_1^m\rangle$, i.e., ν_e practically coincides with the heavier matter-eigenstate, while ν_μ coincides with the lighter one.

Since the neutral current weak interaction of neutrinos in the Standard Model is flavour symmetric, the formulae and results we have obtained are valid for the case of $\nu_e - \nu_\tau$ mixing and $\nu_e \leftrightarrow \nu_\tau$ oscillations in matter as well. The case of $\nu_\mu - \nu_\tau$ mixing, however, is different: to a relatively good precision we have [69] $\kappa(\nu_\mu) \cong \kappa(\nu_\tau)$ and the $\nu_\mu \leftrightarrow \nu_\tau$ oscillations in the matter of the Earth and the Sun proceed practically as in vacuum [70].

The analogs of Eq. (13.35) to Eq. (13.38) for oscillations of antineutrinos, $\bar{\nu}_e \leftrightarrow \bar{\nu}_\mu$, in matter can formally be obtained by replacing N_e with $(-N_e)$ in the indicated equations. It should be clear that depending on the sign of $\Delta m^2 \cos 2\theta$, the presence of matter can lead to resonance enhancement either of the $\nu_e \leftrightarrow \nu_\mu$ or of the $\bar{\nu}_e \leftrightarrow \bar{\nu}_\mu$ oscillations, but not of both types of oscillations [67]. For $\Delta m^2 \cos 2\theta < 0$, for instance, the matter can only suppress the $\nu_e \rightarrow \nu_\mu$ oscillations, while it can enhance the $\bar{\nu}_e \rightarrow \bar{\nu}_\mu$ transitions. This disparity between the behavior of neutrinos and that of antineutrinos is a consequence of the fact that the matter in the Sun or in the Earth we are interested in is not charge-symmetric (it contains e^- , p and n , but does not contain their antiparticles) and therefore the oscillations in matter are neither CP- nor CPT- invariant [54]. Thus, even in the case of 2-neutrino mixing and oscillations we have, e.g., $P_m^{2\nu}(\nu_e \rightarrow \nu_\mu(\tau)) \neq P_m^{2\nu}(\bar{\nu}_e \rightarrow \bar{\nu}_\mu(\tau))$.

The matter effects in the $\nu_e \leftrightarrow \nu_\mu(\tau)$ ($\bar{\nu}_e \leftrightarrow \bar{\nu}_\mu(\tau)$) oscillations will be invariant with respect to the operation of time reversal if the N_e distribution along the neutrino path is symmetric with respect to this operation [55,71]. The latter condition is fulfilled (to a good approximation) for the N_e distribution along a path of a neutrino crossing the Earth [72].

13.3.1. Effects of Earth matter on oscillations of neutrinos :

The formalism we have developed can be applied, e.g., to the study of matter effects in the $\nu_e \leftrightarrow \nu_\mu(\tau)$ ($\nu_\mu(\tau) \leftrightarrow \nu_e$) and $\bar{\nu}_e \leftrightarrow \bar{\nu}_\mu(\tau)$ ($\bar{\nu}_\mu(\tau) \leftrightarrow \bar{\nu}_e$) oscillations of neutrinos which traverse the Earth [73]. Indeed, the Earth density distribution in the existing Earth models [72] is assumed to be spherically symmetric and there are two major density structures - the core and the mantle, and a certain number of substructures (shells or layers). The Earth radius is $R_\oplus = 6371$ km; the Earth core has a radius of $R_c = 3486$ km, so the Earth mantle depth is 2885 km. For a spherically symmetric Earth density distribution, the neutrino trajectory in the Earth is specified by the value of the nadir angle θ_n of the trajectory. For $\theta_n \leq 33.17^\circ$, or path lengths $L \geq 10660$ km, neutrinos cross the Earth core. The path length for neutrinos which cross only the Earth mantle is given by $L = 2R_\oplus \cos \theta_n$. If neutrinos cross the Earth core, the lengths of the paths in the mantle, $2L^{\text{man}}$, and in the core, L^{core} , are determined by: $L^{\text{man}} = R_\oplus \cos \theta_n - (R_c^2 - R_\oplus^2 \sin^2 \theta_n)^{\frac{1}{2}}$, $L^{\text{core}} = 2(R_c^2 - R_\oplus^2 \sin^2 \theta_n)^{\frac{1}{2}}$. The mean electron number densities in the mantle and in the core according to the PREM model read [72]: $\bar{N}_e^{\text{man}} \cong 2.2 \text{ cm}^{-3} N_A$, $\bar{N}_e^{\text{core}} \cong 5.4 \text{ cm}^{-3} N_A$. Thus, we have $\bar{N}_e^{\text{core}} \cong 2.5 \bar{N}_e^{\text{man}}$. The change of \bar{N}_e from the mantle to the core can well be approximated by a step function [72]. The electron number density N_e changes relatively little around the indicated mean values along the trajectories of neutrinos which cross a substantial part of the Earth mantle, or the mantle and the core, and the two-layer constant density approximation, $N_e^{\text{man}} = \text{const.} = \bar{N}_e^{\text{man}}$, $N_e^{\text{core}} = \text{const.} = \bar{N}_e^{\text{core}}$, and \bar{N}_e^{core} being the mean densities along the given neutrino path in

the Earth, was shown to be sufficiently accurate in what concerns the calculation of neutrino oscillation probabilities [55,75,76] (and references quoted in [75,76]) in a large number of specific cases. This is related to the fact that the relatively small changes of density along the path of the neutrinos in the mantle (or in the core) take place over path lengths which are typically considerably smaller than the corresponding oscillation length in matter.

In the case of 3-neutrino mixing and for neutrino energies of $E \gtrsim 2$ GeV, the effects due to Δm_{21}^2 ($|\Delta m_{21}^2| \ll |\Delta m_{31}^2|$, see Eq. (13.21)) in the neutrino oscillation probabilities are sub-dominant and to leading order can be neglected: the corresponding resonance density $|N_{e21}^{res}| \lesssim 0.25 \text{ cm}^{-3} N_A \ll \bar{N}_e^{man,c}$ and the Earth matter strongly suppresses the oscillations due to Δm_{21}^2 . For oscillations in vacuum this approximation is valid as long as the leading order contribution due to Δm_{31}^2 in the relevant probabilities is bigger than approximately 10^{-3} . In this case the 3-neutrino $\nu_e \rightarrow \nu_{\mu(\tau)}$ ($\bar{\nu}_e \rightarrow \bar{\nu}_{\mu(\tau)}$) and $\nu_{\mu(\tau)} \rightarrow \nu_e$ ($\bar{\nu}_{\mu(\tau)} \rightarrow \bar{\nu}_e$) transition probabilities for neutrinos traversing the Earth, reduce effectively to a 2-neutrino transition probability (see, e.g., Refs. [76–78]), with Δm_{31}^2 and θ_{13} playing the role of the relevant 2-neutrino vacuum oscillation parameters. As will be discussed in Sections 13.6 and 13.7, the value of $\sin^2 2\theta_{13}$ has been determined recently with a rather high precision in the Daya Bay [26] and RENO [27] experiments. The best fit values found in the two experiments read, respectively, $\sin^2 2\theta_{13} = 0.092$ and 0.113 , while the 3σ allowed range reported in [26] is $0.04 \lesssim \sin^2 2\theta_{13} \lesssim 0.14$. The 3-neutrino oscillation probabilities of the atmospheric and accelerator $\nu_{e,\mu}$ having energy E and crossing the Earth along a trajectory characterized by a nadir angle θ_n , for instance, have the following form:

$$P_m^{3\nu}(\nu_e \rightarrow \nu_e) \cong 1 - P_m^{2\nu}, \quad (13.40)$$

$$P_m^{3\nu}(\nu_e \rightarrow \nu_\mu) \cong P_m^{3\nu}(\nu_\mu \rightarrow \nu_e) \cong s_{23}^2 P_m^{2\nu}, \quad P_m^{3\nu}(\nu_e \rightarrow \nu_\tau) \cong c_{23}^2 P_m^{2\nu}, \quad (13.41)$$

$$P_m^{3\nu}(\nu_\mu \rightarrow \nu_\mu) \cong 1 - s_{23}^4 P_m^{2\nu} - 2c_{23}^2 s_{23}^2 \left[1 - R_e (e^{-i\kappa} A_m^{2\nu}(\nu' \rightarrow \nu')) \right], \quad (13.42)$$

$$P_m^{3\nu}(\nu_\mu \rightarrow \nu_\tau) = 1 - P_m^{3\nu}(\nu_\mu \rightarrow \nu_\mu) - P_m^{3\nu}(\nu_\mu \rightarrow \nu_e). \quad (13.43)$$

Here $P_m^{2\nu} \equiv P_m^{2\nu}(\Delta m_{31}^2, \theta_{13}; E, \theta_n)$ is the probability of the 2-neutrino $\nu_e \rightarrow \nu' \equiv (s_{23}\nu_\mu + c_{23}\nu_\tau)$ oscillations in the Earth, and κ and $A_m^{2\nu}(\nu' \rightarrow \nu') \equiv A_m^{2\nu}$ are known phase and 2-neutrino transition probability amplitude (see, e.g., Refs. [76,77]). We note that Eq. (13.40) to Eq. (13.42) are based only on the assumptions that $|N_{e21}^{res}|$ is much smaller than the densities in the Earth mantle and core and that $|\Delta m_{21}^2| \ll |\Delta m_{31}^2|$, and does not rely on the constant density approximation. Similar results are valid for the corresponding antineutrino oscillation probabilities: one has just to replace $P_m^{2\nu}$, κ and $A_m^{2\nu}$ in the expressions given above with the corresponding quantities for antineutrinos (the latter are obtained from those for neutrinos by changing the sign in front of N_e). Obviously, we have: $P(\nu_{e(\mu)} \rightarrow \nu_{\mu(e)})$, $P(\bar{\nu}_{e(\mu)} \rightarrow \bar{\nu}_{\mu(e)}) \leq \sin^2 \theta_{23}$, and $P(\nu_e \rightarrow \nu_\tau)$, $P(\bar{\nu}_e \rightarrow \bar{\nu}_\tau) \leq \cos^2 \theta_{23}$. The one Δm^2 dominance approximation and correspondingly Eq. (13.40) to Eq. (13.43) were used by the Super-Kamiokande Collaboration in their 2006 neutrino oscillation analysis of the multi-GeV atmospheric neutrino data [79].

In the case of neutrinos crossing only the Earth mantle and in the constant density approximation, $P_m^{2\nu}$ is given by the r.h.s. of Eq. (13.38) with θ and Δm^2 replaced by θ_{13} and Δm_{31}^2 , while for κ and $A_m^{2\nu}$ we have (see, e.g., Ref. 76):

$$\kappa \cong \frac{1}{2} \left[\frac{\Delta m_{31}^2}{2E} L + \sqrt{2} G_F \bar{N}_e^{man} L - \frac{\Delta M^2 L}{2E} \right],$$

$$A_m^{2\nu} = 1 + (e^{-i\frac{\Delta M^2 L}{2E}} - 1) \cos^2 \theta'_m, \quad (13.44)$$

where ΔM^2 is defined in Eq. (13.37) (with $\theta = \theta_{13}$ and $\Delta m^2 = \Delta m_{31}^2$), θ'_m is the mixing angle in the mantle which coincides in vacuum with θ_{13} (Eq. (13.35) with $N_e = \bar{N}_e^{man}$ and $\theta = \theta_{13}$), and $L = 2R_\oplus \cos \theta_n$ is the distance the neutrino travels in the mantle.

It follows from Eq. (13.40) and Eq. (13.41) that for $\Delta m_{31}^2 \cos 2\theta_{13} > 0$, the oscillation effects of interest, e.g., in the $\nu_{e(\mu)} \rightarrow \nu_{\mu(e)}$ and $\nu_e \rightarrow \nu_\tau$ transitions will be maximal if $P_m^{2\nu} \cong 1$, i.e., if Eq. (13.39)

leading to $\sin^2 2\theta_m \cong 1$ is fulfilled, and ii) $\cos(\Delta M^2 L / (2E)) \cong -1$. Given the value of \bar{N}_e^{man} , the first condition determines the neutrino's energy, while the second determines the path length L , for which one can have $P_m^{2\nu} \cong 1$. For $\Delta m_{31}^2 \cong 2.4 \times 10^{-3} \text{ eV}^2$, $\sin^2 2\theta_{13} \lesssim 0.14$ and $\bar{N}_e^{man} \cong 2.2 N_A \text{ cm}^{-3}$, one finds that $E_{res} \cong 7.2 \text{ GeV}$ and $L \cong 2370 / \sin 2\theta_{13} \text{ km} \gtrsim 6267.3 \text{ km}$. Since for neutrinos crossing only the mantle $L \lesssim 10660 \text{ km}$, the second condition can be satisfied only if $\sin \theta_{13} \gtrsim 0.11$, which falls in the range of the experimentally allowed values of $\sin \theta_{13}$. Thus, for $\Delta m_{31}^2 > 0$, the Earth matter effects can amplify $P_m^{2\nu}$, and therefore $P(\nu_{e(\mu)} \rightarrow \nu_{\mu(e)})$ and $P(\nu_e \rightarrow \nu_\tau)$, maximally when the neutrinos cross only the mantle for $E \sim 7 \text{ GeV}$ and $L \gtrsim 5400 \text{ km}$, or $\cos \theta_n \gtrsim 0.43$, provided $\sin \theta_{13} \gtrsim 0.1$. If $\Delta m_{31}^2 < 0$ the same considerations apply for the corresponding antineutrino oscillation probabilities $\bar{P}_m^{2\nu} = \bar{P}_m^{2\nu}(\bar{\nu}_e \rightarrow (s_{23}\bar{\nu}_\mu + c_{23}\bar{\nu}_\tau))$ and correspondingly for $P(\bar{\nu}_{e(\mu)} \rightarrow \bar{\nu}_{\mu(e)})$ and $P(\bar{\nu}_e \rightarrow \bar{\nu}_\tau)$. For $\Delta m_{31}^2 > 0$, the $\bar{\nu}_{e(\mu)} \rightarrow \bar{\nu}_{\mu(e)}$ and $\bar{\nu}_e \rightarrow \bar{\nu}_\tau$ oscillations are suppressed by the Earth matter, while if $\Delta m_{31}^2 < 0$, the same conclusion holds for the $\nu_{e(\mu)} \rightarrow \nu_{\mu(e)}$ and $\nu_e \rightarrow \nu_\tau$ oscillations.

In the case of neutrinos crossing the Earth core, new resonance-like effects become possible in the $\nu_\mu \rightarrow \nu_e$ and $\nu_e \rightarrow \nu_{\mu(\tau)}$ (or $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ and $\bar{\nu}_e \rightarrow \bar{\nu}_{\mu(\tau)}$) transitions [75–77,80–82]. For $\sin^2 \theta_{13} \lesssim 0.05$ and $\Delta m_{31}^2 > 0$, we can have [81] $P_m^{2\nu}(\Delta m_{31}^2, \theta_{13}) \cong 1$, and correspondingly maximal $P_m^{3\nu}(\nu_e \rightarrow \nu_\mu) = P_m^{3\nu}(\nu_\mu \rightarrow \nu_e) \cong s_{23}^2$, only due to the effect of maximal constructive interference between the amplitudes of the $\nu_e \rightarrow \nu'$ transitions in the Earth mantle and in the Earth core. The effect differs from the MSW one and the enhancement happens in the case of interest at a value of the energy between the MSW resonance energies corresponding to the density in the mantle and that of the core, or at a value of the resonance density N_e^{res} which lies between the values of N_e in the mantle and in the core [75]. In Refs. [75,76] the enhancement was called “neutrino oscillation length resonance”, while in Refs. [77,80] the term “parametric resonance” for the same effect was used [83]. The *mantle-core enhancement effect* is caused by the existence (for a given neutrino trajectory through the Earth core) of points of resonance-like maximal neutrino conversion, $P_m^{2\nu}(\Delta m_{31}^2, \theta_{13}) = 1$, in the corresponding space of neutrino oscillation parameters [81]. For $\Delta m_{31}^2 < 0$ the mantle-core enhancement can take place for the antineutrino transitions, $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ and $\bar{\nu}_e \rightarrow \bar{\nu}_{\mu(\tau)}$.

A rather complete set of values of $\Delta m_{31}^2/E > 0$ and $\sin^2 2\theta_{13}$ for which $P_m^{2\nu}(\Delta m_{31}^2, \theta_{13}) = 1$ was found in Ref. 81. The location of these points in the $\Delta m_{31}^2/E - \sin^2 2\theta_{13}$ plane determines the regions in the plane where $P_m^{2\nu}(\Delta m_{31}^2, \theta_{13})$ is large, $P_m^{2\nu}(\Delta m_{31}^2, \theta_{13}) \gtrsim 0.5$. These regions vary slowly with the nadir angle, being remarkably wide in the nadir angle and rather wide in the neutrino energy [81], so that the transitions of interest can produce noticeable effects in the measured observables. For $\sin^2 \theta_{13} \lesssim 0.05$, there are two sets of values of $(\Delta m_{31}^2/E, \sin^2 \theta_{13})$ for which $P_m^{2\nu}(\Delta m_{31}^2, \theta_{13}) = 1$, and thus two regions in $\Delta m_{31}^2/E - \sin^2 2\theta_{13}$ plane where $P_m^{2\nu}(\Delta m_{31}^2, \theta_{13}) \gtrsim 0.5$. For $\Delta m_{31}^2 = 2.4 \times 10^{-3} \text{ eV}^2$ and nadir angle, e.g., $\theta_n = 0$ (Earth center crossing neutrinos), we have $P_m^{2\nu}(\Delta m_{31}^2, \theta_{13}) = 1$ at $(E, \sin^2 2\theta_{13}) = (3.3 \text{ GeV}, 0.034)$ and $(5.0 \text{ GeV}, 0.15)$. At the same time for $E = 3.3 \text{ GeV}$ (5.0 GeV), the probability $P_m^{2\nu}(\Delta m_{31}^2, \theta_{13}) \gtrsim 0.5$ for the values of $\sin^2 2\theta_{13}$ from the interval $0.02 \lesssim \sin^2 2\theta_{13} \lesssim 0.10$ ($0.04 \lesssim \sin^2 2\theta_{13} \lesssim 0.26$). Similar results hold for neutrinos crossing the Earth core along the trajectories with $\theta_n \neq 0$ (for further details see the last article in Ref. 81; see also the last article in Ref. 82).

The mantle-core enhancement of $P_m^{2\nu}$ (or $\bar{P}_m^{2\nu}$) is relevant, in particular, for the searches of sub-dominant $\nu_{e(\mu)} \rightarrow \nu_{\mu(e)}$ (or $\bar{\nu}_{e(\mu)} \rightarrow \bar{\nu}_{\mu(e)}$) oscillations of atmospheric neutrinos having energies $E \gtrsim 2 \text{ GeV}$ and crossing the Earth core on the way to the detector (see Ref. 75 to Ref. 82 and the references quoted therein). The effects of Earth matter on the oscillations of atmospheric and accelerator neutrinos have not been observed so far. At present there are no compelling evidences for oscillations of the atmospheric ν_e and/or $\bar{\nu}_e$.

The expression for the probability of the $\nu_e \rightarrow \nu_\mu$ oscillations taking place in the Earth mantle in the case of 3-neutrino mixing, in which both neutrino mass squared differences Δm_{21}^2 and Δm_{31}^2 contribute and the CP violation effects due to the Dirac phase in the neutrino mixing matrix are taken into account, has the following

form in the constant density approximation and keeping terms up to second order in the two small parameters $|\alpha| \equiv |\Delta m_{21}^2|/|\Delta m_{31}^2| \ll 1$ and $\sin^2 \theta_{13} \ll 1$ [84]:

$$P_m^{3\nu \text{ man}}(\nu_e \rightarrow \nu_\mu) \cong P_0 + P_{\sin \delta} + P_{\cos \delta} + P_3. \quad (13.45)$$

Here

$$P_0 = \sin^2 \theta_{23} \frac{\sin^2 2\theta_{13}}{(A-1)^2} \sin^2[(A-1)\Delta]$$

$$P_3 = \alpha^2 \cos^2 \theta_{23} \frac{\sin^2 2\theta_{12}}{A^2} \sin^2(A\Delta), \quad (13.46)$$

$$P_{\sin \delta} = \alpha \frac{8 J_{CP}}{A(1-A)} (\sin \Delta) (\sin A\Delta) (\sin[(1-A)\Delta]), \quad (13.47)$$

$$P_{\cos \delta} = \alpha \frac{8 J_{CP} \cot \delta}{A(1-A)} (\cos \Delta) (\sin A\Delta) (\sin[(1-A)\Delta]), \quad (13.48)$$

where

$$\alpha = \frac{\Delta m_{21}^2}{\Delta m_{31}^2}, \quad \Delta = \frac{\Delta m_{31}^2 L}{4E}, \quad A = \sqrt{2} G_F N_e^{man} \frac{2E}{\Delta m_{31}^2}, \quad (13.49)$$

and $\cot \delta = J_{CP}^{-1} \text{Re}(U_{\mu 3} U_{e 3}^* U_{e 2} U_{\mu 2}^*)$, $J_{CP} = \text{Im}(U_{\mu 3} U_{e 3}^* U_{e 2} U_{\mu 2}^*)$. The analytic expression for $P_m^{3\nu \text{ man}}(\nu_e \rightarrow \nu_\mu)$ given above is valid for [84] neutrino path lengths in the mantle ($L \leq 10660$ km) satisfying $L \lesssim 10560$ km $E[\text{GeV}] (7.6 \times 10^{-5} \text{ eV}^2 / \Delta m_{21}^2)$, and energies $E \gtrsim 0.34$ GeV $(\Delta m_{21}^2 / 7.6 \times 10^{-5} \text{ eV}^2) (1.4 \text{ cm}^{-3} N_A / N_e^{man})$. The expression for the $\bar{\nu}_e \rightarrow \bar{\nu}_\mu$ oscillation probability can be obtained formally from that for $P_m^{3\nu \text{ man}}(\nu_e \rightarrow \nu_\mu)$ by making the changes $A \rightarrow -A$ and $J_{CP} \rightarrow -J_{CP}$, with $J_{CP} \cot \delta \equiv \text{Re}(U_{\mu 3} U_{e 3}^* U_{e 2} U_{\mu 2}^*)$ remaining unchanged. The term $P_{\sin \delta}$ in $P_m^{3\nu \text{ man}}(\nu_e \rightarrow \nu_\mu)$ would be equal to zero if the Dirac phase in the neutrino mixing matrix U possesses a CP-conserving value. Even in this case, however, we have $A_{CP}^{(\mu e) \text{ man}} \equiv (P_m^{3\nu \text{ man}}(\nu_e \rightarrow \nu_\mu) - P_m^{3\nu \text{ man}}(\bar{\nu}_e \rightarrow \bar{\nu}_\mu)) \neq 0$ due to the effects of the Earth matter. It will be important to experimentally disentangle the effects of the Earth matter and of J_{CP} in $A_{CP}^{(\mu e) \text{ man}}$: this will allow to get information about the Dirac CP violation phase in U . In the vacuum limit of $N_e^{man} = 0$ ($A = 0$) we have $A_{CP}^{(\mu e) \text{ man}} = A_{CP}^{(\mu e)}$ (see Eq. (13.18)) and only the term $P_{\sin \delta}$ contributes to the asymmetry $A_{CP}^{(\mu e)}$.

13.3.2. Oscillations of solar neutrinos :

Consider next the oscillations of solar ν_e while they propagate from the central part of the Sun, where they are produced, to the surface of the Sun [23,74] (see also Ref. 22 and, *e.g.*, Ref. 85). Details concerning the production, spectrum, magnitude and particularities of the solar neutrino flux, the methods of detection of solar neutrinos, description of solar neutrino experiments and of the data they provided will be discussed in the next section (see also Ref. 86). The electron number density N_e changes considerably along the neutrino path in the Sun: it decreases monotonically from the value of $\sim 100 \text{ cm}^{-3} N_A$ in the center of the Sun to 0 at the surface of the Sun. According to the contemporary solar models (see, *e.g.*, Ref. [86,87]), N_e decreases approximately exponentially in the radial direction towards the surface of the Sun:

$$N_e(t) = N_e(t_0) \exp\left\{-\frac{t-t_0}{r_0}\right\}, \quad (13.50)$$

where $(t-t_0) \cong d$ is the distance traveled by the neutrino in the Sun, $N_e(t_0)$ is the electron number density at the point of ν_e production in the Sun, r_0 is the scale-height of the change of $N_e(t)$ and one has [86,87] $r_0 \sim 0.1 R_\odot$.

Consider the case of 2-neutrino mixing, Eq. (13.34). Obviously, if N_e changes with t (or equivalently with the distance) along the neutrino trajectory, the matter-eigenstates, their energies, the mixing angle and the oscillation length in matter, become, through their dependence on N_e , also functions of t : $|\nu_{1,2}^m(t)\rangle = |\nu_{1,2}^m(t)\rangle$, $E_{1,2}^m = E_{1,2}^m(t)$, $\theta_m = \theta_m(t)$ and $L_m = L_m(t)$. It is not difficult to understand qualitatively the possible behavior of the neutrino system when solar neutrinos propagate from the center to the surface of the

Sun if one realizes that one is dealing effectively with a two-level system whose Hamiltonian depends on time and admits ‘‘jumps’’ from one level to the other (see Eq. (13.32)). Consider the case of $\Delta m^2 \cos 2\theta > 0$. Let us assume first for simplicity that the electron number density at the point of a solar ν_e production in the Sun is much bigger than the resonance density, $N_e(t_0) \gg N_e^{res}$. Actually, this is one of the cases relevant to the solar neutrinos. In this case we have $\theta_m(t_0) \cong \pi/2$ and the state of the electron neutrino in the initial moment of the evolution of the system practically coincides with the heavier of the two matter-eigenstates:

$$|\nu_e\rangle \cong |\nu_2^m(t_0)\rangle. \quad (13.51)$$

Thus, at t_0 the neutrino system is in a state corresponding to the ‘‘level’’ with energy $E_2^m(t_0)$. When neutrinos propagate to the surface of the Sun they cross a layer of matter in which $N_e = N_e^{res}$: in this layer the difference between the energies of the two ‘‘levels’’ ($E_2^m(t) - E_1^m(t)$) has a minimal value on the neutrino trajectory (Eq. (13.37) and Eq. (13.39)). Correspondingly, the evolution of the neutrino system can proceed basically in two ways. First, the system can stay on the ‘‘level’’ with energy $E_2^m(t)$, *i.e.*, can continue to be in the state $|\nu_2^m(t)\rangle$ up to the final moment t_s , when the neutrino reaches the surface of the Sun. At the surface of the Sun $N_e(t_s) = 0$ and therefore $\theta_m(t_s) = \theta$, $|\nu_{1,2}^m(t_s)\rangle \equiv |\nu_{1,2}\rangle$ and $E_{1,2}^m(t_s) = E_{1,2}$. Thus, in this case the state describing the neutrino system at t_0 will evolve continuously into the state $|\nu_2\rangle$ at the surface of the Sun. Using Eq. (13.29) with $l = e$ and $x = \mu$, it is easy to obtain the probabilities to find ν_e and ν_μ at the surface of the Sun:

$$P(\nu_e \rightarrow \nu_e; t_s, t_0) \cong |\langle \nu_e | \nu_2 \rangle|^2 = \sin^2 \theta$$

$$P(\nu_e \rightarrow \nu_\mu; t_s, t_0) \cong |\langle \nu_\mu | \nu_2 \rangle|^2 = \cos^2 \theta. \quad (13.52)$$

It is clear that under the assumption made and if $\sin^2 \theta \ll 1$, practically a total $\nu_e \rightarrow \nu_\mu$ conversion is possible. This type of evolution of the neutrino system and the $\nu_e \rightarrow \nu_\mu$ transitions taking place during the evolution, are called [23] ‘‘adiabatic.’’ They are characterized by the fact that the probability of the ‘‘jump’’ from the upper ‘‘level’’ (having energy $E_2^m(t)$) to the lower ‘‘level’’ (with energy $E_1^m(t)$), P' , or equivalently the probability of the $\nu_2^m(t_0) \rightarrow \nu_1^m(t_s)$ transition, $P' \equiv P'(\nu_2^m(t_0) \rightarrow \nu_1^m(t_s))$, on the whole neutrino trajectory is negligible:

$$P' \equiv P'(\nu_2^m(t_0) \rightarrow \nu_1^m(t_s)) \cong 0 : \text{adiabatic transitions}. \quad (13.53)$$

The second possibility is realized if in the resonance region, where the two ‘‘levels’’ approach each other closest the system ‘‘jumps’’ from the upper ‘‘level’’ to the lower ‘‘level’’ and after that continues to be in the state $|\nu_1^m(t)\rangle$ until the neutrino reaches the surface of the Sun. Evidently, now we have $P' \equiv P'(\nu_2^m(t_0) \rightarrow \nu_1^m(t_s)) \sim 1$. In this case the neutrino system ends up in the state $|\nu_1^m(t_s)\rangle \equiv |\nu_1\rangle$ at the surface of the Sun and

$$P(\nu_e \rightarrow \nu_e; t_s, t_0) \cong |\langle \nu_e | \nu_1 \rangle|^2 = \cos^2 \theta$$

$$P(\nu_e \rightarrow \nu_\mu; t_s, t_0) \cong |\langle \nu_\mu | \nu_1 \rangle|^2 = \sin^2 \theta. \quad (13.54)$$

Obviously, if $\sin^2 \theta \ll 1$, practically no transitions of the solar ν_e into ν_μ will occur. The considered regime of evolution of the neutrino system and the corresponding $\nu_e \rightarrow \nu_\mu$ transitions are usually referred to as ‘‘extremely nonadiabatic.’’

Clearly, the value of the ‘‘jump’’ probability P' plays a crucial role in the the $\nu_e \rightarrow \nu_\mu$ transitions: it fixes the type of the transition and determines to a large extent the $\nu_e \rightarrow \nu_\mu$ transition probability [74,88,89]. We have considered above two limiting cases. Obviously, there exists a whole spectrum of possibilities since P' can have any value from 0 to $\cos^2 \theta$ [90,91]. In general, the transitions are called ‘‘nonadiabatic’’ if P' is non-negligible.

Numerical studies have shown [23] that solar neutrinos can undergo both adiabatic and nonadiabatic $\nu_e \rightarrow \nu_\mu$ transitions in the Sun and the matter effects can be substantial in the solar neutrino oscillations for $10^{-8} \text{ eV}^2 \lesssim \Delta m^2 \lesssim 10^{-4} \text{ eV}^2$, $10^{-4} \lesssim \sin^2 2\theta < 1.0$.

The condition of adiabaticity of the solar ν_e transitions in Sun can be written as [74,88]

$$\gamma(t) \equiv \sqrt{2} G_F \frac{(N_e^{res})^2}{|N_e(t)|} \tan^2 2\theta \left(1 + \tan^{-2} 2\theta_m(t)\right)^{\frac{3}{2}} \gg 1$$

adiabatic transitions, (13.55)

while if $\gamma(t) \lesssim 1$ the transitions are nonadiabatic (see also Ref. 91), where $\dot{N}_e(t) \equiv \frac{d}{dt} N_e(t)$. Condition in Eq. (13.55) implies that the $\nu_e \rightarrow \nu_{\mu(\tau)}$ transitions in the Sun will be adiabatic if $N_e(t)$ changes sufficiently slowly along the neutrino path. In order for the transitions to be adiabatic, condition in Eq. (13.55) has to be fulfilled at any point of the neutrino's path in the Sun.

Actually, the system of evolution equations Eq. (13.32) can be solved exactly for N_e changing exponentially, Eq. (13.50), along the neutrino path in the Sun [90,92]. More specifically, the system in Eq. (13.32) is equivalent to one second order differential equation (with appropriate initial conditions). The latter can be shown [93] to coincide in form, in the case of N_e given by Eq. (13.50), with the Schroedinger equation for the radial part of the nonrelativistic wave function of the Hydrogen atom [94]. On the basis of the exact solution, which is expressed in terms of confluent hypergeometric functions, it was possible to derive a complete, simple and very accurate analytic description of the matter-enhanced transitions of solar neutrinos in the Sun for any values of Δm^2 and θ [22,90,91,95,96] (see also Refs. [23,74,89,97,98]).

The probability that a ν_e , produced at time t_0 in the central part of the Sun, will not transform into $\nu_{\mu(\tau)}$ on its way to the surface of the Sun (reached at time t_s) is given by

$$P_{\odot}^{2\nu}(\nu_e \rightarrow \nu_e; t_s, t_0) = \bar{P}_{\odot}^{2\nu}(\nu_e \rightarrow \nu_e; t_s, t_0) + \text{Oscillating terms.}$$

(13.56)

Here

$$\bar{P}_{\odot}^{2\nu}(\nu_e \rightarrow \nu_e; t_s, t_0) \equiv \bar{P}_{\odot} = \frac{1}{2} + \left(\frac{1}{2} - P'\right) \cos 2\theta_m(t_0) \cos 2\theta,$$

(13.57)

is the average survival probability for ν_e having energy $E \cong p$ [89], where

$$P' = \frac{\exp\left[-2\pi\tau_0 \frac{\Delta m^2}{2E} \sin^2 \theta\right] - \exp\left[-2\pi\tau_0 \frac{\Delta m^2}{2E}\right]}{1 - \exp\left[-2\pi\tau_0 \frac{\Delta m^2}{2E}\right]},$$

(13.58)

is [90] the ‘‘jump’’ probability for exponentially varying N_e , and $\theta_m(t_0)$ is the mixing angle in matter at the point of ν_e production [97]. The expression for $\bar{P}_{\odot}^{2\nu}(\nu_e \rightarrow \nu_e; t_s, t_0)$ with P' given by Eq. (13.58) is valid for $\Delta m^2 > 0$, but for both signs of $\cos 2\theta \neq 0$ [90,98]; it is valid for any given value of the distance along the neutrino trajectory and does not take into account the finite dimensions of the region of ν_e production in the Sun. This can be done by integrating over the different neutrino paths, *i.e.*, over the region of ν_e production.

The oscillating terms in the probability $P_{\odot}^{2\nu}(\nu_e \rightarrow \nu_e; t_s, t_0)$ [95,93] were shown [96] to be strongly suppressed for $\Delta m^2 \gtrsim 10^{-7} \text{ eV}^2$ by the various averagings one has to perform when analyzing the solar neutrino data. The current solar neutrino and KamLAND data suggest that $\Delta m^2 \cong 7.6 \times 10^{-5} \text{ eV}^2$. For $\Delta m^2 \gtrsim 10^{-7} \text{ eV}^2$, the averaging over the region of neutrino production in the Sun *etc.* renders negligible all interference terms which appear in the probability of ν_e survival due to the $\nu_e \leftrightarrow \nu_{\mu(\tau)}$ oscillations in vacuum taking place on the way of the neutrinos from the surface of the Sun to the surface of the Earth. Thus, the probability that ν_e will remain ν_e while it travels from the central part of the Sun to the surface of the Earth is effectively equal to the probability of survival of the ν_e while it propagates from the central part to the surface of the Sun and is given by the average probability $\bar{P}_{\odot}(\nu_e \rightarrow \nu_e; t_s, t_0)$ (determined by Eq. (13.57) and Eq. (13.58)).

If the solar ν_e transitions are adiabatic ($P' \cong 0$) and $\cos 2\theta_m(t_0) \cong -1$ (*i.e.*, $N_e(t_0)/|N_e^{res}| \gg 1, |\tan 2\theta|$), the ν_e are born ‘‘above’’ (in N_e) the resonance region), one has [23]

$$\bar{P}_{\odot}^{2\nu}(\nu_e \rightarrow \nu_e; t_s, t_0) \cong \frac{1}{2} - \frac{1}{2} \cos 2\theta. \quad (13.59)$$

The regime under discussion is realised for $\sin^2 2\theta \cong 0.8$ (suggested by the data, Section 13.4), if $E/\Delta m^2$ lies approximately in the range $(2 \times 10^4 - 3 \times 10^7) \text{ MeV/eV}^2$ (see Ref. 91). This result is relevant for the interpretation of the Super-Kamiokande and SNO solar neutrino data. We see that depending on the sign of $\cos 2\theta \neq 0$, $\bar{P}_{\odot}^{2\nu}(\nu_e \rightarrow \nu_e)$ is either bigger or smaller than 1/2. It follows from the solar neutrino data that in the range of validity (in $E/\Delta m^2$) of Eq. (13.59) we have $\bar{P}_{\odot}^{2\nu}(\nu_e \rightarrow \nu_e) \cong 0.3$. Thus, the possibility of $\cos 2\theta \leq 0$ is ruled out by the data. Given the choice $\Delta m^2 > 0$ we made, the data imply that $\Delta m^2 \cos 2\theta > 0$.

If $E/\Delta m^2$ is sufficiently small so that $N_e(t_0)/|N_e^{res}| \ll 1$, we have $P' \cong 0$, $\theta_m(t_0) \cong \theta$ and the oscillations take place in the Sun as in vacuum [23]:

$$\bar{P}_{\odot}^{2\nu}(\nu_e \rightarrow \nu_e; t_s, t_0) \cong 1 - \frac{1}{2} \sin^2 2\theta, \quad (13.60)$$

which is the average two-neutrino vacuum oscillation probability. This expression describes with good precision the transitions of the solar ν_e neutrinos (Section 13.4). The extremely nonadiabatic ν_e transitions in the Sun, characterised by $\gamma(t) \ll 1$, are also described by the average vacuum oscillation probability (Eq. (13.60)) (for $\Delta m^2 \cos 2\theta > 0$ in this case we have (see *e.g.*, Refs. [90,91]) $\cos 2\theta_m(t_0) \cong -1$ and $P' \cong \cos^2 \theta$).

The probability of ν_e survival in the case 3-neutrino mixing takes a simple form for $|\Delta m_{31}^2| \cong 2.4 \times 10^{-3} \text{ eV}^2 \gg |\Delta m_{21}^2|$. Indeed, for the energies of solar neutrinos $E \lesssim 10 \text{ MeV}$, N_e^{res} corresponding to $|\Delta m_{31}^2|$ satisfies $N_e^{res} \gtrsim 10^3 \text{ cm}^{-3} N_A$ and is by a factor of 10 bigger than N_e in the center of the Sun. As a consequence, the oscillations due to Δm_{31}^2 proceed as in vacuum. The oscillation length associated with $|\Delta m_{31}^2|$ satisfies $L_{31}^{\nu} \lesssim 10 \text{ km} \ll \Delta R$, ΔR being the dimension of the region of ν_e production in the Sun. We have for the different components of the solar ν_e flux [86] $\Delta R \cong (0.04 - 0.20) R_{\odot}$. Therefore the averaging over ΔR strongly suppresses the oscillations due to Δm_{31}^2 and we get [78,99]:

$$P_{\odot}^{3\nu} \cong \sin^4 \theta_{13} + \cos^4 \theta_{13} P_{\odot}^{2\nu}(\Delta m_{21}^2, \theta_{12}; N_e \cos^2 \theta_{13}), \quad (13.61)$$

where $P_{\odot}^{2\nu}(\Delta m_{21}^2, \theta_{12}; N_e \cos^2 \theta_{13})$ is given by Eq. (13.56) to Eq. (13.58) in which $\Delta m^2 = \Delta m_{21}^2$, $\theta = \theta_{12}$ and the solar e^- number density N_e is replaced by $N_e \cos^2 \theta_{13}$. Thus, the solar ν_e transitions observed by the Super-Kamiokande and SNO experiments are described approximately by:

$$P_{\odot}^{3\nu} \cong \sin^4 \theta_{13} + \cos^4 \theta_{13} \sin^2 \theta_{12}. \quad (13.62)$$

The data show that $P_{\odot}^{3\nu} \cong 0.3$, which is a strong evidence for matter effects in the solar ν_e transitions [100] since in the case of oscillations in vacuum $P_{\odot}^{3\nu} \cong \sin^4 \theta_{13} + (1 - 0.5 \sin^2 2\theta_{12}) \cos^4 \theta_{13} \gtrsim 0.49$, where we have used $\sin^2 \theta_{13} \lesssim 0.040$ and $\sin^2 2\theta_{12} \lesssim 0.93$ (see Section 13.7).

13.4. Measurements of Δm_{\odot}^2 and θ_{\odot}

13.4.1. Solar neutrino observations :

Observation of solar neutrinos directly addresses the theory of stellar structure and evolution, which is the basis of the standard solar model (SSM). The Sun as a well-defined neutrino source also provides extremely important opportunities to investigate nontrivial neutrino properties such as nonzero mass and mixing, because of the wide range of matter density and the great distance from the Sun to the Earth.

The solar neutrinos are produced by some of the fusion reactions in the pp chain or CNO cycle. The combined effect of these reactions is written as

Figure 13.2: The solar neutrino spectrum predicted by the BS05(OP) standard solar model [101]. The neutrino fluxes are given in units of $\text{cm}^{-2}\text{s}^{-1}\text{MeV}^{-1}$ for continuous spectra and $\text{cm}^{-2}\text{s}^{-1}$ for line spectra. The numbers associated with the neutrino sources show theoretical errors of the fluxes. This figure is taken from the late John Bahcall's web site, <http://www.sns.ias.edu/~jnb/>.

Positrons annihilate with electrons. Therefore, when considering the solar thermal energy generation, a relevant expression is

$$4p + 2e^- \rightarrow {}^4\text{He} + 2\nu_e + 26.73 \text{ MeV} - E_\nu, \quad (13.64)$$

where E_ν represents the energy taken away by neutrinos, with an average value being $\langle E_\nu \rangle \sim 0.6$ MeV. There have been efforts to calculate solar neutrino fluxes from these reactions on the basis of SSM. A variety of input information is needed in the evolutionary calculations. The most elaborate SSM calculations have been developed by Bahcall and his collaborators, who define their SSM as the solar model which is constructed with the best available physics and input data. Therefore, their SSM calculations have been rather frequently updated. SSM's labelled as BS05(OP) [101], BSB06(GS) and BSB06(AGS) [87], and BPS08(GS) and BPS08(AGS) [102] represent some of recent model calculations. Here, "OP" means that newly calculated radiative opacities from the "Opacity Project" are used. The later models are also calculated with OP opacities. "GS" and "AGS" refer to old and new determinations of solar abundances of heavy elements. There are significant differences between the old, higher heavy element abundances (GS) and the new, lower heavy element abundances (AGS). The models with GS are consistent with helioseismological data, but the models with AGS are not.

The prediction of the BPS08(GS) model for the fluxes from neutrino-producing reactions is given in Table 13.2. Fig. 13.2 shows the solar-neutrino spectra calculated with the BS05(OP) model which is similar to the BPS08(GS) model. Here we note that in Ref. 103 the authors point out that electron capture on ${}^{13}\text{N}$, ${}^{15}\text{O}$, and ${}^{17}\text{F}$ produces line spectra of neutrinos, which have not been considered in the SSM calculations quoted above.

In 2011, a new SSM calculations [104] have been presented by A.M. Serenelli, W.C. Haxton, and C. Peña-Garay, by adopting the newly analyzed nuclear fusion cross sections. Their high metallicity SSM is labelled as SHP11(GS). For the same solar abundances as used in Ref. 101 and Ref. 87, the most significant change is a decrease of ${}^8\text{B}$ flux by $\sim 5\%$.

So far, solar neutrinos have been observed by chlorine (Homestake) and gallium (SAGE, GALLEX, and GNO) radiochemical detectors and water Cherenkov detectors using light water (Kamiokande and Super-Kamiokande) and heavy water (SNO). Recently, a liquid scintillation detector (Borexino) successfully observed low energy solar neutrinos.

A pioneering solar neutrino experiment by Davis and collaborators at Homestake using the ${}^{37}\text{Cl} - {}^{37}\text{Ar}$ method proposed by Pontecorvo [105] started in the late 1960's. This experiment exploited

Table 13.2: Neutrino-producing reactions in the Sun (first column) and their abbreviations (second column). The neutrino fluxes predicted by the BPS08(GS) model [102] are listed in the third column.

Reaction	Abbr.	Flux ($\text{cm}^{-2} \text{s}^{-1}$)
$pp \rightarrow d e^+ \nu$	<i>pp</i>	$5.97(1 \pm 0.006) \times 10^{10}$
$pe^- p \rightarrow d \nu$	<i>pep</i>	$1.41(1 \pm 0.011) \times 10^8$
${}^3\text{He} p \rightarrow {}^4\text{He} e^+ \nu$	<i>hep</i>	$7.90(1 \pm 0.15) \times 10^3$
${}^7\text{Be} e^- \rightarrow {}^7\text{Li} \nu + (\gamma)$	<i>${}^7\text{Be}$</i>	$5.07(1 \pm 0.06) \times 10^9$
${}^8\text{B} \rightarrow {}^8\text{Be}^* e^+ \nu$	<i>${}^8\text{B}$</i>	$5.94(1 \pm 0.11) \times 10^6$
${}^{13}\text{N} \rightarrow {}^{13}\text{C} e^+ \nu$	<i>${}^{13}\text{N}$</i>	$2.88(1 \pm 0.15) \times 10^8$
${}^{15}\text{O} \rightarrow {}^{15}\text{N} e^+ \nu$	<i>${}^{15}\text{O}$</i>	$2.15(1_{-0.16}^{+0.17}) \times 10^8$
${}^{17}\text{F} \rightarrow {}^{17}\text{O} e^+ \nu$	<i>${}^{17}\text{F}$</i>	$5.82(1_{-0.17}^{+0.19}) \times 10^6$

ν_e absorption on ${}^{37}\text{Cl}$ nuclei followed by the produced ${}^{37}\text{Ar}$ decay through orbital e^- capture,

$$\nu_e + {}^{37}\text{Cl} \rightarrow {}^{37}\text{Ar} + e^- \quad (\text{threshold } 814 \text{ keV}). \quad (13.65)$$

The ${}^{37}\text{Ar}$ atoms produced are radioactive, with a half life ($\tau_{1/2}$) of 34.8 days. After an exposure of the detector for two to three times $\tau_{1/2}$, the reaction products were chemically extracted and introduced into a low-background proportional counter, where they were counted for a sufficiently long period to determine the exponentially decaying signal and a constant background. Solar-model calculations predict that the dominant contribution in the chlorine experiment came from ${}^8\text{B}$ neutrinos, but ${}^7\text{Be}$, *pep*, ${}^{13}\text{N}$, and ${}^{15}\text{O}$ neutrinos also contributed (for notations, refer to Table 13.2).

From the very beginning of the solar-neutrino observation [106], it was recognized that the observed flux was significantly smaller than the SSM prediction, provided nothing happens to the electron neutrinos after they are created in the solar interior. This deficit has been called "the solar-neutrino problem."

Table 13.3: Results from radiochemical solar-neutrino experiments. The predictions of a recent standard solar model BPS08(GS) are also shown. The first and the second errors in the experimental results are the statistical and systematic errors, respectively. SNU (Solar Neutrino Unit) is defined as 10^{-36} neutrino captures per atom per second.

	${}^{37}\text{Cl} \rightarrow {}^{37}\text{Ar}$ (SNU)	${}^{71}\text{Ga} \rightarrow {}^{71}\text{Ge}$ (SNU)
Homestake [4]	$2.56 \pm 0.16 \pm 0.16$	–
GALLEX [8]	–	$77.5 \pm 6.2_{-4.7}^{+4.3}$
GALLEX- Reanalysis [107]	–	$73.4_{-6.0-4.1}^{+6.1+3.7}$
GNO [9]	–	$62.9_{-5.3}^{+5.5} \pm 2.5$
GNO+GALLEX [9]	–	$69.3 \pm 4.1 \pm 3.6$
GNO+GALLEX- Reanalysis [107]	–	$67.6_{-4.0-3.2}^{+4.0+3.2}$
SAGE [6]	–	$65.4_{-3.0-2.8}^{+3.1+2.6}$
SSM [BPS08(GS)] [102]	$8.46_{-0.88}^{+0.87}$	$127.9_{-8.2}^{+8.1}$

Gallium experiments (GALLEX and GNO at Gran Sasso in Italy and SAGE at Baksan in Russia) utilize the reaction

$$\nu_e + {}^{71}\text{Ga} \rightarrow {}^{71}\text{Ge} + e^- \quad (\text{threshold } 233 \text{ keV}). \quad (13.66)$$

They are sensitive to the most abundant *pp* solar neutrinos. The solar-model calculations predict that more than 80% of the capture

rate in gallium is due to low energy pp and ${}^7\text{Be}$ solar neutrinos with the pp rate being about twice the ${}^7\text{Be}$ rate. SAGE reported the first results in 1991 [108]. They observed the capture rate to be $20_{-20}^{+15} \pm 32$ SNU, or a 90% confidence-level upper limit of 79 SNU. In 1992, GALLEX reported the observed capture rate of $83 \pm 19 \pm 8$ SNU [7]. It was the first evidence for low-energy solar-neutrino observation. Later, SAGE observed similar flux [109] to GALLEX. The latest SAGE results are published in Ref. 6. The GALLEX Collaboration finished observations in early 1997 [8,107]. Since April, 1998, a newly defined collaboration, GNO (Gallium Neutrino Observatory) continued the observations until April 2003. The GNO results are published in Ref. 9. The GNO + GALLEX joint analysis results are also presented in Ref. 9 and Ref. 107. The results from radiochemical solar neutrino experiments are shown in Table 13.3.

In 1987, the Kamiokande experiment in Japan succeeded in real-time solar neutrino observation, utilizing νe scattering,

$$\nu_x + e^- \rightarrow \nu_x + e^-, \quad (13.67)$$

in a large water-Cherenkov detector. This experiment takes advantage of the directional correlation between the incoming neutrino and the recoil electron. This feature greatly helps the clear separation of the solar-neutrino signal from the background. The Kamiokande result gave the first direct evidence that neutrinos come from the direction of the Sun [110]. Later, the high-statistics Super-Kamiokande experiment [111–114] with a 50-kton water Cherenkov detector replaced the Kamiokande experiment. Due to the high thresholds (7 MeV in Kamiokande and 5 MeV at present in Super-Kamiokande) the experiments observe pure ${}^8\text{B}$ solar neutrinos. It should be noted that the reaction (Eq. (13.67)) is sensitive to all active neutrinos, $x = e, \mu,$ and τ . However, the sensitivity to ν_μ and ν_τ is much smaller than the sensitivity to ν_e , $\sigma(\nu_{\mu,\tau}e) \approx 0.16 \sigma(\nu_e e)$.

In 1999, a new real time solar-neutrino experiment, SNO (Sudbury Neutrino Observatory), in Canada started observation. This experiment used 1000 tons of ultra-pure heavy water (D_2O) contained in a spherical acrylic vessel, surrounded by an ultra-pure H_2O shield. SNO measured ${}^8\text{B}$ solar neutrinos via the charged-current (CC) and neutral-current (NC) reactions

$$\nu_e + d \rightarrow e^- + p + p \quad (\text{CC}), \quad (13.68)$$

and

$$\nu_x + d \rightarrow \nu_x + p + n \quad (\text{NC}), \quad (13.69)$$

as well as νe scattering, (Eq. (13.67)). The CC reaction, (Eq. (13.68)), is sensitive only to ν_e , while the NC reaction, (Eq. (13.69)), is sensitive to all active neutrinos. This is a key feature to solve the solar neutrino problem. If it is caused by flavour transitions such as neutrino oscillations, the solar neutrino fluxes measured by CC and NC reactions would show a significant difference.

The Q -value of the CC reaction is -1.4 MeV and the e^- energy is strongly correlated with the ν_e energy. Thus, the CC reaction provides an accurate measure of the shape of the ${}^8\text{B}$ neutrino spectrum. The contributions from the CC reaction and νe scattering can be distinguished by using different $\cos \theta$ distributions, where θ is the angle of the e^- momentum with respect to the Sun-Earth axis. While the νe scattering events have a strong forward peak, CC events have an approximate angular distribution of $1 - 1/3 \cos \theta$.

The neutrino energy threshold of the NC reaction is 2.2 MeV. In the pure D_2O [11,12], the signal of the NC reaction was neutron capture in deuterium, producing a 6.25-MeV γ -ray. In this case, the capture efficiency was low and the deposited energy was close to the detection threshold of 5 MeV. In order to enhance both the capture efficiency and the total γ -ray energy (8.6 MeV), 2 tons of NaCl were added to the heavy water in the second phase of the experiment [115]. Subsequently NaCl was removed and an array of ${}^3\text{He}$ neutron counters were installed for the third phase measurement [116]. These neutron counters provided independent NC measurement with different systematics from that of the second phase, and thus strengthened the reliability of the NC measurement. The SNO experiment completed data acquisition in 2006. Recently, the SNO group presented the

results of Phase I and Phase II joint analysis [117] as well as the results of a combined analysis of all three phases [118].

Table 13.4 shows the ${}^8\text{B}$ solar neutrino results from real time experiments. The standard solar model predictions are also shown. Table 13.4 includes the results from the SNO group's recent joint analysis of the SNO Phase I and Phase II data with the analysis threshold as low as 3.5 MeV (effective electron kinetic energy) and significantly improved systematic uncertainties [117]. Also, the recent result from a combined analysis of all three phases [118] is included. It is seen from these tables that the results from all the solar-neutrino experiments, except SNO's NC result, indicate significantly less flux than expected from the solar-model predictions.

Table 13.4: ${}^8\text{B}$ solar neutrino results from real time experiments. The predictions of BPS08(GS) and SHP11(GS) standard solar models are also shown. The first and the second errors in the experimental results are the statistical and systematic errors, respectively.

	Reaction	${}^8\text{B}$ ν flux ($10^6 \text{cm}^{-2}\text{s}^{-1}$)
Kamiokande [5]	νe	$2.80 \pm 0.19 \pm 0.33$
Super-K I [112,114]	νe	$2.38 \pm 0.02 \pm 0.08$
Super-K II [113,114]	νe	$2.41 \pm 0.05^{+0.16}_{-0.15}$
Super-K III [114]	νe	$2.32 \pm 0.04 \pm 0.05$
SNO Phase I [12]	CC	$1.76^{+0.06}_{-0.05} \pm 0.09$
(pure D_2O)	νe	$2.39^{+0.24}_{-0.23} \pm 0.12$
	NC	$5.09^{+0.44+0.46}_{-0.43-0.43}$
SNO Phase II [115]	CC	$1.68 \pm 0.06^{+0.08}_{-0.09}$
(NaCl in D_2O)	νe	$2.35 \pm 0.22 \pm 0.15$
	NC	$4.94 \pm 0.21^{+0.38}_{-0.34}$
SNO Phase III [116]	CC	$1.67^{+0.05+0.07}_{-0.04-0.08}$
(${}^3\text{He}$ counters)	νe	$1.77^{+0.24+0.09}_{-0.21-0.10}$
	NC	$5.54^{+0.33+0.36}_{-0.31-0.34}$
SNO Phase I+II [117]	NC	$5.140^{+0.160+0.132}_{-0.158-0.117}$
	Φ_{B} from fit to all reacts.	$5.046^{+0.159+0.107}_{-0.152-0.123}$
SNO Phase I+II+III [118]	Φ_{B} from fit to all reacts.	$5.25 \pm 0.16^{+0.11}_{-0.13}$
Borexino [123]	νe	$2.4 \pm 0.4 \pm 0.1$
SSM [BPS08(GS)] [102]	–	$5.94(1 \pm 0.11)$
SSM [SHP11(GS)] [104]	–	$5.58(1 \pm 0.14)$

Another real time solar neutrino experiment, Borexino at Gran Sasso in Italy, started solar neutrino observation in 2007. This experiment measures solar neutrinos via νe scattering in 300 tons of ultra-pure liquid scintillator. With a detection threshold as low as 250 keV, the flux of monochromatic 0.862 MeV ${}^7\text{Be}$ solar neutrinos has been directly observed for the first time (see Table 13.5). The observed energy spectrum shows the characteristic Compton-edge over the background [119,120]. Borexino also reported an observation of null day-night asymmetry of the ${}^7\text{Be}$ neutrino flux, $A_{dn} = 2(R_N - R_D)/(R_N + R_D) = 0.001 \pm 0.012 \pm 0.007$ [121], where R_N and R_D are the night and day count rates of ${}^7\text{Be}$ neutrinos.

Further, Borexino measured the flux of monochromatic 1.44 MeV pep solar neutrinos [122]. The absence of the pep solar neutrino signal is disfavored at 98% CL. The pep solar neutrino flux measured via νe scattering (calculated from the measured interaction rate and the expected one with the assumption of no neutrino oscillations and the SHP11(GS) SSM [104], both given in [122]) is shown in Table 13.6 and compared with the SSM predictions. Also, an upper limit of the “unoscillated” CNO solar neutrino flux is determined [122] as $< 7.7 \times 10^8 \text{cm}^{-2}\text{s}^{-1}$ (95% CL) by assuming the MSW large mixing angle solution with $\Delta m_{21}^2 = (7.6 \pm 0.2) \times 10^{-5} \text{eV}^2$ and

$\tan^2\theta_{\odot} = 0.47^{+0.05}_{-0.04}$ and the SHP11(GS) SSM prediction [104] for the pep ν flux.

Borexino also measured ${}^8\text{B}$ solar neutrinos with an energy threshold of 3 MeV [123]. Measurements of low energy solar neutrinos are important not only to test the SSM further, but also to study the MSW effect over the energy region spanning from sub-MeV to 10 MeV.

Table 13.5: ${}^7\text{Be}$ solar neutrino result from Borexino [120]. The predictions of BPS08(GS) and SHP11(GS) standard solar models are also shown.

	Reaction	${}^7\text{Be}$ ν flux ($10^9\text{cm}^{-2}\text{s}^{-1}$)
Borexino [120]	νe	3.10 ± 0.15
SSM [BPS08(GS)] [102]	–	$5.07(1 \pm 0.06)$
SSM [SHP11(GS)] [104]	–	$5.00(1 \pm 0.07)$

Table 13.6: pep solar neutrino result from Borexino [122]. The predictions of BPS08(GS) and SHP11(GS) standard solar models are also shown.

	Reaction	pep ν flux ($10^8\text{cm}^{-2}\text{s}^{-1}$)
Borexino [122]	νe	1.0 ± 0.2
SSM [BPS08(GS)] [102]	–	$1.41(1 \pm 0.011)$
SSM [SHP11(GS)] [104]	–	$1.44(1 \pm 0.012)$

13.4.2. Evidence for solar neutrino flavour conversion :

Solar neutrino experiments achieved remarkable progress in the past ten years, and the solar-neutrino problem, which had remained unsolved for more than 30 years, has been understood as due to neutrino flavour conversion. In 2001, the initial SNO CC result combined with the Super-Kamiokande's high-statistics νe elastic scattering result [124] provided direct evidence for flavour conversion of solar neutrinos [11]. Later, SNO's NC measurements further strengthened this conclusion [12,115,116]. From the salt-phase measurement [115], the fluxes measured with CC, ES, and NC events were obtained as

$$\phi_{\text{SNO}}^{\text{CC}} = (1.68 \pm 0.06^{+0.08}_{-0.09}) \times 10^6 \text{cm}^{-2}\text{s}^{-1}, \quad (13.70)$$

$$\phi_{\text{SNO}}^{\text{ES}} = (2.35 \pm 0.22 \pm 0.15) \times 10^6 \text{cm}^{-2}\text{s}^{-1}, \quad (13.71)$$

$$\phi_{\text{SNO}}^{\text{NC}} = (4.94 \pm 0.21^{+0.38}_{-0.34}) \times 10^6 \text{cm}^{-2}\text{s}^{-1}, \quad (13.72)$$

where the first errors are statistical and the second errors are systematic. In the case of $\nu_e \rightarrow \nu_{\mu,\tau}$ transitions, Eq. (13.72) is a mixing-independent result and therefore tests solar models. It shows good agreement with the ${}^8\text{B}$ solar-neutrino flux predicted by the solar model [101]. Fig. 13.3 shows the salt phase result of $\phi(\nu_{\mu}$ or $\tau)$ versus the flux of electron neutrinos $\phi(\nu_e)$ and the 68%, 95%, and 99% joint probability contours. The flux of non- ν_e active neutrinos, $\phi(\nu_{\mu}$ or $\tau)$, can be deduced from these results. It is

$$\phi(\nu_{\mu} \text{ or } \tau) = (3.26 \pm 0.25^{+0.40}_{-0.35}) \times 10^6 \text{cm}^{-2}\text{s}^{-1}. \quad (13.73)$$

The non-zero $\phi(\nu_{\mu}$ or $\tau)$ is strong evidence for neutrino flavor conversion. These results are consistent with those expected from the LMA (large mixing angle) solution of solar neutrino oscillation in matter [22,23] with $\Delta m_{21}^2 \sim 5 \times 10^{-5} \text{eV}^2$ and $\tan^2\theta_{\odot} \sim 0.45$. However, with the SNO data alone, the possibility of other solutions cannot be excluded with sufficient statistical significance.

Figure 13.3: Fluxes of ${}^8\text{B}$ solar neutrinos, $\phi(\nu_e)$, and $\phi(\nu_{\mu}$ or $\tau)$, deduced from the SNO's CC, ES, and NC results of the salt phase measurement [115]. The Super-Kamiokande ES flux is from Ref. 125. The BS05(OP) standard solar model prediction [101] is also shown. The bands represent the 1σ error. The contours show the 68%, 95%, and 99% joint probability for $\phi(\nu_e)$ and $\phi(\nu_{\mu}$ or $\tau)$. The figure is from Ref. 115.

Figure 14.4: The ratio of the background and geoneutrino-subtracted $\bar{\nu}_e$ spectrum to the predicted one without oscillations (survival probability) as a function of L_0/E , where $L_0=180$ km. The histograms show the expected distributions based on the best-fit parameter values from the two- and three-flavor neutrino oscillation analyses. The figure is from Ref. 128.

13.4.3. KamLAND experiment :

KamLAND is a 1-kton ultra-pure liquid scintillator detector located at the old Kamiokande's site in Japan. The primary goal of the KamLAND experiment was a long-baseline (flux-weighted average distance of ~ 180 km) neutrino oscillation studies using $\bar{\nu}_e$'s emitted from nuclear power reactors. The reaction $\bar{\nu}_e + p \rightarrow e^+ + n$ is used to detect reactor $\bar{\nu}_e$'s and a delayed coincidence of the positron with a 2.2 MeV γ -ray from neutron capture on a proton is used to reduce the backgrounds. With the reactor $\bar{\nu}_e$'s energy spectrum (< 8 MeV) and a prompt-energy analysis threshold of 2.6 MeV, this experiment has a sensitive Δm^2 range down to $\sim 10^{-5} \text{eV}^2$. Therefore, if the LMA solution is the real solution of the solar neutrino problem, KamLAND should observe reactor $\bar{\nu}_e$ disappearance, assuming CPT invariance.

The first KamLAND results [15] with 162 ton-yr exposure were reported in December 2002. The ratio of observed to expected (assuming no $\bar{\nu}_e$ oscillations) number of events was

$$\frac{N_{\text{obs}} - N_{\text{BG}}}{N_{\text{NoOsc}}} = 0.611 \pm 0.085 \pm 0.041 \quad (13.74)$$

with obvious notation. This result showed clear evidence of an event deficit expected from neutrino oscillations. The 95% CL allowed

regions are obtained from the oscillation analysis with the observed event rates and positron spectrum shape. A combined global solar + KamLAND analysis showed that the LMA is a unique solution to the solar neutrino problem with $> 5\sigma$ CL [126]. With increased statistics [16,127,128], KamLAND observed not only the distortion of the $\bar{\nu}_e$ spectrum, but also for the first time the periodic feature of the $\bar{\nu}_e$ survival probability expected from neutrino oscillations (see Fig. 13.4).

13.5. Measurements of $|\Delta m^2_{\Lambda}|$ and θ_{Λ}

13.5.1. Atmospheric neutrino results :

The first compelling evidence for the neutrino oscillation was presented by the Super-Kamiokande Collaboration in 1998 [13] from the observation of atmospheric neutrinos produced by cosmic-ray interactions in the atmosphere. The zenith-angle distributions of the μ -like events which are mostly muon-neutrino and muon antineutrino initiated charged-current interactions, showed a clear deficit compared to the no-oscillation expectation. Note that a water Cherenkov detector cannot measure the charge of the final-state leptons, and therefore neutrino and antineutrino induced events cannot be discriminated. Neutrino events having their vertex in the 22.5 kton fiducial volume in Super-Kamiokande are classified into fully contained (FC) events and partially contained (PC) events. The FC events are required to have no activity in the anti-counter. Single-ring events have only one charged lepton which radiates Cherenkov light in the final state, and particle identification is particularly clean for single-ring FC events. A ring produced by an e -like (e^{\pm} , γ) particle exhibits a more diffuse pattern than that produced by a μ -like (μ^{\pm} , π^{\pm}) particle, since an e -like particle produces an electromagnetic shower and low-energy electrons suffer considerable multiple Coulomb scattering in water. All the PC events were assumed to be μ -like since the PC events comprise a 98% pure charged-current ν_{μ} sample.

Figure 13.5: The zenith angle distributions for fully contained 1-ring e -like and μ -like events with visible energy < 1.33 GeV (sub-GeV) and > 1.33 GeV (multi-GeV). For multi-GeV μ -like events, a combined distribution with partially contained (PC) events is shown. The dotted histograms show the non-oscillated Monte Carlo events, and the solid histograms show the best-fit expectations for $\nu_{\mu} \leftrightarrow \nu_{\tau}$ oscillations. (This figure is provided by the Super-Kamiokande Collab.)

Fig. 13.5 shows the zenith-angle distributions of e -like and μ -like events from the SK-I measurement [129]. $\cos\theta = 1$ corresponds to the downward direction, while $\cos\theta = -1$ corresponds to the upward

Figure 13.6: Allowed region for the $\nu_{\mu} \leftrightarrow \nu_{\tau}$ oscillation parameters from the MINOS results published in 2011. The 68 % and 90 % CL allowed regions are shown together with the Super-Kamiokande and MINOS 2008 90% CL allowed regions. This figure is taken from Ref. 130.

direction. Events included in these plots are single-ring FC events subdivided into sub-GeV (visible energy < 1.33 GeV) events and multi-GeV (visible energy > 1.33 GeV) events. The zenith-angle distribution of the multi-GeV μ -like events is shown combined with that of the PC events. The final-state leptons in these events have good directional correlation with the parent neutrinos. The dotted histograms show the Monte Carlo expectation for neutrino events. If the produced flux of atmospheric neutrinos of a given flavour remains unchanged at the detector, the data should have similar distributions to the expectation. However, the zenith-angle distribution of the μ -like events shows a strong deviation from the expectation. On the other hand, the zenith-angle distribution of the e -like events is consistent with the expectation. This characteristic feature may be interpreted that muon neutrinos coming from the opposite side of the Earth's atmosphere, having travelled $\sim 10,000$ km, oscillate into other neutrinos and disappeared, while oscillations still do not take place for muon neutrinos coming from above the detector, having travelled from a few to a few tens km. Disappeared muon neutrinos may have oscillated into tau neutrinos because there is no indication of electron neutrino appearance. The atmospheric neutrinos corresponding to the events shown in Fig. 13.5 have $E = 1 \sim 10$ GeV. With $L = 10000$ km, the hypothesis of neutrino oscillations suggests $\Delta m^2 \sim 10^{-3} - 10^{-4} \text{ eV}^2$. The solid histograms show the best-fit results of a two-neutrino oscillation analysis with the hypothesis of $\nu_{\mu} \leftrightarrow \nu_{\tau}$. For the allowed parameter region, see Fig. 13.6.

Also, a search for a ν_{τ} appearance signal by using the SK-I atmospheric neutrino data has been made by the Super-Kamiokande Collaboration [131], and no ν_{τ} appearance hypothesis is disfavored at 2.4σ .

Although the SK-I atmospheric neutrino observations gave compelling evidence for muon neutrino disappearance which is consistent with two-neutrino oscillation $\nu_{\mu} \leftrightarrow \nu_{\tau}$ [131], the question may be asked whether the observed muon neutrino disappearance is really due to neutrino oscillations. First, other exotic explanations such as neutrino decay [132] and quantum decoherence [133] cannot be completely ruled out from the zenith-angle distributions alone. To confirm neutrino oscillation, characteristic sinusoidal behavior of the conversion probability as a function of neutrino energy E for a fixed distance L in the case of long-baseline neutrino oscillation experiments, or as a function of L/E in the case of atmospheric neutrino experiments, should be observed. By selecting events with

high L/E resolution, evidence for the dip in the L/E distribution was observed at the right place expected from the interpretation of the SK-I data in terms of $\nu_\mu \leftrightarrow \nu_\tau$ oscillations [14], see Fig. 13.7. This dip cannot be explained by alternative hypotheses of neutrino decay and neutrino decoherence, and they are excluded at more than 3σ in comparison with the neutrino oscillation interpretation. For the constraints obtained from the L/E analysis, see Fig. 13.6.

Figure 13.7: Results of the L/E analysis of SK-I atmospheric neutrino data. The points show the ratio of the data to the Monte Carlo prediction without oscillations, as a function of the reconstructed L/E . The error bars are statistical only. The solid line shows the best fit with 2-flavour $\nu_\mu \leftrightarrow \nu_\tau$ oscillations. The dashed and dotted lines show the best fit expectations for neutrino decay and neutrino decoherence hypotheses, respectively. (From Ref. 14.)

13.5.2. Results from accelerator experiments :

The $\Delta m^2 \geq 2 \times 10^{-3} \text{ eV}^2$ region can be explored by accelerator-based long-baseline experiments with typically $E \sim 1 \text{ GeV}$ and $L \sim$ several hundred km. With a fixed baseline distance and a narrower, well understood neutrino spectrum, the value of $|\Delta m_A^2|$ and, with higher statistics, also the mixing angle, are potentially better constrained in accelerator experiments than from atmospheric neutrino observations.

The K2K (KEK-to-Kamioka) long-baseline neutrino oscillation experiment [19] is the first accelerator-based experiment with a neutrino path length extending hundreds of kilometers. K2K aimed at confirmation of the neutrino oscillation in ν_μ disappearance in the $|\Delta m_A^2| \geq 2 \times 10^{-3} \text{ eV}^2$ region. A horn-focused wide-band muon neutrino beam having an average $L/E_\nu \sim 200$ ($L = 250 \text{ km}$, $\langle E_\nu \rangle \sim 1.3 \text{ GeV}$), was produced by 12-GeV protons from the KEK-PS and directed to the Super-Kamiokande detector. The spectrum and profile of the neutrino beam were measured by a near neutrino detector system located 300 m downstream from the production target.

The construction of the K2K neutrino beam line and the near detector began before Super-Kamiokande's discovery of atmospheric neutrino oscillations. K2K experiment started data-taking in 1999 and was completed in 2004. The total number of protons on target (POT) for physics analysis amounted to 0.92×10^{20} . The observed number of beam-originated FC events in the 22.5 kton fiducial volume of Super-Kamiokande was 112, compared with an expectation of $158.1_{-8.6}^{+9.2}$ events without oscillation. For 58 1-ring μ -like subset of the data, the neutrino energy was reconstructed from measured muon momentum and angle, assuming CC quasi-elastic kinematics. The measured energy spectrum showed the distortion expected from neutrino oscillations. The probability that the observations are due to a statistical fluctuation instead of neutrino oscillation is 0.0015% or 4.3σ [19].

MINOS is the second long-baseline neutrino oscillation experiment with near and far detectors. Neutrinos are produced by the NuMI

Figure 13.8: The top panel shows the energy spectra of fully reconstructed events in the MINOS far detector classified as CC interactions. The bottom panel shows the background subtracted ratios of data to the no-oscillation hypothesis. The best fit with the hypothesis of $\nu_\mu \rightarrow \nu_\tau$ oscillations as well as the best fit to alternative models (neutrino decay and decoherence) is also shown. This figure is taken from Ref. 130.

(Neutrinos at the Main Injector) facility using 120 GeV protons from the Fermilab Main Injector. The far detector is a 5.4 kton (total mass) iron-scintillator tracking calorimeter with toroidal magnetic field, located underground in the Soudan mine. The baseline distance is 735 km. The near detector is also an iron-scintillator tracking calorimeter with toroidal magnetic field, with a total mass of 0.98 kton. The neutrino beam is a horn-focused wide-band beam. Its energy spectrum can be varied by moving the target position relative to the first horn and changing the horn current.

MINOS started the neutrino-beam run in 2005. Earlier ν_μ disappearance results were reported in Ref. 20 with 1.27×10^{20} POT and in Ref. 21 with 3.36×10^{20} POT. The updated results corresponding to a total POT of 7.25×10^{20} have been published recently [130]. Most of the data were taken with a “low-energy” option for the spectrum of the neutrino beam (the flux was enhanced in the 1-5 GeV energy range, peaking at 3 GeV). In the far detector, a total of 1986 fully reconstructed CC events were produced by the NuMI beam, compared to the unoscillated expectation of 2451 events. Fig. 13.8 shows the observed energy spectra and the expected spectra with no oscillation. Fig. 13.6 shows the 68% and 90% CL allowed regions obtained from the $\nu_\mu \rightarrow \nu_\tau$ oscillation analysis. The results are compared with the 90% CL allowed regions obtained from the earlier MINOS [21], SK-I zenith-angle dependence [129,79], and the SK-I L/E analysis [14]. The MINOS results constrain the oscillation parameters as $|\Delta m_A^2| = (2.32_{-0.08}^{+0.12}) \times 10^{-3} \text{ eV}^2$ and $\sin^2 2\theta_A > 0.90$ at 90% CL. The alternative models to explain the ν_μ disappearance, neutrino decay and quantum decoherence of neutrinos, are disfavored at the 7σ and 9σ , respectively, by the MINOS data (see Fig. 13.8).

In addition to ν_μ disappearance, MINOS first observed muon antineutrino disappearance [134] with the NuMI beam line optimized for $\bar{\nu}_\mu$ production. MINOS recently released $\bar{\nu}_\mu$ disappearance result corresponding to POT = 2.95×10^{20} [135]. With increased statistics, the best-fit oscillation parameters are $|\Delta \bar{m}_A^2| = (2.62_{-0.28}^{+0.31} \pm 0.09) \times 10^{-3} \text{ eV}^2$ and $\sin^2 2\bar{\theta}_A = 0.95_{-0.11}^{+0.10} \pm 0.01$, or $\sin^2 2\bar{\theta}_A > 0.75$ at 90% CL. These results are consistent with their neutrino counterparts.

The regions of neutrino parameter space favored or excluded by various neutrino oscillation experiments are shown in Fig. 13.9.

Although the atmospheric neutrino oscillations and accelerator long-baseline ν_μ disappearance data are fully consistent with $\nu_\mu \rightarrow \nu_\tau$

Figure 13.9: The regions of squared-mass splitting and mixing angle favored or excluded by various experiments based on two-flavor neutrino oscillation analyses. The figure was contributed by H. Murayama (University of California, Berkeley, and IPMU, University of Tokyo). References to the data used in the figure can be found at <http://hitoshi.berkeley.edu/neutrino>.

oscillations, appearance of ν_τ remained to be confirmed. For this purpose, a promising method is an accelerator long-baseline experiment using emulsion technique to identify short-lived τ leptons event-by-event. The only experiment of this kind is OPERA with a neutrino source at CERN and a detector at Gran Sasso with the baseline distance of 730 km. The detector is a combination of the “Emulsion Cloud Chamber” and magnetized spectrometer. The CNGS (CERN Neutrinos to Gran Sasso) neutrino beam with $\langle E_\nu \rangle = 17$ GeV is produced by high-energy protons from the CERN SPS. So far, OPERA reported observation of one ν_τ candidate in the hadronic decay channel of τ , corresponding to an exposure of 5.30×10^{19} POT with a target mass of 1290 tons in 2008 and 2009 runs [60,61], with expectation of 1.65 signal events [61].

13.6. Measurements of θ_{13}

Reactor $\bar{\nu}_e$ disappearance experiments with $L \sim 1$ km, $\langle E \rangle \sim 3$ MeV are sensitive to $\sim E/L \sim 3 \times 10^{-3}$ eV² $\sim |\Delta m_{\Lambda}^2|$. At this baseline distance, the reactor $\bar{\nu}_e$ oscillations driven by Δm_{21}^2 are negligible. Therefore, as can be seen from Eq. (13.22) and Eq. (13.24), θ_{13} can be directly measured. A reactor neutrino oscillation experiment at the Chooz nuclear power station in France [58] was the first experiment of this kind. The detector was located in an underground laboratory with 300 mwe (meter water equivalent) rock overburden, at about 1 km from the neutrino source. It consisted of a central 5-ton target filled with 0.09% gadolinium loaded liquid scintillator,

surrounded by an intermediate 17-ton and outer 90-ton regions filled with undoped liquid scintillator. Reactor $\bar{\nu}_e$'s were detected via the reaction $\bar{\nu}_e + p \rightarrow e^+ + n$. Gd-doping was chosen to maximize the neutron capture efficiency. The Chooz experiment [58] found no evidence for $\bar{\nu}_e$ disappearance. The 90% CL upper limit for $|\Delta m_{\Lambda}^2| = 2.0 \times 10^{-3}$ eV² is $\sin^2 2\theta_{13} < 0.19$, and for the MINOS 2008 measurement [21] of $|\Delta m_{\Lambda}^2| = 2.43 \times 10^{-3}$ eV it is $\sin^2 2\theta_{13} < 0.15$, both at 90% CL.

In the accelerator neutrino oscillation experiments with conventional neutrino beams, θ_{13} can be measured using $\nu_\mu \rightarrow \nu_e$ appearance. K2K was the first long-baseline experiment to search for ν_e appearance signal due to the $\nu_\mu \rightarrow \nu_e$ oscillations [136]. Based on the dominant term in the probability of $\nu_\mu \rightarrow \nu_e$ oscillations (see Eq. (13.23) and Eq. (13.24)),

$$P(\nu_\mu \rightarrow \nu_e) = \sin^2 2\theta_{13} \cdot \sin^2 2\theta_{23} \cdot \sin^2(1.27\Delta m_{\Lambda}^2 L/E) \\ \sim \frac{1}{2} \sin^2 2\theta_{13} \sin^2(1.27\Delta m_{\Lambda}^2 L/E). \quad (13.75)$$

K2K set the 90% CL upper limit $\sin^2 2\theta_{13} < 0.26$.

By examining the expression for the probability of $\nu_\mu \rightarrow \nu_e$ oscillations in matter (given by Eq. (13.45) in which the sign of the $P_{\text{sin}\delta}$ term is flipped), however, it is understood that subleading terms could have rather large effects and the unknown CP-violating phase δ causes uncertainties in determining the value of θ_{13} . Actually, from the measurement of $\nu_\mu \rightarrow \nu_e$ appearance, θ_{13} is given as a function of δ for a given sign of Δm_{Λ}^2 , or of $\Delta m_{32}^2 \cong \Delta m_{31}^2$. (Also, deviations from maximal θ_{23} mixing would cause a further uncertainty.) Therefore, a single experiment with a neutrino beam cannot determine the value of θ_{13} , although it is possible to establish a non-zero θ_{13} . In 2010, MINOS [137] set the limits for $2 \sin^2 2\theta_{23} \sin^2 2\theta_{13}$ as a function of δ . At $\delta = 0$, the 90% CL upper limit is 0.12 (0.20) for $\Delta m_{\Lambda}^2 > 0$ ($\Delta m_{\Lambda}^2 < 0$).

In 2011, experimental indications of $\nu_\mu \rightarrow \nu_e$ oscillations and a non-zero θ_{13} have been reported by the T2K [24] experiment. Also, MINOS [25] searched for $\nu_\mu \rightarrow \nu_e$ appearance and disfavored the $\theta_{13} = 0$ hypothesis at the 89% CL.

The T2K experiment is the first off-axis long-baseline neutrino oscillation experiment. The baseline distance is 295 km between the J-PARC in Tokai, Japan and Super-Kamiokande. A narrow-band ν_μ beam produced by 30 GeV protons from the J-PARC Main Ring is directed 2.5° off-axis to SK. With this configuration, the ν_μ beam is tuned to the first oscillation maximum. With 1.43×10^{20} POT, the T2K [24] Collaboration observed six candidate ν_e events having all characteristics of being due to $\nu_\mu \rightarrow \nu_e$ oscillations, while the expectation for $\theta_{13} = 0$ is 1.5 ± 0.3 events. The probability to observe six or more candidate events when 1.5 ± 0.3 events are predicted is 7×10^{-3} , implying a non-zero θ_{13} with statistical significance of 2.5σ . At $\delta = 0$, $\sin^2 2\theta_{23} = 1$ and $|\Delta m_{\Lambda}^2| = 2.4 \times 10^{-3}$ eV², this result gives a best fit value of $\sin^2 2\theta_{13} = 0.11$ (0.14) and a 90% CL interval of 0.03 (0.04) $< \sin^2 2\theta_{13} < 0.28$ (0.34) for $\Delta m_{\Lambda}^2 > 0$ ($\Delta m_{\Lambda}^2 < 0$).

The MINOS Collaboration [25] also searched for the $\nu_\mu \rightarrow \nu_e$ appearance signal. Though dependent on the definition of the signal, typically 62 candidate events are observed with an exposure of 8.2×10^{20} POT, while the expectation for $\theta_{13} = 0$ is $49.6 \pm 7.0 \pm 2.7$ events. At the 90% CL, the MINOS result implies that $2 \sin^2 2\theta_{13} \sin^2 2\theta_{23} < 0.12$ (0.20) for $\Delta m_{\Lambda}^2 > 0$ ($\Delta m_{\Lambda}^2 < 0$) and $\delta = 0$, with a best fit value $2 \sin^2 2\theta_{23} \sin^2 2\theta_{13} = 0.041^{+0.04}_{-0.031}$ ($0.079^{+0.071}_{-0.053}$). The MINOS data disfavored the $\theta_{13} = 0$ hypothesis at the 89% CL [25].

Recently, the three reactor neutrino experiments Double Chooz [59], Daya Bay [26], and RENO [27] reported their first results on reactor $\bar{\nu}_e$ disappearance. Daya Bay and RENO measured reactor $\bar{\nu}_e$ s with near and far detectors. The first results of Double Chooz was obtained with only a far detector, though this experiment is planning to have a near detector in 2012. The $\bar{\nu}_e$ detectors of all the three experiments have similar structures; an antineutrino detector consisting of three layers and an optically independent outer veto detector. The innermost layer of the antineutrino detector is filled with Gd-doped liquid scintillator (LS), which is surrounded by a “ γ -catcher” layer filled with Gd-free LS, and outside the γ -catcher is a buffer layer filled with mineral oil.

An outer veto detector is filled with purified water (Daya Bay and RENO) or LS (Double Chooz).

The Daya Bay experiment [26] measured $\bar{\nu}_e$ s from the Daya Bay nuclear power complex (six 2.9 GW_{th} reactors) in China with six functionally identical detectors deployed in two near (470 m and 576 m of flux-weighted baselines) and one far (1648 m) underground halls. With live time of 55 days, the ratio of the observed to expected number of $\bar{\nu}_e$ s at the far hall is $R = 0.940 \pm 0.011 \pm 0.004$ and the rate-only analysis yielded

$$\sin^2 2\theta_{13} = 0.092 \pm 0.016 \pm 0.005. \quad (13.76)$$

From this result, θ_{13} is non-zero with a significance of 5.2σ .

The RENO experiment [27] measured $\bar{\nu}_e$ s from six 2.8 GW_{th} reactors at Yonggwang Nuclear Power Plant in Korea with two identical detectors located at 294 m and 1383 m from the reactor array center. With 229 days of running time, the ratio of the observed to expected number of $\bar{\nu}_e$ s in the far detector is $R = 0.920 \pm 0.009 \pm 0.014$, and from a rate-only analysis the following result is obtained:

$$\sin^2 2\theta_{13} = 0.113 \pm 0.013 \pm 0.019 \quad (13.77)$$

This result excludes the no-oscillation hypothesis at the 4.9σ level.

The Double Chooz experiment [59] measured $\bar{\nu}_e$ s from two 4.25 GW_{th} reactors with a far detector at 1050 m from the two reactor cores. With 101 days of running, this experiment obtained $\sin^2 2\theta_{13} = 0.086 \pm 0.041 \pm 0.030$, or $0.017 < \sin^2 2\theta_{13} < 0.16$ at the 90% CL, by analyzing the rate and energy spectrum of prompt positrons using the reactor $\bar{\nu}_e$ spectrum of Ref. 36 and Ref. 34 and the Bugey4 rate measurement [138].

Turning to atmospheric and solar neutrino observations, Eq. (13.40) to Eq. (13.43) and Eq. (13.62) indicate that they are sensitive to θ_{13} through sub-leading effects. So far, the SK, SNO, and KamLAND Collaborations presented their own θ_{13} analyses by adding or updating their own data. In the atmospheric neutrino sector, the SK group analyzed its atmospheric neutrino data [79,139], and in the solar neutrino sector, SNO [117], SK [114], and KamLAND [128] analyzed the data from all solar neutrino experiments, with or without the KamLAND data, in terms of 3-neutrino oscillations. In addition, KamLAND [128] made a global analysis of all available neutrino data incorporating the Chooz, atmospheric and accelerator data. All these results are consistent with the recent results from accelerator [24,25] and reactor [59,26,27] experiments.

13.7. The three neutrino mixing

All existing compelling data on neutrino oscillations can be described assuming 3-flavour neutrino mixing in vacuum. This is the minimal neutrino mixing scheme which can account for the currently available data on the oscillations of the solar (ν_e), atmospheric (ν_μ and $\bar{\nu}_\mu$), reactor ($\bar{\nu}_e$) and accelerator (ν_μ) neutrinos. The (left-handed) fields of the flavour neutrinos ν_e , ν_μ and ν_τ in the expression for the weak charged lepton current in the CC weak interaction Lagrangian, are linear combinations of the LH components of the fields of three massive neutrinos ν_j :

$$\mathcal{L}_{CC} = -\frac{g}{\sqrt{2}} \sum_{l=e,\mu,\tau} \bar{l}_L(x) \gamma_\alpha \nu_{lL}(x) W^{\alpha\dagger}(x) + h.c.,$$

$$\nu_{lL}(x) = \sum_{j=1}^3 U_{lj} \nu_{jL}(x), \quad (13.78)$$

where U is the 3×3 unitary neutrino mixing matrix [17,18]. The mixing matrix U can be parameterized by 3 angles, and, depending on whether the massive neutrinos ν_j are Dirac or Majorana particles, by 1 or 3 CP violation phases [40,41]:

$$U = \begin{bmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13} \end{bmatrix} \\ \times \text{diag}(1, e^{i\frac{\alpha_{21}}{2}}, e^{i\frac{\alpha_{31}}{2}}). \quad (13.79)$$

where $c_{ij} = \cos \theta_{ij}$, $s_{ij} = \sin \theta_{ij}$, the angles $\theta_{ij} = [0, \pi/2]$, $\delta = [0, 2\pi]$ is the Dirac CP violation phase and α_{21} , α_{31} are two Majorana CP violation phases. Thus, in the case of massive Dirac neutrinos, the neutrino mixing matrix U is similar, in what concerns the number of mixing angles and CP violation phases, to the CKM quark mixing matrix. The presence of two additional physical CP violation phases in U if ν_j are Majorana particles is a consequence of the special properties of the latter (see, *e.g.*, Refs. [39,40]).

As we see, the fundamental parameters characterizing the 3-neutrino mixing are: i) the 3 angles θ_{12} , θ_{23} , θ_{13} , ii) depending on the nature of massive neutrinos ν_j - 1 Dirac (δ), or 1 Dirac + 2 Majorana ($\delta, \alpha_{21}, \alpha_{31}$), CP violation phases, and iii) the 3 neutrino masses, m_1 , m_2 , m_3 . Thus, depending on whether the massive neutrinos are Dirac or Majorana particles, this makes 7 or 9 additional parameters in the minimally extended Standard Model of particle interactions with massive neutrinos.

The neutrino oscillation probabilities depend (Section 13.2), in general, on the neutrino energy, E , the source-detector distance L , on the elements of U and, for relativistic neutrinos used in all neutrino experiments performed so far, on $\Delta m_{ij}^2 \equiv (m_i^2 - m_j^2)$, $i \neq j$. In the case of 3-neutrino mixing there are only two independent neutrino mass squared differences, say $\Delta m_{21}^2 \neq 0$ and $\Delta m_{31}^2 \neq 0$. The numbering of massive neutrinos ν_j is arbitrary. It proves convenient from the point of view of relating the mixing angles θ_{12} , θ_{23} and θ_{13} to observables, to identify $|\Delta m_{21}^2|$ with the smaller of the two neutrino mass squared differences, which, as it follows from the data, is responsible for the solar ν_e and, the observed by KamLAND, reactor $\bar{\nu}_e$ oscillations. We will number (just for convenience) the massive neutrinos in such a way that $m_1 < m_2$, so that $\Delta m_{21}^2 > 0$. With these choices made, there are two possibilities: either $m_1 < m_2 < m_3$, or $m_3 < m_1 < m_2$. Then the larger neutrino mass square difference $|\Delta m_{31}^2|$ or $|\Delta m_{32}^2|$, can be associated with the experimentally observed oscillations of the atmospheric ν_μ and $\bar{\nu}_\mu$ and accelerator ν_μ . The effects of Δm_{31}^2 or Δm_{32}^2 in the oscillations of solar ν_e , and of Δm_{21}^2 in the oscillations of atmospheric ν_μ and $\bar{\nu}_\mu$ and of accelerator ν_μ , are relatively small and subdominant as a consequence of the facts that i) L , E and L/E in the experiments with solar ν_e and with atmospheric ν_μ and $\bar{\nu}_\mu$ or accelerator ν_μ , are very different, ii) the conditions of production and propagation (on the way to the detector) of the solar ν_e and of the atmospheric ν_μ and $\bar{\nu}_\mu$ or accelerator ν_μ , are very different, and iii) $|\Delta m_{21}^2|$ and $|\Delta m_{31}^2|$ ($|\Delta m_{32}^2|$) in the case of $m_1 < m_2 < m_3$ ($m_3 < m_1 < m_2$), as it follows from the data, differ by approximately a factor of 30, $|\Delta m_{21}^2| \ll |\Delta m_{31(32)}^2|$, $|\Delta m_{21}^2|/|\Delta m_{31(32)}^2| \cong 0.03$. This implies that in both cases of $m_1 < m_2 < m_3$ and $m_3 < m_1 < m_2$ we have $\Delta m_{32}^2 \cong \Delta m_{31}^2$ with $|\Delta m_{31}^2 - \Delta m_{32}^2| = |\Delta m_{21}^2| \ll |\Delta m_{31,32}^2|$.

It follows from the results of the Chooz experiment with reactor $\bar{\nu}_e$ [58] and from the more recent data discussed in the preceding subsection that, in the convention we use, in which $0 < \Delta m_{21}^2 < |\Delta m_{31(32)}^2|$, the element $|U_{e3}| = \sin \theta_{13}$ of the neutrino mixing matrix U , as the results of the Daya Bay and RENO experiments show, is small. This makes it possible to identify the angles θ_{12} and θ_{23} as the neutrino mixing angles associated with the solar ν_e and the dominant atmospheric ν_μ (and $\bar{\nu}_\mu$) oscillations, respectively. The angles θ_{12} and θ_{23} are often called ‘‘solar’’ and ‘‘atmospheric’’ neutrino mixing angles, and are often denoted as $\theta_{12} = \theta_\odot$ and $\theta_{23} = \theta_A$ (or θ_{atm}) while Δm_{21}^2 and Δm_{31}^2 are often referred to as the ‘‘solar’’ and ‘‘atmospheric’’ neutrino mass squared differences and are often denoted as $\Delta m_{21}^2 \equiv \Delta m_{\odot}^2$, $\Delta m_{31}^2 \equiv \Delta m_A^2$ (or Δm_{atm}^2).

The solar neutrino data tell us that $\Delta m_{21}^2 \cos 2\theta_{12} > 0$. In the convention employed by us we have $\Delta m_{21}^2 > 0$. Correspondingly, in this convention one must have $\cos 2\theta_{12} > 0$.

Global analyses [140,141] of the existing neutrino oscillation data, including the T2K [24] and MINOS [25] (but not the Daya Bay [26] and RENO [27]) results, allowed us to determine the parameters which drive the solar neutrino and the dominant atmospheric neutrino oscillations, $\Delta m_{\odot}^2 = \Delta m_{21}^2$, θ_{12} , and $|\Delta m_A^2| = |\Delta m_{31}^2| \cong |\Delta m_{32}^2|$, θ_{23} , with a relatively good precision, and to establish that the angle $\theta_{13} \neq 0$ at $\gtrsim 99.73\%$ CL. The Daya Bay and RENO experiments provided a rather precise determination of the angle θ_{13} . Analyses of

the global neutrino oscillation data, in which the Daya Bay and RENO results on θ_{13} are also included, are lacking at present. Therefore we present in Table 13.7 the best fit values and the 99.73% CL allowed ranges of Δm_{21}^2 , $\sin^2 \theta_{12}$, $|\Delta m_{31(32)}^2|$, $\sin^2 \theta_{23}$ and $\sin^2 \theta_{13}$, found in Ref. 140 as well as the PDG average [142] of the results of the three recent reactor experiments [26,27,59]. Since the PDG average of $\sin^2 \theta_{13}$ is very close to that obtained in the global analysis in Ref. 140, and since the other oscillation parameter ranges are almost uncorrelated from θ_{13} , we do not expect that the inclusion of the Daya Bay and RENO data will change significantly the results (neither the central values nor the errors) for Δm_{21}^2 , $\sin^2 \theta_{12}$, $|\Delta m_{31(32)}^2|$ and $\sin^2 \theta_{23}$ obtained in Ref. 140. Obviously, the uncertainty in the value of $\sin^2 \theta_{13}$ will shrink considerably. We note also that the results from Ref. 140 quoted in Table 13.7 are derived by marginalizing over $\text{sgn}(\Delta m_{31}^2) = \pm 1$ and over $\cos \delta = \pm 1$ and that the values (the values in brackets) of $\sin^2 \theta_{12}$ and $\sin^2 \theta_{13}$ are obtained in Ref. 140 using the reactor $\bar{\nu}_e$ fluxes from Ref. 35 (from Ref. 34).

Table 13.7: The best-fit values and 3σ allowed ranges of the 3-neutrino oscillation parameters, derived from a global fit of the current neutrino oscillation data, including the T2K and MINOS (but not the Daya Bay and RENO) results (from [140]). The PDG average of the results of the three recent reactor experiments [26,27,59] is given in the last line [142]. The values (values in brackets) of $\sin^2 \theta_{12}$ and $\sin^2 \theta_{13}$ are obtained using the “old” [35] (“new” [34]) reactor $\bar{\nu}_e$ fluxes in the analysis.

Parameter	best-fit ($\pm 1\sigma$)	3σ
Δm_{\odot}^2 [10^{-5} eV ²]	$7.58_{-0.26}^{+0.22}$	6.99 – 8.18
$ \Delta m_{\text{A}}^2 $ [10^{-3} eV ²]	$2.35_{-0.09}^{+0.12}$	2.06 – 2.67
$\sin^2 \theta_{12}$	0.306 (0.312) $_{-0.015}^{+0.018}$	0.259 (0.265) – 0.359 (0.364)
$\sin^2 \theta_{23}$	$0.42_{-0.03}^{+0.08}$	0.34 – 0.64
$\sin^2 \theta_{13}$ [140]	0.021 (0.025) $_{-0.008}^{+0.007}$	0.001 (0.005) – 0.044 (0.050)
$\sin^2 \theta_{13}$ [142]	0.0251 ± 0.0034	0.015 – 0.036

A combined analysis of the data on θ_{13} from the T2K, MINOS, Double Chooz, Daya Bay and RENO experiments was performed in Ref. 145. The authors find that $\theta_{13} \neq 0$ at 7.7σ :

$$\sin^2 2\theta_{13} = 0.096 \pm 0.013 \quad (\pm 0.040) \text{ at } 1\sigma \quad (3\sigma) \quad (13.80)$$

In this analysis the positive or negative sign of Δm_{A}^2 was used as input and the values of $\sin^2 2\theta_{23}$ and $|\Delta m_{\text{A}}^2|$ were varied imposing Gaussian priors based on the results of the atmospheric neutrino [139] and MINOS [130] experiments. The value of $\sin^2 2\theta_{13}$ thus obtained showed a statistically insignificant dependence on the Dirac phase δ .

It follows from the results given in Table 13.7 that $\theta_{23} \cong \pi/4$, $\theta_{12} \cong \pi/5.4$ and that $\theta_{13} \cong \pi/20$. Correspondingly, the pattern of neutrino mixing is drastically different from the pattern of quark mixing.

Note also that Δm_{21}^2 , $\sin^2 \theta_{12}$, $|\Delta m_{31(32)}^2|$, $\sin^2 \theta_{23}$ and $\sin^2 \theta_{13}$ are determined from the data with a 1σ uncertainty ($= 1/6$ of the 3σ range) of approximately 2.6%, 5.4%, 4.3%, 12% and absolute error 0.42×10^{-2} , respectively.

The existing SK atmospheric neutrino, K2K and MINOS data do not allow to determine the sign of $\Delta m_{31(32)}^2$. Maximal solar neutrino mixing, *i.e.*, $\theta_{12} = \pi/4$, is ruled out at more than 6σ by the data. Correspondingly, one has $\cos 2\theta_{12} \geq 0.27$ (at 99.73% CL).

At present no experimental information on the Dirac and Majorana CP violation phases in the neutrino mixing matrix is available. Thus, the status of CP symmetry in the lepton sector is unknown. With $\theta_{13} \neq 0$, the Dirac phase δ can generate CP violation effects in neutrino oscillations [40,52,53]. The magnitude of CP violation in $\nu_l \rightarrow \nu_{l'}$ and $\bar{\nu}_l \rightarrow \bar{\nu}_{l'}$ oscillations, $l \neq l' = e, \mu, \tau$, is determined, as we have seen, by the rephasing invariant J_{CP} (see Eq. (13.19)), which

in the “standard” parametrisation of the neutrino mixing matrix (Eq. (13.79)) has the form:

$$J_{CP} \equiv \text{Im}(U_{\mu 3} U_{e 3}^* U_{e 2} U_{\mu 2}^*) = \frac{1}{8} \cos \theta_{13} \sin 2\theta_{12} \sin 2\theta_{23} \sin 2\theta_{13} \sin \delta. \quad (13.81)$$

Thus, given the fact that $\sin 2\theta_{12}$, $\sin 2\theta_{23}$ and $\sin 2\theta_{13}$ have been determined experimentally with a relatively good precision, the size of CP violation effects in neutrino oscillations depends essentially only on the magnitude of the currently unknown value of the Dirac phase δ . The current data implies $|J_{CP}| \lesssim 0.045$, where we have used the 3σ ranges of $\sin^2 \theta_{12}$, $\sin^2 \theta_{23}$ and $\sin^2 \theta_{13}$ given in Table 13.7 and Eq. (13.76), respectively.

As we have indicated, the existing data do not allow one to determine the sign of $\Delta m_{\text{A}}^2 = \Delta m_{31(2)}^2$. In the case of 3-neutrino mixing, the two possible signs of $\Delta m_{31(2)}^2$ correspond to two types of neutrino mass spectrum. In the widely used conventions of numbering the neutrinos with definite mass in the two cases, the two spectra read:

– *i) spectrum with normal ordering:*

$$m_1 < m_2 < m_3, \Delta m_{\text{A}}^2 = \Delta m_{21}^2 > 0,$$

$$\Delta m_{\odot}^2 \equiv \Delta m_{21}^2 > 0, m_{2(3)} = (m_1^2 + \Delta m_{21(31)}^2)^{\frac{1}{2}};$$

– *ii) spectrum with inverted ordering (IO):*

$$m_3 < m_1 < m_2, \Delta m_{\text{A}}^2 = \Delta m_{32}^2 < 0, \Delta m_{\odot}^2 \equiv \Delta m_{21}^2 > 0,$$

$$m_2 = (m_3^2 + \Delta m_{23}^2)^{\frac{1}{2}}, m_1 = (m_3^2 + \Delta m_{23}^2 - \Delta m_{21}^2)^{\frac{1}{2}}.$$

Depending on the values of the lightest neutrino mass [143], $\min(m_j)$, the neutrino mass spectrum can also be:

– *Normal Hierarchical (NH):*

$$m_1 \ll m_2 < m_3, m_2 \cong (\Delta m_{\odot}^2)^{\frac{1}{2}} \cong 0.0086 \text{ eV},$$

$$m_3 \cong |\Delta m_{\text{A}}^2|^{\frac{1}{2}} \cong 0.048 \text{ eV}; \text{ or}$$

– *Inverted Hierarchical (IH):*

$$m_3 \ll m_1 < m_2, \text{ with } m_{1,2} \cong |\Delta m_{\text{A}}^2|^{\frac{1}{2}} \cong 0.048 \text{ eV}; \text{ or}$$

– *Quasi-Degenerate (QD):*

$$m_1 \cong m_2 \cong m_3 \cong m_0, m_j^2 \gg |\Delta m_{\text{A}}^2|, m_0 \gtrsim 0.10 \text{ eV}.$$

All three types of spectrum are compatible with the existing constraints on the absolute scale of neutrino masses m_j . Information about the latter can be obtained, *e.g.*, by measuring the spectrum of electrons near the end point in ^3H β -decay experiments [146–149] and from cosmological and astrophysical data. The most stringent upper bounds on the $\bar{\nu}_e$ mass were obtained in the Troitzk [147,148] experiment:

$$m_{\bar{\nu}_e} < 2.05 \text{ eV} \quad \text{at } 95\% \text{ CL}. \quad (13.82)$$

We have $m_{\bar{\nu}_e} \cong m_{1,2,3}$ in the case of QD spectrum. The KATRIN experiment [149] is planned to reach sensitivity of $m_{\bar{\nu}_e} \sim 0.20 \text{ eV}$, *i.e.*, it will probe the region of the QD spectrum.

The Cosmic Microwave Background (CMB) data of the WMAP experiment, combined with supernovae data and data on galaxy clustering can be used to obtain an upper limit on the sum of neutrinos masses (see review on Cosmological Parameters [150] and, *e.g.*, Ref. 151). Depending on the model complexity and the input data used one obtains [151]: $\sum_j m_j \lesssim (0.3 - 1.3) \text{ eV}$, 95% CL.

It follows from these data that neutrino masses are much smaller than the masses of charged leptons and quarks. If we take as an indicative upper limit $m_j \lesssim 0.5 \text{ eV}$, we have $m_j/m_{l,q} \lesssim 10^{-6}$, $l = e, \mu, \tau$, $q = d, s, b, u, c, t$. It is natural to suppose that the remarkable smallness of neutrino masses is related to the existence of a new fundamental mass scale in particle physics, and thus to new physics beyond that predicted by the Standard Model.

13.7.1. The see-saw mechanism and the baryon asymmetry of the Universe :

A natural explanation of the smallness of neutrino masses is provided by the (type I) see-saw mechanism of neutrino mass generation [3]. An integral part of this rather simple mechanism [152] are the RH neutrinos ν_{lR} (RH neutrino fields $\nu_{lR}(x)$). The latter are assumed to possess a Majorana mass term as well as Yukawa type coupling $\mathcal{L}_Y(x)$ with the Standard Model lepton and Higgs doublets, $\psi_{lL}(x)$ and $\Phi(x)$, respectively, $(\psi_{lL}(x))^T = (\nu_{lL}^T(x) \ l_l^T(x))$, $l = e, \mu, \tau$, $(\Phi(x))^T = (\Phi^{(0)} \ \Phi^{(-)})$. In the basis in which the Majorana mass matrix of RH neutrinos is diagonal, we have:

$$\mathcal{L}_{Y,M}(x) = \left(\lambda_{il} \overline{N_{iR}}(x) \Phi^\dagger(x) \psi_{lL}(x) + \text{h.c.} \right) - \frac{1}{2} M_i \overline{N_i}(x) N_i(x), \quad (13.83)$$

where λ_{il} is the matrix of neutrino Yukawa couplings and N_i ($N_i(x)$) is the heavy RH Majorana neutrino (field) possessing a mass $M_i > 0$. When the electroweak symmetry is broken spontaneously, the neutrino Yukawa coupling generates a Dirac mass term: $m_{il}^D \overline{N_{iR}}(x) \nu_{lL}(x) + \text{h.c.}$, with $m^D = v\lambda$, $v = 174$ GeV being the Higgs doublet v.e.v. In the case when the elements of m^D are much smaller than M_k , $|m_{il}^D| \ll M_k$, $i, k = 1, 2, 3$, $l = e, \mu, \tau$, the interplay between the Dirac mass term and the mass term of the heavy (RH) Majorana neutrinos N_i generates an effective Majorana mass (term) for the LH flavour neutrinos [3]: $m_{il}^{LL} \cong -(m^D)_{ij}^T M_j^{-1} m_{jl}^D$. In grand unified theories, m^D is typically of the order of the charged fermion masses. In $SO(10)$ theories, for instance, m^D coincides with the up-quark mass matrix. Taking indicatively $m^{LL} \sim 0.1$ eV, $m^D \sim 100$ GeV, one finds $M \sim 10^{14}$ GeV, which is close to the scale of unification of the electroweak and strong interactions, $M_{GUT} \cong 2 \times 10^{16}$ GeV. In GUT theories with RH neutrinos one finds that indeed the heavy Majorana neutrinos N_j naturally obtain masses which are by few to several orders of magnitude smaller than M_{GUT} . Thus, the enormous disparity between the neutrino and charged fermion masses is explained in this approach by the huge difference between effectively the electroweak symmetry breaking scale and M_{GUT} .

An additional attractive feature of the see-saw scenario is that the generation and smallness of neutrino masses is related via the leptogenesis mechanism [2] to the generation of the baryon asymmetry of the Universe. The Yukawa coupling in Eq. (13.83), in general, is not CP conserving. Due to this CP-nonconserving coupling the heavy Majorana neutrinos undergo, *e.g.*, the decays $N_j \rightarrow l^+ + \Phi^{(-)}$, $N_j \rightarrow l^- + \Phi^{(+)}$, which have different rates: $\Gamma(N_j \rightarrow l^+ + \Phi^{(-)}) \neq \Gamma(N_j \rightarrow l^- + \Phi^{(+)})$. When these decays occur in the Early Universe at temperatures somewhat below the mass of, say, N_1 , so that the latter are out of equilibrium with the rest of the particles present at that epoch, CP violating asymmetries in the individual lepton charges L_l , and in the total lepton charge L , of the Universe are generated. These lepton asymmetries are converted into a baryon asymmetry by $(B - L)$ conserving, but $(B + L)$ violating, sphaleron processes, which exist in the Standard Model and are effective at temperatures $T \sim (100 - 10^{12})$ GeV. If the heavy neutrinos N_j have hierarchical spectrum, $M_1 \ll M_2 \ll M_3$, the observed baryon asymmetry can be reproduced provided the mass of the lightest one satisfies $M_1 \gtrsim 10^9$ GeV [153]. Thus, in this scenario, the neutrino masses and mixing and the baryon asymmetry have the same origin - the neutrino Yukawa couplings and the existence of (at least two) heavy Majorana neutrinos. Moreover, quantitative studies based on recent advances in leptogenesis theory [154] have shown that the Dirac and/or Majorana phases in the neutrino mixing matrix U can provide the CP violation, necessary in leptogenesis for the generation of the observed baryon asymmetry of the Universe [155]. This implies, in particular, that if the CP symmetry is established not to hold in the lepton sector due to U , at least some fraction (if not all) of the observed baryon asymmetry might be due to the Dirac and/or Majorana CP violation present in the neutrino mixing.

13.7.2. The nature of massive neutrinos :

The experiments studying flavour neutrino oscillations cannot provide information on the nature - Dirac or Majorana, of massive neutrinos [40,54]. Establishing whether the neutrinos with definite mass ν_j are Dirac fermions possessing distinct antiparticles, or Majorana fermions, i.e. spin 1/2 particles that are identical with their antiparticles, is of fundamental importance for understanding the origin of ν -masses and mixing and the underlying symmetries of particle interactions (see *e.g.*, Ref. 66). The neutrinos with definite mass ν_j will be Dirac fermions if the particle interactions conserve some additive lepton number, *e.g.*, the total lepton charge $L = L_e + L_\mu + L_\tau$. If no lepton charge is conserved, ν_j will be Majorana fermions (see *e.g.*, Ref. 39). The massive neutrinos are predicted to be of Majorana nature by the see-saw mechanism of neutrino mass generation [3]. The observed patterns of neutrino mixing and of neutrino mass squared differences can be related to Majorana massive neutrinos and the existence of an approximate symmetry in the lepton sector corresponding, *e.g.*, to the conservation of the lepton charge $L' = L_e - L_\mu - L_\tau$ [156]. Determining the nature of massive neutrinos ν_j is one of the fundamental and most challenging problems in the future studies of neutrino mixing.

Figure 13.10: The effective Majorana mass $|\langle m \rangle|$ (including a 2σ uncertainty), as a function of $\min(m_j)$ for $\sin^2 \theta_{13} = 0.0236 \pm 0.0042$ [26] and $\delta = 0$. The figure is obtained using also the best fit values and 1σ errors of Δm_{21}^2 , $\sin^2 \theta_{12}$, and $|\Delta m_{31}^2| \cong |\Delta m_{32}^2|$ from Ref. 140 (given in Table 13.7). For $\sin^2 \theta_{12}$ the results found with the “old” reactor $\bar{\nu}_e$ fluxes [35] were employed. The phases $\alpha_{21,31}$ are varied in the interval $[0, \pi]$. The predictions for the NH, IH and QD spectra are indicated. The red regions correspond to at least one of the phases $\alpha_{21,31}$ and $(\alpha_{31} - \alpha_{21})$ having a CP violating value, while the blue and green areas correspond to $\alpha_{21,31}$ possessing CP conserving values. (Update by S. Pascoli of a figure from the last article quoted in Ref. 160.)

The Majorana nature of massive neutrinos ν_j manifests itself in the existence of processes in which the total lepton charge L changes by two units: $K^+ \rightarrow \pi^- + \mu^+ + \mu^+$, $\mu^- + (A, Z) \rightarrow \mu^+ + (A, Z - 2)$, *etc.* Extensive studies have shown that the only feasible experiments having the potential of establishing that the massive neutrinos are Majorana particles are at present the experiments searching for $(\beta\beta)_{0\nu}$ -decay: $(A, Z) \rightarrow (A, Z + 2) + e^- + e^-$ (see *e.g.*, Ref. 157). The observation of $(\beta\beta)_{0\nu}$ -decay and the measurement of the corresponding half-life with sufficient accuracy, would not only be a proof that the total lepton charge is not conserved, but might also provide unique information on the i) type of neutrino mass spectrum (see, *e.g.*, Ref. 158), ii) Majorana phases in U [144,159] and iii) the absolute scale of neutrino masses (for details see Ref. 157 to Ref. 160 and references quoted therein).

Under the assumptions of 3- ν mixing, of massive neutrinos ν_j being Majorana particles, and of $(\beta\beta)_{0\nu}$ -decay generated only by the (V-A) charged current weak interaction via the exchange of the

three Majorana neutrinos ν_j having masses $m_j \lesssim$ few MeV, the $(\beta\beta)_{0\nu}$ -decay amplitude has the form (see, *e.g.*, Ref. 39 and Ref. 157): $A(\beta\beta)_{0\nu} \cong \langle m \rangle / M$, where M is the corresponding nuclear matrix element which does not depend on the neutrino mixing parameters, and

$$\begin{aligned} |\langle m \rangle| &= \left| m_1 U_{e1}^2 + m_2 U_{e2}^2 + m_3 U_{e3}^2 \right| \\ &= \left| \left(m_1 c_{12}^2 + m_2 s_{12}^2 e^{i\alpha_{21}} \right) c_{13}^2 + m_3 s_{13}^2 e^{i(\alpha_{31}-2\delta)} \right|, \end{aligned} \quad (13.84)$$

is the effective Majorana mass in $(\beta\beta)_{0\nu}$ -decay. In the case of CP-invariance one has [42], $\eta_{21} \equiv e^{i\alpha_{21}} = \pm 1$, $\eta_{31} \equiv e^{i\alpha_{31}} = \pm 1$, $e^{-i2\delta} = 1$. The three neutrino masses $m_{1,2,3}$ can be expressed in terms of the two measured Δm_{jk}^2 and, *e.g.*, $\min(m_j)$. Thus, given the neutrino oscillation parameters Δm_{21}^2 , $\sin^2 \theta_{12}$, Δm_{31}^2 and $\sin^2 \theta_{13}$, $|\langle m \rangle|$ is a function of the lightest neutrino mass $\min(m_j)$, the Majorana (and Dirac) CP violation phases in U and of the type of neutrino mass spectrum. In the case of NH, IH and QD spectrum we have (see, *e.g.*, Ref. 144 and Ref. 160):

$$|\langle m \rangle| \cong \left| \sqrt{\Delta m_{21}^2 s_{12}^2 c_{13}^2} + \sqrt{\Delta m_{31}^2 s_{13}^2} e^{i(\alpha_{31}-\alpha_{21}-2\delta)} \right|, \quad \text{NH}, \quad (13.85)$$

$$|\langle m \rangle| \cong \tilde{m} \left(1 - \sin^2 2\theta_{12} \sin^2 \frac{\alpha_{21}}{2} \right)^{\frac{1}{2}}, \quad \text{IH (IO) and QD}, \quad (13.86)$$

where $\tilde{m} \equiv \sqrt{\Delta m_{23}^2 + m_3^2}$ and $\tilde{m} \equiv m_0$ for IH (IO) and QD spectrum, respectively. In Eq. (13.86) we have exploited the fact that $\sin^2 \theta_{13} \ll \cos 2\theta_{12}$. The CP conserving values of the Majorana phases $(\alpha_{31} - \alpha_{21})$ and α_{21} determine the intervals of possible values of $|\langle m \rangle|$, corresponding to the different types of neutrino mass spectrum. Using the 3σ ranges of the allowed values of the neutrino oscillation parameters from Table 13.7 and Eq. (13.76) one finds that: i) $2.3 \times 10^{-4} \text{ eV} \lesssim |\langle m \rangle| \lesssim 5.0 \times 10^{-3} \text{ eV}$ in the case of NH spectrum; ii) $\sqrt{\Delta m_{23}^2} \cos 2\theta_{12} \lesssim |\langle m \rangle| \lesssim \sqrt{\Delta m_{23}^2}$, or $1.3 \times 10^{-2} \text{ eV} \lesssim |\langle m \rangle| \lesssim 5.2 \times 10^{-2} \text{ eV}$ in the case of IH spectrum; iii) $m_0 \cos 2\theta_{12} \lesssim |\langle m \rangle| \lesssim m_0$, or $2.8 \times 10^{-2} \text{ eV} \lesssim |\langle m \rangle| \lesssim m_0 \text{ eV}$, $m_0 \gtrsim 0.10 \text{ eV}$, in the case of QD spectrum. The difference in the ranges of $|\langle m \rangle|$ in the cases of NH, IH and QD spectrum opens up the possibility to get information about the type of neutrino mass spectrum from a measurement of $|\langle m \rangle|$ [158]. The predicted $(\beta\beta)_{0\nu}$ -decay effective Majorana mass $|\langle m \rangle|$ as a function of the lightest neutrino mass $\min(m_j)$ is shown in Fig. 13.10.

13.8. Outlook

After the spectacular experimental progress made in the studies of neutrino oscillations, further understanding of the pattern of neutrino masses and neutrino mixing, of their origins and of the status of CP symmetry in the lepton sector requires an extensive and challenging program of research. The main goals of such a research program, outlined in the 2010 PDG edition of the Review of Particle Physics, included:

- Determining the nature - Dirac or Majorana, of massive neutrinos ν_j . This is of fundamental importance for making progress in our understanding of the origin of neutrino masses and mixing and of the symmetries governing the lepton sector of particle interactions.
- Determination of the sign of Δm_{Λ}^2 (Δm_{31}^2) and of the type of neutrino mass spectrum.
- Determining or obtaining significant constraints on the absolute scale of neutrino masses.
- Measurement of, or improving by at least a factor of (5 - 10) the existing upper limit on, the small neutrino mixing angle θ_{13} . Together with the Dirac CP-violating phase, the angle θ_{13} determines the magnitude of CP-violation effects in neutrino oscillations.
- Determining the status of CP symmetry in the lepton sector.
- High precision measurement of Δm_{21}^2 , θ_{12} , and $|\Delta m_{31}^2|$, θ_{23} .

- Understanding at a fundamental level the mechanism giving rise to neutrino masses and mixing and to L_1 -non-conservation. This includes understanding the origin of the patterns of ν -mixing and ν -masses suggested by the data. Are the observed patterns of ν -mixing and of $\Delta m_{21,31}^2$ related to the existence of a new fundamental symmetry of particle interactions? Is there any relation between quark mixing and neutrino mixing, *e.g.*, does the relation $\theta_{12} + \theta_c = \pi/4$, where θ_c is the Cabibbo angle, hold? What is the physical origin of CP violation phases in the neutrino mixing matrix U ? Is there any relation (correlation) between the (values of) CP violation phases and mixing angles in U ? Progress in the theory of neutrino mixing might also lead to a better understanding of the mechanism of generation of baryon asymmetry of the Universe.

The successful realization of this research program, which would be a formidable task and would require many years, already began during the last two years with the results of the T2K and MINOS experiments on the value of θ_{13} , of the global analyses of the neutrino oscillation data, which showed that $\theta_{13} \neq 0$ at 3σ , and with the subsequent rather precise measurements of the value of $\sin^2 2\theta_{13}$ in the Daya Bay and RENO experiments. Averaging the results of the three recent reactor experiments with the standard PDG method, one obtains $\sin^2 2\theta_{13} = 0.098 \pm 0.013$ [142]. These results on θ_{13} have far reaching implications. The measured relatively large value of θ_{13} opens up the possibilities, in particular,

i) for searching for CP violation effects in neutrino oscillation experiments with high intensity accelerator neutrino beams, like T2K, NO ν A, etc. NO ν A [63], an off-axis ν_e appearance experiment using the NuMI beam, is under construction and expected to be complete in 2014. The sensitivities of T2K and NO ν A on CP violation in neutrino oscillations are discussed in, *e.g.*, Ref. 162.

ii) for determining the sign of Δm_{32}^2 , and thus the type of neutrino mass spectrum in the long baseline neutrino oscillation experiments at accelerators, in the experiments studying the oscillations of atmospheric neutrinos (see, *e.g.*, Ref. 82), as well as in experiments with reactor antineutrinos [161]. A value of $\sin \theta_{13} \gtrsim 0.09$ is a necessary condition for a successful “flavoured” leptogenesis with hierarchical heavy Majorana neutrinos when the CP violation required for the generation of the matter-antimatter asymmetry of the Universe is provided entirely by the Dirac CP violating phase in the neutrino mixing matrix [155].

With the measurement of θ_{13} , the first steps on the long “road” leading to a comprehensive understanding of the patterns of neutrino masses and mixing, of their origin and implications, were made.

 97. An expression for the “jump” probability P' for N_e varying linearly along the neutrino path was derived in W.C. Haxton, Phys. Rev. Lett. **57**, 1271 (1986) and in Ref. 89 on the basis of the old Landau-Zener result: L.D. Landau, Phys. Z. USSR **1**, 426 (1932), C. Zener, Proc. R. Soc. A **137**, 696 (1932). An analytic description of the solar ν_e transitions based on the Landau-Zener jump probability was proposed in Ref. 89 and in W.C. Haxton, Phys. Rev. **D35**, 2352 (1987). The precision limitations of this description, which is less accurate than that based on the exponential density approximation, were discussed in S.T. Petcov, Phys. Lett. **B191**, 299 (1987) and in Ref. 91.

14. QUARK MODEL

Revised August 2011 by C. Amsler (University of Zürich), T. DeGrand (University of Colorado, Boulder), and B. Krusche (University of Basel).

14.1. Quantum numbers of the quarks

Quantum chromodynamics (QCD) is the theory of the strong interactions. QCD is a quantum field theory and its constituents are a set of fermions, the quarks, and gauge bosons, the gluons. Strongly interacting particles, the hadrons, are bound states of quark and gluon fields. As gluons carry no intrinsic quantum numbers beyond color charge, and because color is believed to be permanently confined, most of the quantum numbers of strongly interacting particles are given by the quantum numbers of their constituent quarks and antiquarks. The description of hadronic properties which strongly emphasizes the role of the minimum-quark-content part of the wave function of a hadron is generically called the quark model. It exists on many levels: from the simple, almost dynamics-free picture of strongly interacting particles as bound states of quarks and antiquarks, to more detailed descriptions of dynamics, either through models or directly from QCD itself. The different sections of this review survey the many approaches to the spectroscopy of strongly interacting particles which fall under the umbrella of the quark model.

Quarks are strongly interacting fermions with spin 1/2 and, by convention, positive parity. Antiquarks have negative parity. Quarks have the additive baryon number 1/3, antiquarks -1/3. Table 14.1 gives the other additive quantum numbers (flavors) for the three generations of quarks. They are related to the charge Q (in units of the elementary charge e) through the generalized Gell-Mann-Nishijima formula

$$Q = I_z + \frac{B + S + C + B + T}{2}, \quad (14.1)$$

where B is the baryon number. The convention is that the *flavor* of a quark (I_z , S , C , B , or T) has the same sign as its *charge* Q . With this convention, any flavor carried by a charged meson has the same sign as its charge, *e.g.*, the strangeness of the K^+ is +1, the bottomness of the B^+ is +1, and the charm and strangeness of the D_s^- are each -1. Antiquarks have the opposite flavor signs.

14.2. Mesons

Mesons have baryon number $B = 0$. In the quark model, they are $q\bar{q}'$ bound states of quarks q and antiquarks \bar{q}' (the flavors of q and q' may be different). If the orbital angular momentum of the $q\bar{q}'$ state is ℓ , then the parity P is $(-1)^{\ell+1}$. The meson spin J is given by the usual relation $|\ell - s| \leq J \leq |\ell + s|$, where s is 0 (antiparallel quark spins) or 1 (parallel quark spins). The charge conjugation, or C -parity $C = (-1)^{\ell+s}$, is defined only for the $q\bar{q}$ states made of quarks and their own antiquarks. The C -parity can be generalized to the G -parity $G = (-1)^{I+\ell+s}$ for mesons made of quarks and their own antiquarks (isospin $I_z = 0$), and for the charged $u\bar{d}$ and $d\bar{u}$ states (isospin $I = 1$).

Table 14.1: Additive quantum numbers of the quarks.

	d	u	s	c	b	t
Q – electric charge	$-\frac{1}{3}$	$+\frac{2}{3}$	$-\frac{1}{3}$	$+\frac{2}{3}$	$-\frac{1}{3}$	$+\frac{2}{3}$
I – isospin	$\frac{1}{2}$	$\frac{1}{2}$	0	0	0	0
I_z – isospin z -component	$-\frac{1}{2}$	$+\frac{1}{2}$	0	0	0	0
S – strangeness	0	0	-1	0	0	0
C – charm	0	0	0	+1	0	0
B – bottomness	0	0	0	0	-1	0
T – topness	0	0	0	0	0	+1

The mesons are classified in J^{PC} multiplets. The $\ell = 0$ states are the pseudoscalars (0^{-+}) and the vectors (1^{--}). The orbital excitations $\ell = 1$ are the scalars (0^{++}), the axial vectors (1^{++}) and (1^{+-}), and the tensors (2^{++}). Assignments for many of the known mesons are given in Tables 14.2 and 14.3. Radial excitations are denoted by the principal quantum number n . The very short lifetime of the t quark makes it likely that bound-state hadrons containing t quarks and/or antiquarks do not exist.

States in the natural spin-parity series $P = (-1)^J$ must, according to the above, have $s = 1$ and hence, $CP = +1$. Thus, mesons with natural spin-parity and $CP = -1$ (0^{+-} , 1^{-+} , 2^{+-} , 3^{-+} , *etc.*) are forbidden in the $q\bar{q}'$ model. The $J^{PC} = 0^{-}$ state is forbidden as well. Mesons with such *exotic* quantum numbers may exist, but would lie outside the $q\bar{q}'$ model (see section below on exotic mesons).

Following SU(3), the nine possible $q\bar{q}'$ combinations containing the light u , d , and s quarks are grouped into an octet and a singlet of light quark mesons:

$$3 \otimes \bar{3} = 8 \oplus 1. \quad (14.2)$$

A fourth quark such as charm c can be included by extending SU(3) to SU(4). However, SU(4) is badly broken owing to the much heavier c quark. Nevertheless, in an SU(4) classification, the sixteen mesons are grouped into a 15-plet and a singlet:

$$4 \otimes \bar{4} = 15 \oplus 1. \quad (14.3)$$

The *weight diagrams* for the ground-state pseudoscalar (0^{-+}) and vector (1^{--}) mesons are depicted in Fig. 14.1. The light quark mesons are members of nonets building the middle plane in Fig. 14.1(a) and (b).

Figure 14.1: SU(4) weight diagram showing the 16-plets for the pseudoscalar (a) and vector mesons (b) made of the u , d , s , and c quarks as a function of isospin I , charm C , and hypercharge $Y = S + B - \frac{C}{3}$. The nonets of light mesons occupy the central planes to which the $c\bar{c}$ states have been added.

Isoscalar states with the same J^{PC} will mix, but mixing between the two light quark isoscalar mesons, and the much heavier charmonium or bottomonium states, are generally assumed to be negligible. In the

Table 14.2: Suggested $q\bar{q}$ quark-model assignments for some of the observed light mesons. Mesons in bold face are included in the Meson Summary Table. The wave functions f and f' are given in the text. The singlet-octet mixing angles from the quadratic and linear mass formulae are also given for the well established nonets. The classification of the 0^{++} mesons is tentative and the mixing angle uncertain due to large uncertainties in some of the masses. Also, the $f_0(1710)$ and $f_0(1370)$ are expected to mix with the $f_0(1500)$. The latter is not in this table as it is hard to accommodate in the scalar nonet. The light scalars $a_0(980)$, $f_0(980)$, and $f_0(500)$ are often considered as meson-meson resonances or four-quark states, and are therefore not included in the table. See the “Note on Scalar Mesons” in the Meson Listings for details and alternative schemes.

$n^{2s+1}\ell_J$	J^{PC}	$l = 1$ $u\bar{d}, \bar{u}d, \frac{1}{\sqrt{2}}(d\bar{d} - u\bar{u})$	$l = \frac{1}{2}$ $u\bar{s}, d\bar{s}; \bar{d}s, -\bar{u}s$	$l = 0$ f'	$l = 0$ f	θ_{quad} [°]	θ_{lin} [°]

† The $1^{+\pm}$ and $2^{-\pm}$ isospin $\frac{1}{2}$ states mix. In particular, the K_{1A} and K_{1B} are nearly equal (45°) mixtures of the $K_1(1270)$ and $K_1(1400)$. The physical vector mesons listed under 1^3D_1 and 2^3S_1 may be mixtures of 1^3D_1 and 2^3S_1 , or even have hybrid components.

† The masses of these states are considerably smaller than most theoretical predictions. They have also been considered as four-quark states (See the “Note on Non- $q\bar{q}$ Mesons” at the end of the Meson Listings). The open flavor states in the 1^{+-} and 1^{++} rows are mixtures of the $1^{+\pm}$ states.

following, we shall use the generic names a for the $I = 1$, K for the $I = 1/2$, and f and f' for the $I = 0$ members of the light quark nonets. Thus, the physical isoscalars are mixtures of the SU(3) wave function ψ_8 and ψ_1 :

$$f' = \psi_8 \cos \theta - \psi_1 \sin \theta, \quad (14.4)$$

$$f = \psi_8 \sin \theta + \psi_1 \cos \theta, \quad (14.5)$$

where θ is the nonet mixing angle and

$$\psi_8 = \frac{1}{\sqrt{6}}(u\bar{u} + d\bar{d} - 2s\bar{s}), \quad (14.6)$$

$$\psi_1 = \frac{1}{\sqrt{3}}(u\bar{u} + d\bar{d} + s\bar{s}). \quad (14.7)$$

These mixing relations are often rewritten to exhibit the $u\bar{u} + d\bar{d}$ and $s\bar{s}$ components which decouple for the “ideal” mixing angle θ_i , such that $\tan \theta_i = 1/\sqrt{2}$ (or $\theta_i = 35.3^\circ$). Defining $\alpha = \theta + 54.7^\circ$, one obtains the physical isoscalar in the flavor basis

$$f' = \frac{1}{\sqrt{2}}(u\bar{u} + d\bar{d}) \cos \alpha - s\bar{s} \sin \alpha, \quad (14.8)$$

and its orthogonal partner f (replace α by $\alpha - 90^\circ$). Thus for ideal mixing ($\alpha_i = 90^\circ$), the f' becomes pure $s\bar{s}$ and the f pure $u\bar{u} + d\bar{d}$. The mixing angle θ can be derived from the mass relation

$$\tan \theta = \frac{4m_K - m_a - 3m_{f'}}{2\sqrt{2}(m_a - m_K)}, \quad (14.9)$$

which also determines its sign or, alternatively, from

$$\tan^2 \theta = \frac{4m_K - m_a - 3m_{f'}}{-4m_K + m_a + 3m_f}. \quad (14.10)$$

Eliminating θ from these equations leads to the sum rule [1]

$$(m_f + m_{f'})(4m_K - m_a) - 3m_f m_{f'} = 8m_K^2 - 8m_K m_a + 3m_a^2. \quad (14.11)$$

This relation is verified for the ground-state vector mesons. We identify the $\phi(1020)$ with the f' and the $\omega(783)$ with the f . Thus

$$\phi(1020) = \psi_8 \cos \theta_V - \psi_1 \sin \theta_V, \quad (14.12)$$

$$\omega(782) = \psi_8 \sin \theta_V + \psi_1 \cos \theta_V, \quad (14.13)$$

with the vector mixing angle $\theta_V = 35^\circ$ from Eq. (14.9), very close to ideal mixing. Thus $\phi(1020)$ is nearly pure $s\bar{s}$. For ideal mixing, Eq. (14.9) and Eq. (14.10) lead to the relations

$$m_K = \frac{m_f + m_{f'}}{2}, \quad m_a = m_f, \quad (14.14)$$

which are satisfied for the vector mesons.

The situation for the pseudoscalar and scalar mesons is not so clear cut, either theoretically or experimentally. For the pseudoscalars, the mixing angle is small. This can be understood qualitatively via gluon-line counting of the mixing process. The size of the mixing process between the nonstrange and strange mass bases scales as α_s^2 , not α_s^3 , because of two rather than three gluon exchange as it does for the vector mesons. It may also be that the lightest isoscalar pseudoscalars mix more strongly with excited states or with states of substantial non- $\bar{q}q$ content, as will be discussed below.

A variety of analysis methods lead to similar results: First, for these states, Eq. (14.11) is satisfied only approximately. Then Eq. (14.9) and Eq. (14.10) lead to somewhat different values for the mixing angle. Identifying the η with the f' one gets

$$\eta = \psi_8 \cos \theta_P - \psi_1 \sin \theta_P, \quad (14.15)$$

$$\eta' = \psi_8 \sin \theta_P + \psi_1 \cos \theta_P. \quad (14.16)$$

Following chiral perturbation theory, the meson masses in the mass formulae (Eq. (14.9) and Eq. (14.10)) might be replaced by their squares. Table 14.2 lists the mixing angle θ_{in} from Eq. (14.10) and the corresponding θ_{quad} obtained by replacing the meson masses by their squares throughout.

The pseudoscalar mixing angle θ_P can also be measured by comparing the partial widths for radiative J/ψ decay into a vector and a pseudoscalar [2], radiative $\phi(1020)$ decay into η and η' [3], or $\bar{p}p$ annihilation at rest into a pair of vector and pseudoscalar or into two pseudoscalars [4,5]. One obtains a mixing angle between -10° and -20° . More recently, a lattice QCD simulation, Ref. 6, has successfully reproduced the masses of the η and η' , and as a byproduct find a mixing angle $\theta_{\text{in}} = -14.1(2.8)^\circ$. We return to this point in Sec. 14.6.

The nonet mixing angles can be measured in $\gamma\gamma$ collisions, *e.g.*, for the 0^{-+} , 0^{++} , and 2^{++} nonets. In the quark model, the amplitude for the coupling of neutral mesons to two photons is proportional to $\sum_i Q_i^2$, where Q_i is the charge of the i -th quark. The 2γ partial width of an isoscalar meson with mass m is then given in terms of the mixing angle α by

$$\Gamma_{2\gamma} = C(5 \cos \alpha - \sqrt{2} \sin \alpha)^2 m^3, \quad (14.17)$$

for f' and f ($\alpha \rightarrow \alpha - 90^\circ$). The coupling C may depend on the meson mass. It is often assumed to be a constant in the nonet. For the isovector a , one then finds $\Gamma_{2\gamma} = 9 C m^3$. Thus the members of an ideally mixed nonet couple to 2γ with partial widths in the ratios $f' : a = 25 : 2 : 9$. For tensor mesons, one finds from the ratios of the measured 2γ partial widths for the $f_2(1270)$ and $f_2'(1525)$ mesons a mixing angle α_T of $(81 \pm 1)^\circ$, or $\theta_T = (27 \pm 1)^\circ$, in accord with the linear mass formula. For the pseudoscalars, one finds from the ratios of partial widths $\Gamma(\eta' \rightarrow 2\gamma)/\Gamma(\eta \rightarrow 2\gamma)$ a mixing angle $\theta_P = (-18 \pm 2)^\circ$, while the ratio $\Gamma(\eta' \rightarrow 2\gamma)/\Gamma(\pi^0 \rightarrow 2\gamma)$ leads to $\sim -24^\circ$. SU(3) breaking effects for pseudoscalars are discussed in Ref. 7.

Table 14.4: SU(3) couplings γ^2 for quarkonium decays as a function of nonet mixing angle α , up to a common multiplicative factor C ($\phi \equiv 54.7^\circ + \theta_P$).

Isospin	Decay channel	γ^2
0	$\pi\pi$	$3 \cos^2 \alpha$
	$K\bar{K}$	$(\cos \alpha - \sqrt{2} \sin \alpha)^2$
	$\eta\eta$	$(\cos \alpha \cos^2 \phi - \sqrt{2} \sin \alpha \sin^2 \phi)^2$
	$\eta\eta'$	$\frac{1}{2} \sin^2 2\phi (\cos \alpha + \sqrt{2} \sin \alpha)^2$
1	$\eta\pi$	$2 \cos^2 \phi$
	$\eta'\pi$	$2 \sin^2 \phi$
	$K\bar{K}$	1
$\frac{1}{2}$	$K\pi$	$\frac{3}{2}$
	$K\eta$	$(\sin \phi - \frac{\cos \phi}{\sqrt{2}})^2$
	$K\eta'$	$(\cos \phi + \frac{\sin \phi}{\sqrt{2}})^2$

The partial width for the decay of a scalar or a tensor meson into a pair of pseudoscalar mesons is model-dependent. Following Ref. 8,

$$\Gamma = C \times \gamma^2 \times |F(q)|^2 \times q. \quad (14.18)$$

C is a nonet constant, q the momentum of the decay products, $F(q)$ a form factor, and γ^2 the SU(3) coupling. The model-dependent form factor may be written as

$$|F(q)|^2 = q^{2\ell} \times \exp\left(-\frac{q^2}{8\beta^2}\right), \quad (14.19)$$

where ℓ is the relative angular momentum between the decay products. The decay of a $q\bar{q}$ meson into a pair of mesons involves the creation of a $q\bar{q}$ pair from the vacuum, and SU(3) symmetry assumes that the

matrix elements for the creation of $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ pairs are equal. The couplings γ^2 are given in Table 14.4, and their dependence upon the mixing angle α is shown in Fig. 14.2 for isoscalar decays. The generalization to unequal $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ couplings is given in Ref. 8. An excellent fit to the tensor meson decay widths is obtained assuming SU(3) symmetry, with $\beta \simeq 0.5$ GeV/c, $\theta_V \simeq 26^\circ$ and $\theta_P \simeq -17^\circ$ [8].

Figure 14.2: SU(3) couplings as a function of mixing angle α for isoscalar decays, up to a common multiplicative factor C and for $\theta_P = -17.3^\circ$.

14.3. Exotic mesons

The existence of a light nonet composed of four quarks with masses below 1 GeV was suggested a long time ago [9]. Coupling two triplets of light quarks u , d , and s , one obtains nine states, of which the six symmetric (uu , dd , ss , $ud+du$, $us+su$, $ds+sd$) form the six dimensional representation $\mathbf{6}$, while the three antisymmetric ($ud-du$, $us-su$, $ds-sd$) form the three dimensional representation $\bar{\mathbf{3}}$ of SU(3):

$$\mathbf{3} \otimes \mathbf{3} = \mathbf{6} \oplus \bar{\mathbf{3}}. \quad (14.20)$$

Combining with spin and color and requiring antisymmetry, one finds that the most deeply bound diquark (and hence the lightest) is the one in the $\bar{\mathbf{3}}$ and spin singlet state. The combination of the diquark with an antiquark in the $\mathbf{3}$ representation then gives a light nonet of four-quark scalar states. Letting the number of strange quarks determine the mass splitting, one obtains a mass inverted spectrum with a light isosinglet ($u\bar{d}\bar{u}\bar{d}$), a medium heavy isodoublet (e.g., $u\bar{d}\bar{s}\bar{d}$) and a heavy isotriplet (e.g., $ds\bar{u}\bar{s}$) + isosinglet (e.g., $us\bar{u}\bar{s}$). It is then tempting to identify the lightest state with the $f_0(500)$, and the heaviest states with the $a_0(980)$, and $f_0(980)$. Then the meson with strangeness $\kappa(800)$ would lie in between.

QCD predicts the existence of extra isoscalar mesons. In the pure gauge theory, they contain only gluons, and are called the glueballs. The ground state glueball is predicted by lattice gauge theories to be 0^{++} , the first excited state 2^{++} . Errors on the mass predictions are large. From Ref. 11 one obtains 1750 (50) (80) MeV for the mass of the lightest 0^{++} glueball from quenched QCD. As an example for the glueball mass spectrum, we show in Fig. 14.3 a recent calculation from Ref. 10. A mass of 1710 MeV is predicted for the ground state, also with an error of about 100 MeV. Earlier work by other groups produced masses at 1650 MeV [12] and 1550 MeV [13] (see also [14]). The first excited state has a mass of about 2.4 GeV, and the lightest glueball with exotic quantum numbers (2^{+-}) has a mass of about 4 GeV.

These calculations are made in the so-called “quenched approximation” which neglects $q\bar{q}$ loops. However, both glue and $q\bar{q}$ states will couple to singlet scalar mesons. Therefore glueballs will mix

Figure 14.3: Predicted glueball mass spectrum from the lattice, in quenched approximation, (from Ref. 10).

with nearby $q\bar{q}$ states of the same quantum numbers. For example, the two isoscalar 0^{++} mesons around 1500 MeV will mix with the pure ground state glueball to generate the observed physical states $f_0(1370)$, $f_0(1500)$, and $f_0(1710)$ [8,15]. Lattice calculations are only beginning to include these effects. We return to a discussion of this point in Sec. 14.6.

The existence of three singlet scalar mesons around 1.5 GeV suggests additional degrees of freedom such as glue, since only two mesons are predicted in this mass range. The $f_0(1500)$ [8,15] or, alternatively, the $f_0(1710)$ [12], have been proposed as candidates for the scalar glueball, both states having considerable mixing also with the $f_0(1370)$. Other mixing schemes, in particular with the $f_0(500)$ and the $f_0(980)$, have also been proposed (more details can be found in the “Note on Scalar Mesons” in the Meson Listings and in Ref. 16).

Mesons made of $q\bar{q}$ pairs bound by excited gluons g , the hybrid states $q\bar{q}g$, are also predicted. They should lie in the 1.9 GeV mass region, according to gluon flux tube models [17]. Lattice QCD also predicts the lightest hybrid, an exotic 1^{-+} , at a mass of 1.8 to 1.9 GeV [18]. However, the bag model predicts four nonets, among them an exotic 1^{-+} around or above 1.4 GeV [19,20]. There are so far two candidates for exotic states with quantum numbers 1^{-+} , the $\pi_1(1400)$ and $\pi_1(1600)$, which could be hybrids or four-quark states (see the “Note on Non- $q\bar{q}$ Mesons” in the 2006 issue of this *Review* [21] and in Ref. 16).

14.4. Baryons: qqq states

Baryons are fermions with baryon number $B = 1$, *i.e.*, in the most general case, they are composed of three quarks plus any number of quark - antiquark pairs. So far all established baryons are 3-quark (qqq) configurations. The color part of their state functions is an SU(3) singlet, a completely antisymmetric state of the three colors. Since the quarks are fermions, the state function must be antisymmetric under interchange of any two equal-mass quarks (up and down quarks in the limit of isospin symmetry). Thus it can be written as

$$|qqq\rangle_A = |\text{color}\rangle_A \times |\text{space, spin, flavor}\rangle_S, \quad (14.21)$$

where the subscripts S and A indicate symmetry or antisymmetry under interchange of any two equal-mass quarks. Note the contrast with the state function for the three nucleons in ${}^3\text{H}$ or ${}^3\text{He}$:

$$|NNN\rangle_A = |\text{space, spin, isospin}\rangle_A. \quad (14.22)$$

This difference has major implications for internal structure, magnetic moments, *etc.* (For a nice discussion, see Ref. 22.)

Figure 14.4: SU(4) multiplets of baryons made of u , d , s , and c quarks. (a) The 20-plet with an SU(3) octet. (b) The 20-plet with an SU(3) decuplet.

The “ordinary” baryons are made up of u , d , and s quarks. The three flavors imply an approximate flavor SU(3), which requires that baryons made of these quarks belong to the multiplets on the right side of

$$\mathbf{3} \otimes \mathbf{3} \otimes \mathbf{3} = \mathbf{10}_S \oplus \mathbf{8}_M \oplus \mathbf{8}_M \oplus \mathbf{1}_A \quad (14.23)$$

(see Sec. 42, on “SU(n) Multiplets and Young Diagrams”). Here the subscripts indicate symmetric, mixed-symmetric, or antisymmetric states under interchange of any two quarks. The $\mathbf{1}$ is a uds state (Λ_1), and the octet contains a similar state (Λ_8). If these have the same spin and parity, they can mix. The mechanism is the same as for the mesons (see above). In the ground state multiplet, the SU(3) flavor singlet Λ_1 is forbidden by Fermi statistics. Section 41, on “SU(3) Isoscalar Factors and Representation Matrices,” shows how relative decay rates in, say, $\mathbf{10} \rightarrow \mathbf{8} \otimes \mathbf{8}$ decays may be calculated.

The addition of the c quark to the light quarks extends the flavor symmetry to SU(4). However, due to the large mass of the c quark, this symmetry is much more strongly broken than the SU(3) of the three light quarks. Figures 14.4(a) and 14.4(b) show the SU(4) baryon multiplets that have as their bottom levels an SU(3) octet, such as the octet that includes the nucleon, or an SU(3) decuplet, such as the decuplet that includes the $\Delta(1232)$. All particles in a given SU(4) multiplet have the same spin and parity. The charmed baryons are discussed in more detail in the “Note on Charmed Baryons” in the Particle Listings. The addition of a b quark extends the flavor symmetry to SU(5); the existence of baryons with t -quarks is very unlikely due to the short lifetime of the top.

Table 14.5: N and Δ states in the $N=0,1,2$ harmonic oscillator bands. L^P denotes angular momentum and parity, S the three-quark spin and ‘sym’=A,S,M the symmetry of the spatial wave function. Only dominant components indicated. Assignments in the $N=2$ band are partly tentative.

N	sym	L^P	S	$N(I = 1/2)$			$\Delta(I = 3/2)$		
2	A	1^+	$1/2$	$1/2^+$	$3/2^+$				
2	M	2^+	$3/2$	$1/2^+$	$3/2^+$	$5/2^+$	$7/2^+$		
2	M	2^+	$1/2$		$3/2^+$	$5/2^+$		$3/2^+$	$5/2^+$
2	M	0^+	$3/2$		$3/2^+$				
2	M	0^+	$1/2$	$1/2^+$			$1/2^+$		
				P ₁₁ (1710)			P ₃₁ (1750)		
2	S	2^+	$3/2$					$1/2^+$	$3/2^+$
								$5/2^+$	$7/2^+$
								P ₃₁ (1910) P ₃₃ (1920) F ₃₅ (1905) F ₃₇ (1950)	
2	S	2^+	$1/2$		$3/2^+$	$5/2^+$			
					P ₁₃ (1720) F ₁₅ (1680)				
2	S	0^+	$3/2$					$3/2^+$	
								P ₃₃ (1600)	
2	S	0^+	$1/2$	$1/2^+$					
				P ₁₁ (1440)					
1	M	1^-	$3/2$	$1/2^-$	$3/2^-$	$5/2^-$			
				S ₁₁ (1650) D ₁₃ (1700) D ₁₅ (1675)					
1	M	1^-	$1/2$	$1/2^-$	$3/2^-$			$1/2^-$	$3/2^-$
				S ₁₁ (1535) D ₁₃ (1520)			S ₃₁ (1620) D ₃₃ (1700)		
0	S	0^+	$3/2$					$3/2^+$	
								P ₃₃ (1232)	
0	S	0^+	$1/2$	$1/2^+$					
				P ₁₁ (938)					

For the “ordinary” baryons (no c or b quark), flavor and spin may be combined in an approximate flavor-spin SU(6), in which the six basic states are $d \uparrow, d \downarrow, \dots, s \downarrow$ (\uparrow, \downarrow = spin up, down). Then the baryons belong to the multiplets on the right side of

$$\mathbf{6} \otimes \mathbf{6} \otimes \mathbf{6} = \mathbf{56}_S \oplus \mathbf{70}_M \oplus \mathbf{70}_M \oplus \mathbf{20}_A. \quad (14.24)$$

These SU(6) multiplets decompose into flavor SU(3) multiplets as follows:

$$\mathbf{56} = {}^4\mathbf{10} \oplus {}^2\mathbf{8} \quad (14.25a)$$

$$\mathbf{70} = {}^2\mathbf{10} \oplus {}^4\mathbf{8} \oplus {}^2\mathbf{8} \oplus {}^2\mathbf{1} \quad (14.25b)$$

$$\mathbf{20} = {}^2\mathbf{8} \oplus {}^4\mathbf{1}, \quad (14.25c)$$

where the superscript $(2S+1)$ gives the net spin S of the quarks for each particle in the SU(3) multiplet. The $J^P = 1/2^+$ octet containing the nucleon and the $J^P = 3/2^+$ decuplet containing the $\Delta(1232)$ together make up the “ground-state” 56-plet, in which the orbital angular momenta between the quark pairs are zero (so that the spatial part of the state function is trivially symmetric). The $\mathbf{70}$ and $\mathbf{20}$ require some excitation of the spatial part of the state function in order to make the overall state function symmetric. States with nonzero orbital angular momenta are classified in SU(6) \otimes O(3) supermultiplets.

It is useful to classify the baryons into bands that have the same number N of quanta of excitation. Each band consists of a number of supermultiplets, specified by (D, L_N^P) , where D is the dimensionality of the SU(6) representation, L is the total quark orbital angular momentum, and P is the total parity. Supermultiplets contained in bands up to $N = 12$ are given in Ref. 24. The $N = 0$ band, which contains the nucleon and $\Delta(1232)$, consists only of the $(56, 0_0^+)$ supermultiplet. The $N = 1$ band consists only of the $(70, 1_1^-)$ multiplet and contains the negative-parity baryons with masses below about 1.9 GeV. The $N = 2$ band contains five supermultiplets: $(56, 0_2^+)$, $(70, 0_2^+)$, $(56, 2_2^+)$, $(70, 2_2^+)$, and $(20, 1_2^+)$.

The wave functions of the non-strange baryons in the harmonic oscillator basis are often labeled by $|X^{2S+1}L_\pi J^P\rangle$, where S, L, J, P are as above, $X = N$ or Δ , and $\pi = S, M$ or A denotes the symmetry of the spatial wave function. The possible model states for the bands with $N=0,1,2$ are given in Table 14.5. The assignment of experimentally observed states is only complete and well established up to the $N=1$ band. Some more tentative assignments for higher multiplets are suggested in Ref. 25.

In Table 14.6, quark-model assignments are given for many of the established baryons whose SU(6) \otimes O(3) compositions are relatively unmixed. One must, however, keep in mind that apart from the mixing of the Λ singlet and octet states, states with same J^P but different L, S combinations can also mix. In the quark model with one-gluon exchange motivated interactions, the size of the mixing is determined by the relative strength of the tensor term with respect to the contact term (see below). The mixing is more important for the decay patterns of the states than for their positions. An example are the lowest lying $(70, 1_1^-)$ states with $J^P=1/2^-$ and $3/2^-$. The physical states are:

$$|S_{11}(1535)\rangle = \cos(\Theta_S)|N^2P_M 1/2^-\rangle - \sin(\Theta_S)|N^4P_M 1/2^-\rangle \quad (14.26)$$

$$|D_{13}(1520)\rangle = \cos(\Theta_D)|N^2P_M 3/2^-\rangle - \sin(\Theta_D)|N^4P_M 3/2^-\rangle \quad (14.27)$$

and the orthogonal combinations for $S_{11}(1650)$ and $D_{13}(1700)$. The mixing is large for the $J^P=1/2^-$ states ($\Theta_S \approx -32^\circ$), but small for the $J^P=3/2^-$ states ($\Theta_D \approx +6^\circ$) [26,31].

All baryons of the ground state multiplets are known. Many of their properties, in particular their masses, are in good agreement even with the most basic versions of the quark model, including harmonic (or linear) confinement and a spin-spin interaction, which is responsible for the octet - decuplet mass shifts. A consistent description of the ground-state electroweak properties, however, requires refined relativistic constituent quark models.

Table 14.6: Quark-model assignments for some of the known baryons in terms of a flavor-spin SU(6) basis. Only the dominant representation is listed. Assignments for several states, especially for the $\Lambda(1810)$, $\Lambda(2350)$, $\Xi(1820)$, and $\Xi(2030)$, are merely educated guesses. \dagger recent suggestions for assignments and re-assignments from ref. [28]. For assignments of the charmed baryons, see the “Note on Charmed Baryons” in the Particle Listings.

J^P	$(D, L_N^P)S$	Octet members			Singlets

The situation for the excited states is much less clear. The assignment of some experimentally observed states with strange quarks to model configurations is only tentative and in many cases candidates are completely missing. Recently, Melde, Plessas and Sengl [28] have calculated baryon properties in relativistic constituent quark models, using one-gluon exchange and Goldstone-boson exchange for the modeling of the hyperfine interactions (see Sec. 14.5 on Dynamics). Both types of models give qualitatively comparable results, and underestimate in general experimentally observed decay widths. Nevertheless, in particular on the basis of the observed decay patterns, the authors have assigned some additional states with strangeness to the SU(3) multiplets and suggest re-assignments for a few others. Among the new assignments are states with weak experimental evidence (two or three star ratings) and partly without firm spin/parity assignments, so that further experimental efforts are necessary before final conclusions can be drawn. We have added their suggestions in Table 14.6.

In the non-strange sector there are two main problems which are illustrated in Fig. 14.5, where the experimentally observed excitation spectrum of the nucleon (N and Δ resonances) is compared to the results of a typical quark model calculation [27]. The lowest states from the $N=2$ band, the $P_{11}(1440)$, and the $P_{33}(1600)$, appear lower than the negative parity states from the $N=1$ band (see Table 14.5) and much lower than predicted by most models. Also negative parity Δ states from the $N=3$ band ($S_{31}(1900)$, $D_{33}(1940)$, and $D_{35}(1930)$) are too low in energy. Part of the problem could be experimental. Among the negative parity Δ states, only the D_{35} has three stars and

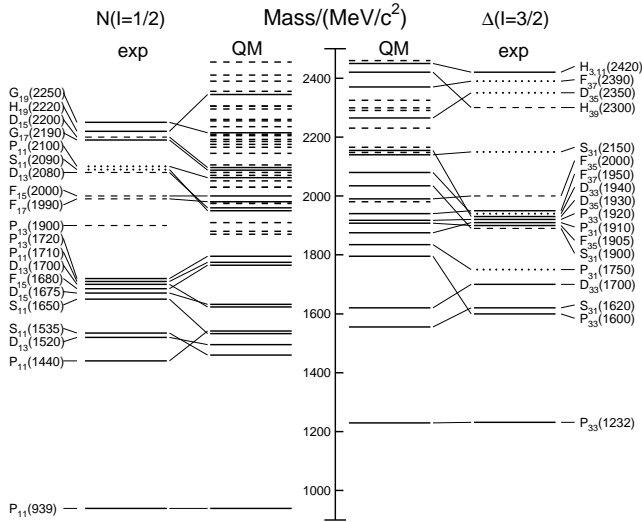

Figure 14.5: Excitation spectrum of the nucleon. Compared are the positions of the excited states identified in experiment, to those predicted by a relativized quark model calculation. Left hand side: isospin $I = 1/2$ N -states, right hand side: isospin $I = 3/2$ Δ -states. Experimental: (columns labeled 'exp'), three- and four-star states are indicated by full lines (two-star dashed lines, one-star dotted lines). At the very left and right of the figure, the spectroscopic notation of these states is given. Quark model [27]: (columns labeled 'QM'), all states for the $N=1,2$ bands, low-lying states for the $N=3,4,5$ bands. Full lines: at least tentative assignment to observed states, dashed lines: so far no observed counterparts. Many of the assignments between predicted and observed states are highly tentative.

the uncertainty in the position of the $P_{33}(1600)$ is large (1550 - 1700 MeV).

Furthermore, many more states are predicted than observed. This has been known for a long time as the 'missing resonance' problem [26]. Up to an excitation energy of 2.4 GeV, about 45 N states are predicted, but only 12 are established (four- or three-star; see Note on N and Δ Resonances for the rating of the status of resonances) and 7 are tentative (two- or one-star). Even for the $N=2$ band, up to now only half of the predicted states have been observed. The most recent partial wave analysis of elastic pion scattering and charge exchange data by Arndt and collaborators [29] has made the situation even worse. They found no evidence for almost half of the states listed in this review (and included in Fig. 14.5). Such analyses are of course biased against resonances which couple only weakly to the $N\pi$ channel. Quark model predictions for the couplings to other hadronic channels and to photons are given in Ref. 27. A large experimental effort is ongoing at several electron accelerators to study the baryon resonance spectrum with real and virtual photon-induced meson production reactions. This includes the search for as-yet-unobserved states, as well as detailed studies of the properties of the low lying states (decay patterns, electromagnetic couplings, magnetic moments, *etc.*) (see Ref. 30 for recent reviews). This experimental effort has currently entered its final phase with the measurement of single and double polarization observables for many different meson production channels, so that a much better understanding of the experimental spectrum can be expected for the near future.

In quark models, the number of excited states is determined by the effective degrees of freedom, while their ordering and decay properties are related to the residual quark - quark interaction. An overview of quark models for baryons is given in Ref. 31, a recent discussion of baryon spectroscopy is given in Ref. 25. The effective degrees of freedom in the standard nonrelativistic quark model are three equivalent valence quarks with one-gluon exchange-motivated, flavor-independent color-magnetic interactions. A different class of models uses interactions which give rise to a quark - diquark clustering

of the baryons (for a review see Ref. 32). If there is a tightly bound diquark, only two degrees of freedom are available at low energies, and thus *fewer* states are predicted. Furthermore, selection rules in the decay pattern may arise from the quantum numbers of the diquark. *More* states are predicted by collective models of the baryon like the algebraic approach in Ref. 33. In this approach, the quantum numbers of the valence quarks are distributed over a Y-shaped string-like configuration, and additional states arise *e.g.*, from vibrations of the strings. *More* states are also predicted in the framework of flux-tube models (see Ref. 34), which are motivated by lattice QCD. In addition to the quark degrees of freedom, flux-tubes responsible for the confinement of the quarks are considered as degrees of freedom. These models include hybrid baryons containing explicit excitations of the gluon fields. However, since all half integral J^P quantum numbers are possible for ordinary baryons, such 'exotics' will be very hard to identify, and probably always mix with ordinary states. So far, the experimentally observed number of states is still far lower even than predicted by the quark-diquark models.

Recently, the influence of chiral symmetry on the excitation spectrum of the nucleon has been hotly debated from a somewhat new perspective. Chiral symmetry, the fundamental symmetry of QCD, is strongly broken for the low lying states, resulting in large mass differences of parity partners like the $J^P=1/2^+$ $P_{11}(938)$ ground state and the $J^P=1/2^-$ $S_{11}(1535)$ excitation. However, at higher excitation energies there is some evidence for parity doublets and even some very tentative suggestions for full chiral multiplets of N^* and Δ resonances. An effective restoration of chiral symmetry at high excitation energies due to a decoupling from the quark condensate of the vacuum has been discussed (see Ref. 35 for recent reviews) as a possible cause. In this case, the mass generating mechanisms for low and high lying states would be essentially different. As a further consequence, the parity doublets would decouple from pions, so that experimental bias would be worse. However, parity doublets might also arise from the spin-orbital dynamics of the 3-quark system. Presently, the status of data does not allow final conclusions.

The most recent developments on the theory side are the first unquenched lattice calculations for the excitation spectrum discussed in Sec. 14.6. The results are basically consistent with the level counting of $SU(6) \otimes O(3)$ in the standard non-relativistic quark model and show no indication for quark-diquark structures or parity doubling. Consequently, there is as yet no indication from lattice that the mis-match between the excitation spectrum predicted by the standard quark model and experimental observations is due to inappropriate degrees of freedom in the quark model.

14.5. Dynamics

Quantum chromodynamics (QCD) is well-established as the theory for the strong interactions. As such, one of the goals of QCD is to predict the spectrum of strongly-interacting particles. To date, the only first-principles calculations of spectroscopy from QCD use lattice methods. These are the subject of Sec. 14.6. These calculations are difficult and unwieldy, and many interesting questions do not have a good lattice-based method of solution. Therefore, it is natural to build models, whose ingredients are abstracted from QCD, or from the low-energy limit of QCD (such as chiral Lagrangians) or from the data itself. The words "quark model" are a shorthand for such phenomenological models. Many specific quark models exist, but most contain a similar basic set of dynamical ingredients. These include:

- i) A confining interaction, which is generally spin-independent (*e.g.*, harmonic oscillator or linear confinement);
- ii) Different types of spin-dependent interactions:
 - a) commonly used is a color-magnetic flavor-independent interaction modeled after the effects of gluon exchange in QCD (see *e.g.*, Ref. 36). For example, in the S -wave states, there is a spin-spin hyperfine interaction of the form

$$H_{HF} = -\alpha_S M \sum_{i>j} (\vec{\sigma} \lambda_a)_i (\vec{\sigma} \lambda_a)_j, \quad (14.28)$$

where M is a constant with units of energy, λ_a ($a = 1, \dots, 8$) is the set of $SU(3)$ unitary spin matrices, defined in Sec. 41,

on “SU(3) Isoscalar Factors and Representation Matrices,” and the sum runs over constituent quarks or antiquarks. Spin-orbit interactions, although allowed, seem to be small in general, but a tensor term is responsible for the mixing of states with the same J^P but different L, S combinations.

b) other approaches include flavor-dependent short-range quark forces from instanton effects (see *e.g.*, Ref. 37). This interaction acts only on scalar, isoscalar pairs of quarks in a relative S -wave state:

$$\langle q^2; S, L, T | W | q^2; S, L, T \rangle = -4g\delta_{S,0}\delta_{L,0}\delta_{T,0}\mathcal{W} \quad (14.29)$$

where \mathcal{W} is the radial matrix element of the contact interaction.

c) a rather different and controversially discussed approach is based on flavor-dependent spin-spin forces arising from one-boson exchange. The interaction term is of the form:

$$H_{HF} \propto \sum_{i<j} V(\vec{r}_{ij}) \lambda_i^F \cdot \lambda_j^F \vec{\sigma}_i \cdot \vec{\sigma}_j \quad (14.30)$$

where the λ_i^F are in flavor space (see *e.g.*, Ref. 38).

- iii) A strange quark mass somewhat larger than the up and down quark masses, in order to split the SU(3) multiplets;
- iv) In the case of spin-spin interactions (ii,c), a flavor-symmetric interaction for mixing $q\bar{q}$ configurations of different flavors (*e.g.*, $u\bar{u} \leftrightarrow d\bar{d} \leftrightarrow s\bar{s}$), in isoscalar channels, so as to reproduce *e.g.*, the $\eta - \eta'$ and $\omega - \phi$ mesons.

These ingredients provide the basic mechanisms that determine the hadron spectrum in the standard quark model.

14.6. Lattice Calculations of Hadronic Spectroscopy

Lattice calculations are a major source of information about QCD masses and matrix elements. The necessary theoretical background is given in Sec. 17 of this *Review*. Here we confine ourselves to some general comments and illustrations of lattice calculations for spectroscopy.

In general, the cleanest lattice results come from computations of processes in which there is only one particle in the simulation volume. These quantities include masses of hadrons, simple decay constants, like pseudoscalar meson decay constants, and semileptonic form factors (such as the ones appropriate to $B \rightarrow D\nu, K\nu, \pi\nu$). The cleanest predictions for masses are for states which have narrow decay widths and are far below any thresholds to open channels, since the effects of final state interactions are not yet under complete control on the lattice. As a simple corollary, the lightest state in a channel is easier to study than the heavier ones. “Difficult” states for the quark model (such as exotics) are also difficult for the lattice because of the lack of simple operators which couple well to them.

Good-quality modern lattice calculations will present multi-part error budgets with their predictions. A small part of the uncertainty is statistical, from sample size. Typically, the quoted statistical uncertainty includes uncertainty from a fit: it is rare that a simulation computes one global quantity which is the desired observable. Simulations which include virtual quark-antiquark pairs (also known as “dynamical quarks” or “sea quarks”) are often done at up and down quark mass values heavier than the experimental ones, and it is then necessary to extrapolate in these quark masses. Simulations can work at the physical values of the heavier quarks’ masses. They are always done at nonzero lattice spacing, and so it is necessary to extrapolate to zero lattice spacing. Some theoretical input is needed to do this. Much of the uncertainty in these extrapolations is systematic, from the choice of fitting function. Other systematics include the effect of finite simulation volume, the number of flavors of dynamical quarks actually simulated, and technical issues with how these dynamical quarks are included. The particular choice of a fiducial mass (to normalize other predictions) is not standardized; there are many possible choices, each with its own set of strengths and weaknesses, and determining it usually requires a second lattice simulation from that used to calculate the quantity under consideration.

Figure 14.6: A recent calculation of spectroscopy with dynamical $u, d,$ and s quarks. The pion and kaon fix the light quark masses. Only the mass splittings relative to the $1S$ states in the heavy quark sectors are shown. The $\Upsilon 2S - 1S$ splitting sets the overall energy scale.

A systematic error of major historical interest is the “quenched approximation,” in which dynamical quarks are simply left out of the simulation. This was done because the addition of these virtual pairs presented an expensive computational problem. No generally-accepted methodology has ever allowed one to correct for quenching effects, short of redoing all calculations with dynamical quarks. Recent advances in algorithms and computer hardware have rendered it obsolete.

With these brief remarks, we turn to examples. The field of lattice QCD simulations is vast, and so it is not possible to give a comprehensive review of them in a small space. The history of lattice QCD simulations is a story of thirty years of incremental improvements in physical understanding, algorithm development, and ever faster computers, which have combined to bring the field to a present state where it is possible to carry out very high quality calculations. We present a few representative illustrations, to show the current state of the art.

By far, the major part of all lattice spectroscopy is concerned with that of the light hadrons, and so we illustrate results from two groups. First, a recent calculation of spectroscopy with dynamical $u, d,$ and s quarks is shown in Fig. 14.6. The pion and kaon masses are used to set the light quark masses. The $\Upsilon 2S - 1S$ splitting is used to set the lattice spacing or equivalently, the overall energy scale in the lattice calculation. This is an updated figure from Ref. 39, using results from Ref. 41 and Ref. 42 (D. Toussaint, private communication).

These results come from simulations using dynamical up and down quarks which are heavier than their physical values. As a result, the error bars on all the particles which decay strongly and are above their decay thresholds (the vector mesons and the Δ , for example) do not include the effect of coupling to the decay channels.

A more recent result by Ref. 40 goes farther, in that its simulations include the coupling of resonances to open channels in their analysis. Their plot of light hadron spectroscopy is shown in Fig. 14.7.

Flavor singlet mesons are at the frontier of lattice QCD calculations, because one must include the effects of “annihilation graphs,” for the valence q and \bar{q} . Recently, the RBC and UKQCD collaborations, Ref. 6, have reported a calculation of the η and η' mesons, finding masses of 573(6) and 947(142) MeV, respectively. The singlet-octet mixing angle (in the conventions of Table 14.2) is $\theta_{in} = -14.1(2.8)^\circ$.

The spectroscopy of mesons containing heavy quarks has become a truly high-precision endeavor. These simulations use Non-Relativistic QCD (NRQCD) or Heavy Quark Effective Theory (HQET), systematic expansions of the QCD Lagrangian in powers of the heavy quark velocity, or the heavy quark mass. Terms in the Lagrangian have obvious quark model analogs, but are derived directly from QCD. For example, the heavy quark potential is a derived quantity, extracted from simulations. Fig. 14.8 shows the mass spectrum for mesons containing at least one heavy (b or c) quark from Ref. 42 and Ref. 43.

Figure 14.7: Light hadron spectroscopy from Ref. 40.

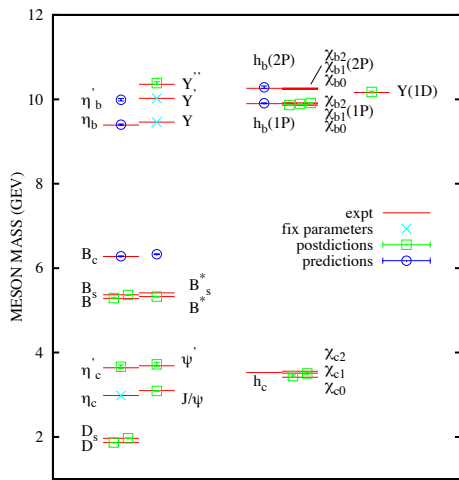

Figure 14.8: Spectroscopy for mesonic systems containing one or more heavy quarks (adapted from Ref. 42 and Ref. 43). Particles whose masses are used to fix lattice parameters are shown with crosses; the authors distinguish between “predictions” and “postdictions” of their calculation. Lines represent experiment.

The calculations use a discretization of nonrelativistic QCD for bottom quarks with charm and lighter quarks being handled with an improved relativistic action. Three flavors of light dynamical quarks are included.

Finally, Fig. 14.9 shows recent lattice calculations of singly and double charmed baryons. Here we are at the forefront of theory and experiment.

Recall that lattice calculations take operators which are interpolating fields with quantum numbers appropriate to the desired states, compute correlation functions of these operators, and fit the correlation functions to functional forms parameterized by a set of masses and matrix elements. As we move away from hadrons which can be created by the simplest quark model operators (appropriate to the lightest meson and baryon multiplets) we encounter a host of new problems: either no good interpolating fields, or too many possible interpolating fields, and many states with the same quantum numbers. Techniques for dealing with these interrelated problems vary from collaboration to collaboration, but all share common features: typically, correlation functions from many different interpolating fields are used, and the signal is extracted in what amounts to a variational calculation using the chosen operator basis. In addition to mass spectra, wave function information can be garnered from the form of the best variational wave function. Of course, the same problems which are present in the spectroscopy of the lightest hadrons (the need to extrapolate to infinite volume, physical values of the light quark masses, and zero lattice spacing) are also present. We briefly touch on three different kinds of hadrons: excited states of baryons, glueballs,

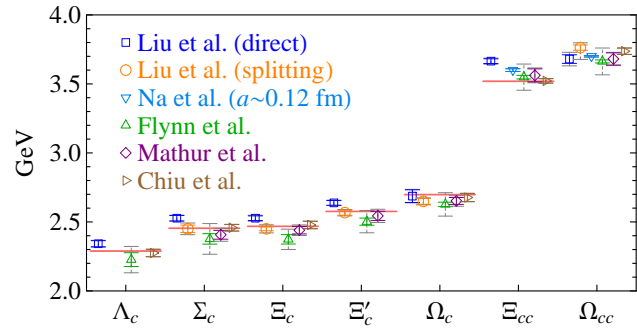

Figure 14.9: Lattice predictions for masses of charmed baryons. Data are Liu, *et al.*, Ref. 44; Na *et al.*, Ref. 45; Flynn *et al.*, Ref. 46; Mathur *et al.*, Ref. 47; and Chiu *et al.*, Ref. 48. The first two references use full QCD; the latter three are quenched. Two mass extractions are taken from Ref. 44; the lighter (orange) circular points come from a calculation of mass splittings while the darker (blue) square points are from a direct mass extrapolation. Lines are from experiment.

and hybrid mesons. The quality of the data is not as good as for the ground states, and so the results continue to evolve.

Ref. 49 is a good recent review of excited baryon spectroscopy. The interesting physics questions to be addressed are precisely those enumerated in the last section. An example of a recent calculation, due to Ref. 50 is shown in Fig. 14.10. Notice that the pion is not yet at its physical value. The lightest positive parity state is the nucleon, and the Roper resonance has not yet appeared as a light state.

Figure 14.10: Spin-identified spectrum of nucleons and deltas, from lattices where $m_\pi = 396$ MeV, in units of the calculated Ω mass, from Ref. 50. The colors just correspond to the different J assignments: grey for $J = 1/2$, red for $J = 3/2$, green for $J = 5/2$, blue for $J = 7/2$.

Exotic mesons share the difficulties of ordinary excited states, and some recent calculations actually include both kinds of states in their combined fits. Ref. 51 provides a good summary of the theoretical and experimental situation regarding mesons with exotic quantum numbers, including a compilation of lattice data. The lightest exotics, the h_0 , η_1 , and h_2 , have long been targets of lattice studies. Recently, the authors of Ref. 52 have presented new results for isoscalar and isovector meson spectroscopy, which observe the three states around 2 GeV. Again, the light quark masses in the simulations are higher than in nature; the pion is at 396 MeV.

Finally, glueballs. In Fig. 14.3 we showed a figure from Ref. 10 showing a lattice prediction for the glueball mass spectrum in quenched approximation. A true QCD prediction of the glueball spectrum requires dynamical light quarks and (because glueball operators are intrinsically noisy) high statistics. Only recently have the first useful such calculations appeared. Fig. 14.11 shows results from Ref. 53, done with dynamical u , d and s quarks at two lattice spacings, 0.123 and 0.092 fm, along with comparisons to the quenched lattice calculation of Ref. 11 and to experimental isosinglet mesons.

The dynamical simulation is, of course, not the last word on this subject, but it shows that the effects of quenching seem to be small.

Figure 14.11: Lattice QCD predictions for glueball masses. The open and closed circles are the larger and smaller lattice spacing data of the full QCD calculation of glueball masses of Ref. 53. Squares are the quenched data for glueball masses of Ref. 11. The bursts labeled by particle names are experimental states with the appropriate quantum numbers.

15. GRAND UNIFIED THEORIES

Revised October 2011 by S. Raby (Ohio State University).

15.1. Grand Unification

15.1.1. Standard Model : An Introduction :

In spite of all the successes of the Standard Model [SM] it is unlikely to be the final theory. It leaves many unanswered questions. Why the local gauge interactions $SU(3)_C \times SU(2)_L \times U(1)_Y$ and why 3 families of quarks and leptons? Moreover why does one family consist of the states $[Q, u^c, d^c; L, e^c]$ transforming as $[(3, 2, 1/3), (\bar{3}, 1, -4/3), (\bar{3}, 1, 2/3); (1, 2, -1), (1, 1, 2)]$, where $Q = (u, d)$ and $L = (\nu, e)$ are $SU(2)_L$ doublets and u^c, d^c, e^c are charge conjugate $SU(2)_L$ singlet fields with the $U(1)_Y$ quantum numbers given? [We use the convention that electric charge $Q_{EM} = T_{3L} + Y/2$ and all fields are left handed Weyl spinors.] Note the SM gauge interactions of quarks and leptons are completely fixed by their gauge charges. Thus if we understood the origin of this charge quantization, we would also understand why there are no fractionally charged hadrons. Finally, what is the origin of quark and lepton masses or the apparent hierarchy of family masses and quark and leptonic mixing angles? Perhaps if we understood this, we would also know the origin of CP violation, the solution to the strong CP problem, the origin of the cosmological matter - antimatter asymmetry. In addition, it lacks an explanation for the observed dark matter and dark energy of the universe.

The SM has 19 arbitrary parameters; their values are chosen to fit the data. Three arbitrary gauge couplings: g_3, g, g' (where g, g' are the $SU(2)_L, U(1)_Y$ couplings, respectively) or equivalently $\alpha_s = (g_3^2/4\pi), \alpha_{EM} = (e^2/4\pi)$ ($e = g \sin\theta_W$) and $\sin^2\theta_W = (g')^2/(g^2 + (g')^2)$. In addition there are 13 parameters associated with the 9 charged fermion masses and the four mixing angles in the CKM matrix. The remaining 3 parameters are v, λ [the Higgs VEV and quartic coupling] (or equivalently M_Z, m_h^0) and the QCD θ parameter. In addition, data from neutrino oscillation experiments provide convincing evidence for neutrino masses. With 3 light Majorana neutrinos there are at least 9 additional parameters in the neutrino sector; 3 masses and 6 mixing angles and phases. In summary, the SM has too many arbitrary parameters and leaves open too many unresolved questions to be considered complete. These are the problems which grand unified theories hope to address.

15.1.2. Charge Quantization :

In the Standard Model, quarks and leptons are on an equal footing; both fundamental particles without substructure. It is now clear that they may be two faces of the same coin; unified, for example, by extending QCD (or $SU(3)_C$) to include leptons as the fourth color, $SU(4)_C$ [1]. The complete Pati-Salam gauge group is $SU(4)_C \times SU(2)_L \times SU(2)_R$ with the states of one family $[(Q, L), (Q^c, L^c)]$ transforming as $[(4, 2, 1), (\bar{4}, 1, \bar{2})]$ where $Q^c = (d^c, u^c), L^c = (e^c, \nu^c)$ are doublets under $SU(2)_R$. Electric charge is now given by the relation $Q_{EM} = T_{3L} + T_{3R} + 1/2(B - L)$ and $SU(4)_C$ contains the subgroup $SU(3)_C \times (B - L)$ where B (L) is baryon (lepton) number. Note ν^c has no SM quantum numbers and is thus completely "sterile". It is introduced to complete the $SU(2)_R$ lepton doublet. This additional state is desirable when considering neutrino masses.

Although quarks and leptons are unified with the states of one family forming two irreducible representations of the gauge group; there are still 3 independent gauge couplings (two if one also imposes parity, i.e. $L \leftrightarrow R$ symmetry). As a result the three low energy gauge couplings are still independent arbitrary parameters. This difficulty is resolved by embedding the SM gauge group into the simple unified gauge group, Georgi-Glashow $SU(5)$, with one universal gauge coupling α_G defined at the grand unification scale M_G [2]. Quarks and leptons still sit in two irreducible representations, as before, with a $\mathbf{10} = [Q, u^c, e^c]$ and $\bar{\mathbf{5}} = [d^c, L]$. Nevertheless, the three low energy gauge couplings are now determined in terms of two independent parameters : α_G and M_G . Hence there is one prediction.

In order to break the electroweak symmetry at the weak scale and give mass to quarks and leptons, Higgs doublets are needed which can sit in either a $\mathbf{5}_H$ or $\bar{\mathbf{5}}_H$. The additional 3 states are color triplet Higgs scalars. The couplings of these color triplets violate baryon and

lepton number and nucleons decay via the exchange of a single color triplet Higgs scalar. Hence in order not to violently disagree with the non-observation of nucleon decay, their mass must be greater than $\sim 10^{11}$ GeV [3]. Moreover, in supersymmetric GUTs, in order to cancel anomalies as well as give mass to both up and down quarks, both Higgs multiplets $\mathbf{5}_H, \bar{\mathbf{5}}_H$ are required. As we shall discuss later, nucleon decay now constrains the color triplet Higgs states in a SUSY GUT to have mass significantly greater than M_G .

Complete unification is possible with the symmetry group $SO(10)$ with one universal gauge coupling α_G and one family of quarks and leptons sitting in the 16 dimensional spinor representation $\mathbf{16} = [\mathbf{10} + \bar{\mathbf{5}} + \mathbf{1}]$ [4]. The $SU(5)$ singlet $\mathbf{1}$ is identified with ν^c . In Table 1 we present the states of one family of quarks and leptons, as they appear in the $\mathbf{16}$. It is an amazing and perhaps even profound fact that all the states of a single family of quarks and leptons can be represented digitally as a set of 5 zeros and/or ones or equivalently as the tensor product of 5 "spin" $1/2$ states with $\pm = |\pm \frac{1}{2} >$ and with the condition that we have an even number of $|+ >$ spins. The first three "spins" correspond to $SU(3)_C$ color quantum numbers, while the last two are $SU(2)_L$ weak quantum numbers. In fact an $SU(3)_C$ rotation just raises one color index and lowers another, thereby changing colors $\{r, b, y\}$. Similarly an $SU(2)_L$ rotation raises one weak index and lowers another, thereby flipping the weak isospin from up to down or vice versa. In this representation weak hypercharge Y is given by the simple relation $Y = -2/3(\sum \text{color spins}) + (\sum \text{weak spins})$. $SU(5)$ rotations [in particular, the ones NOT in $SU(3)_C \times SU(2)_L \times U(1)_Y$] then raise (or lower) a color index, while at the same time lowering (or raising) a weak index. It is easy to see that such rotations can mix the states $\{Q, u^c, e^c\}$ and $\{d^c, L\}$ among themselves and ν^c is a singlet. The new $SO(10)$ rotations [not in $SU(5)$] are then given by either raising or lowering any two spins. For example, by raising the two weak indices ν^c rotates into e^c , etc.

Table 15.1: The quantum numbers of the $\mathbf{16}$ dimensional representation of $SO(10)$.

State	Y	Color	Weak
ν^c	0	---	--
e^c	2	---	++
u_r	1/3	+- -	-+
d_r	1/3	+- -	+-
u_b	1/3	-+ -	-+
d_b	1/3	-+ -	+-
u_y	1/3	-- +	-+
d_y	1/3	-- +	+-
u_r^c	-4/3	-+ +	--
u_b^c	-4/3	-+ +	--
u_y^c	-4/3	+ + -	--
d_r^c	2/3	-+ +	++
d_b^c	2/3	-+ +	++
d_y^c	2/3	+ + -	++
ν	-1	+ + +	-+
e	-1	+ + +	+-

$SO(10)$ has two inequivalent maximal breaking patterns. $SO(10) \rightarrow SU(5) \times U(1)_X$ and $SO(10) \rightarrow SU(4)_C \times SU(2)_L \times SU(2)_R$. In the first case we obtain Georgi-Glashow $SU(5)$ if Q_{EM} is given in terms of $SU(5)$ generators alone or so-called flipped $SU(5)$ [5] if Q_{EM} is partly in $U(1)_X$. In the latter case we have the Pati-Salam symmetry. If $SO(10)$ breaks directly to the SM at M_G , then we retain the prediction for gauge coupling unification. However more possibilities for breaking (hence more breaking scales and more parameters) are available in $SO(10)$. Nevertheless with one breaking pattern $SO(10) \rightarrow SU(5) \rightarrow SM$, where the last breaking scale is M_G , the predictions from gauge coupling unification are preserved. The Higgs multiplets in

minimal $SO(10)$ are contained in the fundamental $\mathbf{10}_H = [\mathbf{5}_H, \bar{\mathbf{5}}_H]$ representation. Note, only in $SO(10)$ does the gauge symmetry distinguish quark and lepton multiplets from Higgs multiplets.

Finally, larger symmetry groups have been considered. For example, $E(6)$ has a fundamental representation $\mathbf{27}$ which under $SO(10)$ transforms as a $[\mathbf{16} + \mathbf{10} + \mathbf{1}]$. The breaking pattern $E(6) \rightarrow SU(3)_C \times SU(3)_L \times SU(3)_R$ is also possible. With the additional permutation symmetry $Z(3)$ interchanging the three $SU(3)$ s we obtain so-called “trification” [6] with a universal gauge coupling. The latter breaking pattern has been used in phenomenological analyses of the heterotic string [7]. However, in larger symmetry groups, such as $E(6)$, $SU(6)$, etc., there are now many more states which have not been observed and must be removed from the effective low energy theory. In particular, three families of $\mathbf{27}$ s in $E(6)$ contain three Higgs type multiplets transforming as $\mathbf{10}$ s of $SO(10)$. This makes these larger symmetry groups unattractive starting points for model building.

15.1.3. String Theory and Orbifold GUTs :

Orbifold compactification of the heterotic string [8–10], and recent field theoretic constructions known as orbifold GUTs [11], contain grand unified symmetries realized in 5 and 6 dimensions. However, upon compactifying all but four of these extra dimensions, only the MSSM is recovered as a symmetry of the effective four dimensional field theory.¹ These theories can retain many of the nice features of four dimensional SUSY GUTs, such as charge quantization, gauge coupling unification and sometimes even Yukawa unification; while at the same time resolving some of the difficulties of 4d GUTs, in particular problems with unwieldy Higgs sectors necessary for spontaneously breaking the GUT symmetry, and problems with doublet-triplet Higgs splitting or rapid proton decay. We will comment further on the corrections to the four dimensional GUT picture due to orbifold GUTs in the following sections. Finally, recent progress has been made in finding MSSM-like theories in the string landscape. This success is made possible by incorporating SUSY GUTs at an intermediate step in the construction. For a brief discussion, see Sec. 15.1.

15.1.4. Gauge coupling unification :

The biggest paradox of grand unification is to understand how it is possible to have a universal gauge coupling g_G in a grand unified theory [GUT] and yet have three unequal gauge couplings at the weak scale with $g_3 > g > g'$. The solution is given in terms of the concept of an effective field theory [EFT] [18]. The GUT symmetry is spontaneously broken at the scale M_G and all particles not in the SM obtain mass of order M_G . When calculating Green’s functions with external energies $E \gg M_G$, we can neglect the mass of all particles in the loop and hence all particles contribute to the renormalization group running of the universal gauge coupling. However, for $E \ll M_G$ one can consider an effective field theory

¹ Also, in recent years there has been a great deal of progress in constructing three and four family models in Type IIA string theory with intersecting D6 branes [12]. Although these models can incorporate $SU(5)$ or a Pati-Salam symmetry group in four dimensions, they typically have problems with gauge coupling unification. In the former case this is due to charged exotics which affect the RG running, while in the latter case the $SU(4) \times SU(2)_L \times SU(2)_R$ symmetry never unifies. Local models, however, with D-branes at singularities have had some more success in obtaining gauge coupling unification [13]. Note, heterotic string theory models also exist whose low energy effective 4d field theory is a SUSY GUT [14]. These models have all the virtues and problems of 4d GUTs. Finally, many heterotic string models have been constructed with the standard model gauge symmetry in 4d and no intermediate GUT symmetry in less than 10d. Some minimal 3 family supersymmetric models have been constructed [15,16]. These theories may retain some of the symmetry relations of GUTs, however the unification scale would typically be the string scale, of order 5×10^{17} GeV, which is inconsistent with low energy data. A way out of this problem was discovered in the context of the strongly coupled heterotic string, defined in an effective 11 dimensions [17]. In this case the 4d Planck scale (which controls the value of the string scale) now unifies with the GUT scale.

Figure 15.1: Gauge coupling unification in non-SUSY GUTs on the left vs. SUSY GUTs on the right using the LEP data as of 1991. Note, the difference in the running for SUSY is the inclusion of supersymmetric partners of standard model particles at scales of order a TeV (Fig. taken from Ref. 24). Given the present accurate measurements of the three low energy couplings, in particular $\alpha_s(M_Z)$, GUT scale threshold corrections are now needed to precisely fit the low energy data. The dark blob in the plot on the right represents these model dependent corrections.

including only the states with mass $< E \ll M_G$. The gauge symmetry of the EFT is $SU(3)_C \times SU(2)_L \times U(1)_Y$ and the three gauge couplings renormalize independently. The states of the EFT include only those of the SM; 12 gauge bosons, 3 families of quarks and leptons and one or more Higgs doublets. At M_G the two effective theories [the GUT itself is most likely the EFT of a more fundamental theory defined at a higher scale] must give identical results; hence we have the boundary conditions $g_3 = g_2 = g_1 \equiv g_G$ where at any scale $\mu < M_G$ we have $g_2 \equiv g$ and $g_1 = \sqrt{5/3} g'$. Then using two low energy couplings, such as $\alpha_s(M_Z)$, $\alpha_{EM}(M_Z)$, the two independent parameters α_G , M_G can be fixed. The third gauge coupling, $\sin^2 \theta_W$ in this case, is then predicted. This was the procedure up until about 1991 [19,20]. Subsequently, the uncertainties in $\sin^2 \theta_W$ were reduced ten fold. Since then, $\alpha_{EM}(M_Z)$, $\sin^2 \theta_W$ have been used as input to predict α_G , M_G and $\alpha_s(M_Z)$ [21].

We emphasize that the above boundary condition is only valid when using one loop renormalization group [RG] running. With precision electroweak data, however, it is necessary to use two loop RG running. Hence one must include one loop threshold corrections to gauge coupling boundary conditions at both the weak and GUT scales. In this case it is always possible to define the GUT scale as the point where $\alpha_1(M_G) = \alpha_2(M_G) \equiv \bar{\alpha}_G$ and $\alpha_3(M_G) = \bar{\alpha}_G (1 + \epsilon_3)$. The threshold correction ϵ_3 is a logarithmic function of all states with mass of order M_G and $\bar{\alpha}_G = \alpha_G + \Delta$ where α_G is the GUT coupling constant above M_G and Δ is a one loop threshold correction. Note, the popular code “SOFTSUSY” [22] has defined the GUT scale in just this way. The value of ϵ_3 can be read off from the output data. To the extent that gauge coupling unification is perturbative, the GUT threshold corrections are small and calculable. This presumes that the GUT scale is sufficiently below the Planck scale or any other strong coupling extension of the GUT, such as a strongly coupled string theory.

Supersymmetric grand unified theories [SUSY GUTs] are an extension of non-SUSY GUTs [23]. The key difference between SUSY GUTs and non-SUSY GUTs is the low energy effective theory. The low energy effective field theory in a SUSY GUT is assumed to satisfy $N=1$ supersymmetry down to scales of order the weak scale in addition to the SM gauge symmetry. Hence the spectrum includes all the SM states plus their supersymmetric partners. It also includes one pair (or more) of Higgs doublets; one to give mass to up-type quarks and the other to down-type quarks and charged leptons. Two doublets with opposite hypercharge Y are also needed to cancel fermionic triangle anomalies. Finally, it is important to recognize that a low energy SUSY breaking scale (the scale at which the SUSY partners of SM particles obtain mass) is necessary to solve the gauge hierarchy problem.

Simple non-SUSY $SU(5)$ is ruled out; initially by the increased accuracy in the measurement of $\sin^2 \theta_W$ and by early bounds on the proton lifetime (see below) [20]. However, by now LEP data [21] has conclusively shown that SUSY GUTs is the *new standard model*; by which we mean the theory used to guide the search for new physics beyond the present SM (see Fig. Fig. 15.1). SUSY extensions of the SM have the property that their effects decouple as the effective SUSY breaking scale is increased. Any theory beyond the SM must have this property simply because the SM works so well. However, the SUSY breaking scale cannot be increased with impunity, since this would reintroduce a gauge hierarchy problem. Unfortunately there is no clear-cut answer to the question, when is the SUSY breaking scale too high. A conservative bound would suggest that the third generation quarks and leptons must be lighter than about 1 TeV, in order that the one loop corrections to the Higgs mass from Yukawa interactions remains of order the Higgs mass bound itself.

At present gauge coupling unification within SUSY GUTs works extremely well. Exact unification at M_G , with two loop renormalization group running from M_G to M_Z , and one loop threshold corrections at the weak scale, fits to within 3σ of the present precise low energy data. A small threshold correction at M_G ($\epsilon_3 \sim -3\%$ to -4%) is sufficient to fit the low energy data precisely [25,26,27].² This may be compared to non-SUSY GUTs where the fit misses by $\sim 12\sigma$ and a precise fit requires new weak scale states in incomplete GUT multiplets or multiple GUT breaking scales.³

Following the analysis of Ref. 27 let us try to understand the need for the GUT threshold correction and its order of magnitude. The renormalization group equations relate the low energy gauge coupling constants $\alpha_i(M_Z)$, $i = 1, 2, 3$ to the value of the unification scale Λ_U and the GUT coupling α_U by the expression

$$\frac{1}{\alpha_i(M_Z)} = \frac{1}{\alpha_U} + \frac{b_i}{2\pi} \log \left(\frac{\Lambda_U}{M_Z} \right) + \delta_i \quad (15.1)$$

where Λ_U is the GUT scale evaluated at one loop and the threshold corrections, δ_i , are given by $\delta_i = \delta_i^{(2)} + \delta_i^{(l)} + \delta_i^{(g)}$ with $\delta_i^{(2)}$ representing two loop running effects, $\delta_i^{(l)}$ the light threshold corrections at the SUSY breaking scale and $\delta_i^{(g)} = \delta_i^{(h)} + \delta_i^{(b)}$ representing GUT scale threshold corrections. Note, in this analysis, the two loop RG running is treated on the same footing as weak and GUT scale threshold corrections. One then obtains the prediction

$$(\alpha_3(M_Z) - \alpha_3^{LO}(M_Z))/\alpha_3^{LO}(M_Z) = -\alpha_3^{LO}(M_Z) \delta_s \quad (15.2)$$

where $\alpha_3^{LO}(M_Z)$ is the leading order one loop RG result and $\delta_s = \frac{1}{7}(5\delta_1 - 12\delta_2 + 7\delta_3)$ is the net threshold correction. [A similar formula applies at the GUT scale with the GUT threshold correction, ϵ_3 , given by $\epsilon_3 = -\bar{\alpha}_G \delta_s^{(g)}$.] Given the experimental inputs [31,32]:

$$\begin{aligned} \alpha_{em}^{-1}(M_Z) &= 127.916 \pm 0.015 \\ \sin^2 \theta_W(M_Z) &= 0.23116 \pm 0.00013 \\ \alpha_3(M_Z) &= 0.1184 \pm 0.0007 \end{aligned} \quad (15.3)$$

² This result implicitly assumes universal GUT boundary conditions for soft SUSY breaking parameters at M_G . In the simplest case we have a universal gaugino mass $M_{1/2}$, a universal mass for squarks and sleptons m_{16} and a universal Higgs mass m_{10} , as motivated by $SO(10)$. In some cases, threshold corrections to gauge coupling unification can be exchanged for threshold corrections to soft SUSY parameters. See for example, Ref. 28 and references therein.

³ Non-SUSY GUTs with a more complicated breaking pattern can still fit the data. For example, non-SUSY $SO(10) \rightarrow SU(4)_C \times SU(2)_L \times SU(2)_R \rightarrow SM$ with the second breaking scale of order an intermediate scale, determined by light neutrino masses using the see-saw mechanism, can fit the low energy data for gauge couplings [29] and at the same time survive nucleon decay bounds [30], discussed in the following section.

and taking into account the light threshold corrections, assuming an ensemble of 10 SUSY spectra [27] (corresponding to the Snowmass benchmark points), we have

$$\alpha_3^{LO}(M_Z) \approx 0.118 \quad (15.4)$$

and

$$\begin{aligned} \delta_s^{(2)} &\approx -0.82 \\ \delta_s^{(l)} &\approx -0.50 + \frac{19}{28\pi} \log \frac{M_{SUSY}}{M_Z}. \end{aligned}$$

For $M_{SUSY} = 1$ TeV, we have $\delta_s^{(2)} + \delta_s^{(l)} \approx -0.80$. Since the one loop result $\alpha_3^{LO}(M_Z)$ is very close to the experimental value, we need $\delta_s \approx 0$ or equivalently, $\delta_s^{(g)} \approx 0.80$. This corresponds, at the GUT scale, to $\epsilon_3 \approx -3\%$. Note, this result depends implicitly on the assumption of universal soft SUSY breaking masses at the GUT scale, which directly affect the spectrum of SUSY particles at the weak scale. For example, if gaugino masses were not unified at M_G and, in particular, gluinos were lighter than winos at the weak scale, then it is possible that, due to weak scale threshold corrections, a much smaller or even slightly positive threshold correction at the GUT scale would be consistent with gauge coupling unification [34].

In four dimensional SUSY GUTs, the threshold correction ϵ_3 receives a positive contribution from Higgs doublets and triplets.⁴ Thus a larger, negative contribution must come from the GUT breaking sector of the theory. This is certainly possible in specific $SO(10)$ [35] or $SU(5)$ [36] models, but it is clearly a significant constraint on the 4d GUT sector of the theory. In five or six dimensional orbifold GUTs, on the other hand, the ‘‘GUT scale’’ threshold correction comes from the Kaluza-Klein modes between the compactification scale, M_c , and the effective cutoff scale M_* .⁵ Thus, in orbifold GUTs, gauge coupling unification at two loops is only consistent with the low energy data with a fixed value for M_c and M_* .⁶ Typically, one finds $M_c < M_G = 3 \times 10^{16}$ GeV, where M_G is the 4d GUT scale. Since the grand unified gauge bosons, responsible for nucleon decay, get mass at the compactification scale, the result $M_c < M_G$ for orbifold GUTs has significant consequences for nucleon decay.

A few final comments are in order. We do not consider the scenario of split supersymmetry [39] in this review. In this scenario squarks and sleptons have mass at a scale $\tilde{m} \gg M_Z$, while gauginos and Higgsinos have mass of order the weak scale. Gauge coupling unification occurs at a scale of order 10^{16} GeV, *provided that the scale \tilde{m} lies in the range $10^3 - 10^{11}$ GeV* [40]. A serious complaint concerning the split SUSY scenario is that it does not provide a solution to the gauge hierarchy problem. Moreover, it is only consistent with grand unification if it also postulates an ‘‘intermediate’’ scale, \tilde{m} , for scalar masses. In addition, it is in conflict with $b - \tau$ Yukawa unification, unless $\tan \beta$ is fine-tuned to be close to 1 [40].⁷

⁴ Note, the Higgs contribution is given by $\epsilon_3 = \frac{3\bar{\alpha}_G}{5\pi} \log |\frac{\tilde{M}_t \gamma}{M_G}|$ where \tilde{M}_t is the effective color triplet Higgs mass (setting the scale for dimension 5 baryon and lepton number violating operators) and $\gamma = \lambda_b/\lambda_t$ at M_G . Since \tilde{M}_t is necessarily greater than M_G , the Higgs contribution to ϵ_3 is positive.

⁵ In string theory, the cutoff scale is the string scale.

⁶ It is interesting to note that a ratio $M_*/M_c \sim 100$, needed for gauge coupling unification to work in orbifold GUTs is typically the maximum value for this ratio consistent with perturbativity [37]. In addition, in orbifold GUTs brane-localized gauge kinetic terms may destroy the successes of gauge coupling unification. However, for values of $M_*/M_c = M_*\pi R \gg 1$ the unified bulk gauge kinetic terms can dominate over the brane-localized terms [38].

⁷ $b - \tau$ Yukawa unification only works for $\tilde{m} < 10^4$ for $\tan \beta \geq 1.5$. This is because the effective theory between the gaugino mass scale and \tilde{m} includes only one Higgs doublet, as in the standard model. In this case, the large top quark Yukawa coupling tends to increase the ratio λ_b/λ_τ as one runs down in energy below \tilde{m} . This is opposite to what happens in MSSM where the large top quark Yukawa coupling decreases the ratio λ_b/λ_τ [41].

We have also neglected to discuss non-supersymmetric GUTs in four dimensions which still survive once one allows for several scales of GUT symmetry breaking [29]. Finally, it has been shown that non-supersymmetric GUTs in warped 5 dimensional orbifolds can be consistent with gauge coupling unification, assuming that the right-handed top quark and the Higgs doublets are composite-like objects with a compositeness scale of order a TeV [42]. However perturbative unification seems to fail.

15.1.5. Nucleon Decay :

Baryon number is necessarily violated in any GUT [43]. In $SU(5)$, nucleons decay via the exchange of gauge bosons with GUT scale masses, resulting in dimension 6 baryon number violating operators suppressed by $(1/M_G^2)$. The nucleon lifetime is calculable and given by $\tau_N \propto M_G^4/(\alpha_G^2 m_p^5)$. The dominant decay mode of the proton (and the baryon violating decay mode of the neutron), via gauge exchange, is $p \rightarrow e^+ \pi^0$ ($n \rightarrow e^+ \pi^-$). In any simple gauge symmetry, with one universal GUT coupling and scale (α_G, M_G) , the nucleon lifetime from gauge exchange is calculable. Hence, the GUT scale may be directly observed via the extremely rare decay of the nucleon. Experimental searches for nucleon decay began with the Kolar Gold Mine, Homestake, Soudan, NUSEX, Frejus, HPW, and IMB detectors [19]. The present experimental bounds come from Super-Kamiokande and Soudan II. We discuss these results shortly. Non-SUSY GUTs are also ruled out by the non-observation of nucleon decay [20]. In SUSY GUTs, the GUT scale is of order 3×10^{16} GeV, as compared to the GUT scale in non-SUSY GUTs which is of order 10^{15} GeV. Hence the dimension 6 baryon violating operators are significantly suppressed in SUSY GUTs [23] with $\tau_p \sim 10^{34-38}$ yrs.

However, in SUSY GUTs there are additional sources for baryon number violation – dimension 4 and 5 operators [44]. Although our notation does not change, when discussing SUSY GUTs all fields are implicitly chiral superfields and the operators considered are the so-called F terms which contain two fermionic components and the rest scalars or products of scalars. Within the context of $SU(5)$ the dimension 4 and 5 operators have the form $(\mathbf{10} \mathbf{5} \mathbf{5}) \supset (u^c d^c d^c) + (Q L d^c) + (e^c L L)$ and $(\mathbf{10} \mathbf{10} \mathbf{10} \mathbf{5}) \supset (Q Q Q L) + (u^c u^c d^c e^c) + B$ and L conserving terms, respectively. The dimension 4 operators are renormalizable with dimensionless couplings; similar to Yukawa couplings. On the other hand, the dimension 5 operators have a dimensionful coupling of order $(1/M_G)$.

The dimension 4 operators violate baryon number or lepton number, respectively, but not both. The nucleon lifetime is extremely short if both types of dimension 4 operators are present in the low energy theory. However both types can be eliminated by requiring R parity. In $SU(5)$ the Higgs doublets reside in a $\mathbf{5}_H$, $\mathbf{5}_{\bar{H}}$ and R parity distinguishes the $\mathbf{5}$ (quarks and leptons) from $\mathbf{5}_H$ (Higgs). R parity [45] (or its cousin, family reflection symmetry (or *matter parity*) (see Dimopoulos and Georgi [23] and DRW [46]) takes $F \rightarrow -F$, $H \rightarrow H$ with $F = \{\mathbf{10}, \mathbf{5}\}$, $H = \{\mathbf{5}_H, \mathbf{5}_{\bar{H}}\}$. This forbids the dimension 4 operator $(\mathbf{10} \mathbf{5} \mathbf{5})$, but allows the Yukawa couplings of the form $(\mathbf{10} \mathbf{5} \mathbf{5}_{\bar{H}})$ and $(\mathbf{10} \mathbf{10} \mathbf{5}_H)$. It also forbids the dimension 3, lepton number violating, operator $(\mathbf{5} \mathbf{5}_H) \supset (L H_u)$ with a coefficient with dimensions of mass which, like the μ parameter, could be of order the weak scale and the dimension 5, baryon number violating, operator $(\mathbf{10} \mathbf{10} \mathbf{10} \mathbf{5}_H) \supset (Q Q Q H_d) + \dots$.

Note, in the MSSM it is possible to retain R parity violating operators at low energy as long as they violate either baryon number or lepton number only but not both. Such schemes are natural if one assumes a low energy symmetry, such as lepton number, baryon number, baryon triality [47] or proton hexality [48]. However these symmetries cannot be embedded in a GUT. Thus, in a SUSY GUT, only R parity can prevent all the dimension three and four baryon and lepton number violating operators. This does not mean to say that R parity is guaranteed to be satisfied in any GUT. For example the authors of Refs. [51,52] use constrained matter content to selectively generate safe effective R parity violating operators in a GUT. For a review on R parity violating interactions, see [53]. In Ref. [52], the authors show how to obtain the effective R parity violating operator $O^{ijk} = (\mathbf{5}^j \cdot \mathbf{5}^k)_{\mathbf{15}} \cdot (\mathbf{10}^i \cdot \Sigma)_{15}$ where Σ is an $SU(5)$ adjoint field and the subscripts 15, 15 indicate that the product of fields in parentheses

have been projected into these $SU(5)$ directions. As a consequence the operator O^{ijk} is symmetric under interchange of the two $\mathbf{5}$ states, $O^{ijk} = O^{ikj}$, and out of $\mathbf{10} \mathbf{5} \mathbf{5}$ only the lepton number/R parity violating operator $QL\bar{D}$ survives.

Note also, R parity distinguishes Higgs multiplets from ordinary families. In $SU(5)$, Higgs and quark/lepton multiplets have identical quantum numbers; while in $E(6)$, Higgs and families are unified within the fundamental $\mathbf{27}$ representation. Only in $SO(10)$ are Higgs and ordinary families distinguished by their gauge quantum numbers. Moreover the $Z(4)$ center of $SO(10)$ distinguishes $\mathbf{10}$ s from $\mathbf{16}$ s and can be associated with R parity [49].

Dimension 5 baryon number violating operators may be forbidden at tree level by symmetries in $SU(5)$, etc. These symmetries are typically broken however by the VEVs responsible for the color triplet Higgs masses. Consequently these dimension 5 operators are generically generated via color triplet Higgsino exchange. Hence, the color triplet partners of Higgs doublets must necessarily obtain mass of order the GUT scale. [It is also important to note that Planck or string scale physics may independently generate dimension 5 operators, even without a GUT. These contributions must be suppressed by some underlying symmetry; for example, the same flavor symmetry which may be responsible for hierarchical fermion Yukawa matrices.]

The dominant decay modes from dimension 5 operators are $p \rightarrow K^+ \bar{\nu}$ ($n \rightarrow K^0 \bar{\nu}$). This is due to a simple symmetry argument; the operators $(Q_i Q_j Q_k L_l)$, $(u_i^c u_j^c d_k^c e_l^c)$ (where $i, j, k, l = 1, 2, 3$ are family indices and color and weak indices are implicit) must be invariant under $SU(3)_C$ and $SU(2)_L$. As a result their color and weak doublet indices must be anti-symmetrized. However since these operators are given by bosonic superfields, they must be totally symmetric under interchange of all indices. Thus the first operator vanishes for $i = j = k$ and the second vanishes for $i = j$. Hence a second or third generation member must exist in the final state [46].

Recent Super-Kamiokande bounds on the proton lifetime severely constrain these dimension 6 and 5 operators with (172.8 kt-yr) of data they find $\tau_{(p \rightarrow e^+ \pi^0)} > 1.0 \times 10^{34}$ yrs, $\tau_{(p \rightarrow K^+ \bar{\nu})} > 3.3 \times 10^{33}$ yrs and $\tau_{(n \rightarrow e^+ \pi^-)} > 2 \times 10^{33}$ yrs at (90% CL) [54]. These constraints are now sufficient to rule out minimal SUSY $SU(5)$ [55].⁸ Non-minimal Higgs sectors in $SU(5)$ or $SO(10)$ theories still survive [26,36]. The upper bound on the proton lifetime from these theories are approximately a factor of 10 above the experimental bounds. They are also being pushed to their theoretical limits. Hence if SUSY GUTs are correct, then nucleon decay must be seen soon.

Is there a way out of this conclusion? Orbifold GUTs and string theories, see Sec. 15.1, contain grand unified symmetries realized in higher dimensions. In the process of compactification and GUT symmetry breaking, color triplet Higgs states are removed (projected out of the massless sector of the theory). In addition, the same projections typically rearrange the quark and lepton states so that the massless states which survive emanate from different GUT multiplets. In these models, proton decay due to dimension 5 operators can be severely suppressed or eliminated completely. However, proton decay due to dimension 6 operators may be enhanced, since the gauge bosons mediating proton decay obtain mass at the compactification scale, M_C , which is typically less than the 4d GUT scale (see the discussion at the end of Sec. 15.1), or suppressed, if the states of one family come from different irreducible representations. Which effect dominates is a model dependent issue. In some complete 5d orbifold

⁸ This conclusion relies on the mild assumption that the three-by-three matrices diagonalizing squark and slepton mass matrices are not so different from their fermionic partners. It has been shown that if this caveat is violated, then dimension five proton decay in minimal SUSY $SU(5)$ may not be ruled out [56]. This is however a very fine-tuned resolution of the problem. Another possible way out is to allow for a more complicated $SU(5)$ breaking Higgs sector in the otherwise minimal model [57]. I have also implicitly assumed a hierarchical structure for Yukawa matrices in this analysis. It is however possible to fine-tune a hierarchical structure for quarks and leptons which baffles the family structure. In this case it is possible to avoid the present constraints on minimal SUSY $SU(5)$, for example see [58].

GUT models [59,27] the lifetime for the decay $\tau(p \rightarrow e^+\pi^0)$ can be near the excluded bound of 1×10^{34} years with, however, large model dependent and/or theoretical uncertainties. In other cases, the modes $p \rightarrow K^+\bar{\nu}$ and $p \rightarrow K^0\mu^+$ may be dominant [27]. To summarize, in either 4d or orbifold string/field theories, nucleon decay remains a premier signature for SUSY GUTs. Moreover, the observation of nucleon decay may distinguish extra-dimensional orbifold GUTs from four dimensional ones.

As a final note, in orbifold GUTs or string theory new discrete symmetries consistent with SUSY GUTs can forbid all dimension 3 and 4 baryon [B] and lepton [L] number violating operators and even forbid the mu term and dimension 5 B and L violating operators to all orders in perturbation theory [50]. The mu term and dimension 5 B and L violating operators may then be generated, albeit sufficiently suppressed, via non-perturbative effects. The simplest example of this is a Z_4^R symmetry which is the unique discrete R symmetry consistent with $SO(10)$ [50]. In this case, proton decay is completely dominated by dimension 6 operators.

Before concluding the topic of baryon number violation, consider the status of $\Delta B = 2$ neutron- anti-neutron oscillations. Generically the leading operator for this process is the dimension 9 six quark operator $G_{(\Delta B=2)}(u^c d^c d^c u^c d^c d^c)$ with dimensionful coefficient $G_{(\Delta B=2)} \sim 1/M^5$. The present experimental bound $\tau_{n-\bar{n}} \geq 0.86 \times 10^8$ sec. at 90% CL [60] probes only up to the scale $M \leq 10^6$ GeV. For $M \sim M_G$, $n - \bar{n}$ oscillations appear to be unobservable for any GUT (for a recent discussion see [61]).

15.1.6. Yukawa coupling unification :

15.1.6.1. 3rd generation, $b - \tau$ or $t - b - \tau$ unification:

If quarks and leptons are two sides of the same coin, related by a new grand unified gauge symmetry, then that same symmetry relates the Yukawa couplings (and hence the masses) of quarks and leptons. In $SU(5)$, there are two independent renormalizable Yukawa interactions given by $\lambda_t(\mathbf{10} \mathbf{10} \mathbf{5}_H) + \lambda(\mathbf{10} \mathbf{5} \mathbf{5}_H)$. These contain the SM interactions $\lambda_t(\mathbf{Q} u^c \mathbf{H}_u) + \lambda(\mathbf{Q} d^c \mathbf{H}_d + \mathbf{e}^c \mathbf{L} \mathbf{H}_d)$. Hence, at the GUT scale we have the tree level relation, $\lambda_b = \lambda_\tau \equiv \lambda$ [41]. In $SO(10)$ there is only one independent renormalizable Yukawa interaction given by $\lambda(\mathbf{16} \mathbf{16} \mathbf{10}_H)$ which gives the tree level relation, $\lambda_t = \lambda_b = \lambda_\tau \equiv \lambda$ [62,63]. Note, in the discussion above we assume the minimal Higgs content with Higgs in $\mathbf{5}, \bar{\mathbf{5}}$ for $SU(5)$ and $\mathbf{10}$ for $SO(10)$. With Higgs in higher dimensional representations there are more possible Yukawa couplings [75,76,77].

In order to make contact with the data, one now renormalizes the top, bottom and τ Yukawa couplings, using two loop RG equations, from M_G to M_Z . One then obtains the running quark masses $m_t(M_Z) = \lambda_t(M_Z) v_u$, $m_b(M_Z) = \lambda_b(M_Z) v_d$ and $m_\tau(M_Z) = \lambda_\tau(M_Z) v_d$ where $\langle H_u^0 \rangle \equiv v_u = \sin \beta v/\sqrt{2}$, $\langle H_d^0 \rangle \equiv v_d = \cos \beta v/\sqrt{2}$, $v_u/v_d \equiv \tan \beta$ and $v \sim 246$ GeV is fixed by the Fermi constant, G_μ .

Including one loop threshold corrections at M_Z and additional RG running, one finds the top, bottom and τ pole masses. In SUSY, $b - \tau$ unification has two possible solutions with $\tan \beta \sim 1$ or 40 – 50. The small $\tan \beta$ solution is now disfavored by the LEP limit, $\tan \beta > 2.4$ [64].⁹ The large $\tan \beta$ limit overlaps the $SO(10)$ symmetry relation.

When $\tan \beta$ is large there are significant weak scale threshold corrections to down quark and charged lepton masses from either gluino and/or chargino loops [66]. Yukawa unification (consistent with low energy data) is only possible in a restricted region of SUSY parameter space with important consequences for SUSY searches [67]. More recent analyses of Yukawa unification can be found in Refs. [68,69,70,71]. There seems to be at least four possible choices of soft SUSY breaking parameters which fit the data, possibly more. Each case then leads to a distinct sparticle spectrum and phenomenology for LHC and dark matter experiments. They correspond to:

⁹ However, this bound disappears if one takes $M_{SUSY} = 2$ TeV and $m_t = 180$ GeV [65]. This apparent loop hole is now inconsistent with the observed top quark mass.

- universal squark and slepton masses (m_{16}), universal A parameter (A_0) and gaugino masses ($M_{1/2}$), and non-universal Higgs masses (m_{H_u}, m_{H_d}) with “just-so” splitting [67,68].
- a universal squark and slepton mass term for the first two families ($m_{16_{1,2}}$) which is larger than the universal scalar mass for the third family (m_{16_3}), universal A parameter (A_0) and gaugino masses ($M_{1/2}$) and universal Higgs mass term (m_{10}). However all scalar masses then receive a D-term contribution to their masses given by the $U(1)$ from $SO(10)$ which commutes with $SU(5)$. This is of the form

$$\begin{aligned} m_Q^2 &= m_E^2 = m_U^2 = m_{16}^2 + M_D^2, \\ m_D^2 &= m_L^2 = m_{16}^2 - 3M_D^2, \\ m_{\bar{\nu}}^2 &= m_{16}^2 + 5M_D^2, \\ m_{H_{u,d}}^2 &= m_{10}^2 \mp 2M_D^2. \end{aligned}$$

This is the so-called “DR3 splitting” [69]. The R is associated with taking into account the renormalization group [RG] running of the right-handed neutrino from the GUT scale to the nominal value of its mass of order 10^{10-14} GeV, as indicated by light neutrino masses via the See-Saw mechanism. This RG running contributes to an additional splitting of the H_u and H_d masses [67].

- universal squark and slepton masses (m_0), split Higgs masses and non-universal gaugino masses satisfying ($M_1 = \frac{3}{5}M_2 + \frac{2}{5}M_3$), and $\mu, M_2 < 0$ [70], and
- universal squark and slepton mass term (m_{16}), A parameter (A_0), Higgs mass term (m_{10}). All scalar masses then receive a D-term contribution to their masses given by the $U(1)$ from $SO(10)$ which commutes with $SU(5)$, as above. Finally, non-universal gaugino masses satisfying ($M_3 : M_2 : M_1 = 2 : -3 : -1$) with $M_3 > 0$ and $\mu < 0$ [71].

15.1.6.2. Three families:

Simple Yukawa unification is not possible for the first two generations of quarks and leptons. Consider the $SU(5)$ GUT scale relation $\lambda_b = \lambda_\tau$. If extended to the first two generations one would have $\lambda_s = \lambda_\mu$, $\lambda_d = \lambda_e$ which gives $\lambda_s/\lambda_d = \lambda_\mu/\lambda_e$. The last relation is a renormalization group invariant and is thus satisfied at any scale. In particular, at the weak scale one obtains $m_s/m_d = m_\mu/m_e$ which is in serious disagreement with the data with $m_s/m_d \sim 20$ and $m_\mu/m_e \sim 200$. An elegant solution to this problem was given by Georgi and Jarlskog [72]. For a recent analysis in the context of supersymmetric GUTs, see Ref. [73]. Of course, a three family model must also give the observed CKM mixing in the quark sector. Note, although there are typically many more parameters in the GUT theory above M_G , it is possible to obtain effective low energy theories with many fewer parameters making strong predictions for quark and lepton masses.

Three family models which make significant predictions for low energy experiments have been constructed in the context of supersymmetric GUTs. It is important to note that grand unification alone is not sufficient to obtain predictive theories of fermion masses and mixing angles. Other ingredients are needed. In one approach additional global family symmetries are introduced (non-abelian family symmetries can significantly reduce the number of arbitrary parameters in the Yukawa matrices). These family symmetries constrain the set of effective higher dimensional fermion mass operators. In addition, sequential breaking of the family symmetry is correlated with the hierarchy of fermion masses. Three-family models exist which fit all the data, including neutrino masses and mixing [74]. In a completely separate approach for $SO(10)$ models, the Standard Model Higgs bosons are contained in the higher dimensional Higgs representations including the $\mathbf{10}, \overline{\mathbf{126}}$ and/or $\mathbf{120}$. Such theories have been shown to make predictions for neutrino masses and mixing angles [75–77]. A recent paper on this subject argues the necessity of split supersymmetry [78].

15.1.7. Neutrino Masses :

Atmospheric and solar neutrino oscillations, along with long baseline accelerator and reactor experiments, require neutrino masses. Adding three “sterile” neutrinos ν^c with the Yukawa coupling λ_ν ($\nu^c \mathbf{L} \mathbf{H}_u$), one easily obtains three massive Dirac neutrinos with mass $m_\nu = \lambda_\nu v_u$.¹⁰ However in order to obtain a tau neutrino with mass of order 0.1 eV, one needs $\lambda_{\nu\tau}/\lambda_\tau \leq 10^{-10}$. The see-saw mechanism, on the other hand, can naturally explain such small neutrino masses [79,80]. Since ν^c has no SM quantum numbers, there is no symmetry (other than global lepton number) which prevents the mass term $\frac{1}{2} \nu^c M \nu^c$. Moreover one might expect $M \sim M_G$. Heavy “sterile” neutrinos can be integrated out of the theory, defining an effective low energy theory with only light active Majorana neutrinos with the effective dimension 5 operator $\frac{1}{2} (\mathbf{L} \mathbf{H}_u) \lambda_\nu^T M^{-1} \lambda_\nu (\mathbf{L} \mathbf{H}_u)$. This then leads to a 3×3 Majorana neutrino mass matrix $\mathbf{m} = m_\nu^T M^{-1} m_\nu$.

Atmospheric neutrino oscillations require neutrino masses with $\Delta m_\nu^2 \sim 3 \times 10^{-3} \text{ eV}^2$ with maximal mixing, in the simplest two neutrino scenario. With hierarchical neutrino masses $m_{\nu\tau} = \sqrt{\Delta m_\nu^2} \sim 0.055 \text{ eV}$. Moreover via the “see-saw” mechanism $m_{\nu\tau} = m_t(m_t)^2/(3M)$. Hence one finds $M \sim 2 \times 10^{14} \text{ GeV}$; remarkably close to the GUT scale. Note we have related the neutrino Yukawa coupling to the top quark Yukawa coupling $\lambda_{\nu\tau} = \lambda_t$ at M_G as given in $SO(10)$ or $SU(4) \times SU(2)_L \times SU(2)_R$. However at low energies they are no longer equal and we have estimated this RG effect by $\lambda_{\nu\tau}(M_Z) \approx \lambda_t(M_Z)/\sqrt{3}$.

Neutrinos pose a special problem for SUSY GUTs. The question is why are the quark mixing angles in the CKM matrix small, while there are two large lepton mixing angles in the PMNS matrix. For a recent discussion of neutrino masses and mixing angles, see Refs. [81] and [82]. For SUSY GUT models which fit quark and lepton masses, see Ref. [74]. Finally, for a compilation of the range of SUSY GUT predictions for neutrino mixing, see [83].

15.1.8. Selected Topics :

15.1.8.1. Magnetic Monopoles:

In the broken phase of a GUT there are typically localized classical solutions carrying magnetic charge under an unbroken $U(1)$ symmetry [84]. These magnetic monopoles with mass of order M_G/α_G are produced during the GUT phase transition in the early universe. The flux of magnetic monopoles is experimentally found to be less than $\sim 10^{-16} \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$ [85]. Many more are however predicted, hence the GUT monopole problem. In fact, one of the original motivations for an inflationary universe is to solve the monopole problem by invoking an epoch of rapid inflation after the GUT phase transition [86]. This would have the effect of diluting the monopole density as long as the reheat temperature is sufficiently below M_G . Other possible solutions to the monopole problem include: sweeping them away by domain walls [87], $U(1)$ electromagnetic symmetry breaking at high temperature [88] or GUT symmetry non-restoration [89]. Parenthetically, it was also shown that GUT monopoles can catalyze nucleon decay [90]. A significantly lower bound on the monopole flux can then be obtained by considering X-ray emission from radio pulsars due to monopole capture and the subsequent nucleon decay catalysis [91].

15.1.8.2. Baryogenesis via Leptogenesis:

Baryon number violating operators in $SU(5)$ or $SO(10)$ preserve the global symmetry $B - L$. Hence the value of the cosmological $B - L$ density is an initial condition of the theory and is typically assumed to be zero. On the other hand, anomalies of the electroweak symmetry violate $B + L$ while also preserving $B - L$. Hence thermal fluctuations in the early universe, via so-called sphaleron processes, can drive $B + L$ to zero, washing out any net baryon number generated in the early universe at GUT temperatures.

¹⁰ Note, these “sterile” neutrinos are quite naturally identified with the right-handed neutrinos necessarily contained in complete families of $SO(10)$ or Pati-Salam.

One way out of this dilemma is to generate a net $B - L$ dynamically in the early universe. We have just seen that neutrino oscillations suggest a new scale of physics of order 10^{14} GeV . This scale is associated with heavy Majorana neutrinos with mass M . If in the early universe, the decay of the heavy neutrinos is out of equilibrium and violates both lepton number and CP, then a net lepton number may be generated. This lepton number will then be partially converted into baryon number via electroweak processes [92].

15.1.8.3. GUT symmetry breaking:

The grand unification symmetry is necessarily broken spontaneously. Scalar potentials (or superpotentials) exist whose vacua spontaneously break $SU(5)$ and $SO(10)$. These potentials are ad hoc (just like the Higgs potential in the SM) and therefore it is hoped that they may be replaced with better motivated sectors. Gauge coupling unification now tests GUT breaking sectors, since it is one of the two dominant corrections to the GUT threshold correction ϵ_3 . The other dominant correction comes from the Higgs sector and doublet-triplet splitting. This latter contribution is always positive $\epsilon_3 \propto \ln(M_T/M_G)$ (where M_T is an effective color triplet Higgs mass), while the low energy data typically requires $\epsilon_3 < 0$. Hence the GUT breaking sector must provide a significant (of order -8%) contribution to ϵ_3 to be consistent with the Super-K bound on the proton lifetime [35,26,36,74].

In string theory (and GUTs in extra-dimensions), GUT breaking may occur due to boundary conditions in the compactified dimensions [8,11]. This is still ad hoc. The major benefit is that it does not require complicated GUT breaking sectors.

15.1.8.4. Doublet-triplet splitting:

The minimal supersymmetric standard model has a μ problem; why is the coefficient of the bilinear Higgs term in the superpotential $\mu (\mathbf{H}_u \mathbf{H}_d)$ of order the weak scale when, since it violates no low energy symmetry, it could be as large as M_G . In a SUSY GUT, the μ problem is replaced by the problem of *doublet-triplet* splitting — giving mass of order M_G to the color triplet Higgs and mass μ to the Higgs doublets. Several mechanisms for natural doublet-triplet splitting have been suggested, such as the sliding singlet [93], missing partner or missing VEV [94], and pseudo-Nambu-Goldstone boson mechanisms. Particular examples of the missing partner mechanism for $SU(5)$ [36], the missing VEV mechanism for $SO(10)$ [74,26] and the pseudo-Nambu-Goldstone boson mechanism for $SU(6)$ [95] have been shown to be consistent with gauge coupling unification and proton decay. There are also several mechanisms for explaining why μ is of order the SUSY breaking scale [96]. Finally, for a recent review of the μ problem and some suggested solutions in SUSY GUTs and string theory, see Ref. [97,10,98,50] and references therein.

Once again, in string theory (and orbifold GUTs), the act of breaking the GUT symmetry via orbifolding projects certain states out of the theory. It has been shown that it is possible to remove the color triplet Higgs while retaining the Higgs doublets in this process. Hence the doublet-triplet splitting problem is finessed. As discussed earlier (see Sec. 15.1), this can have the effect of eliminating the contribution of dimension 5 operators to nucleon decay.

15.1.9. String theory :

String theory has made significant progress in locating the minimal supersymmetric standard model [MSSM] in the string landscape. Random searches for MSSM-like models have found some success, see for example Ref. 99. However, recently a solid leap forward has been made by imposing a supersymmetric GUT locally in the extra dimensions of the string. Many MSSM-like models have been found in $E(8) \times E(8)$ heterotic orbifold constructions [100–103] or more recently on smooth Calabi-Yau three-folds [104]. See also in F theory constructions [105–107]. There appear, however, to be some problems associated with large threshold corrections to gauge coupling unification in the F theory constructions which make use of a non-vanishing hypercharge field strength to break $SU(5)$ to $SU(3)_C \times SU(2)_L \times U(1)_Y$ [108]. Nevertheless, a SUSY GUT guarantees the correct particle content of the Standard Model and also allows for reasonable looking hierarchical Yukawa matrices. For a more detailed discussion, see [109].

15.2. Conclusion

Grand unification of the strong and electroweak interactions requires that the three low energy gauge couplings unify (up to small threshold corrections) at a unique scale, M_G . Supersymmetric grand unified theories provide, by far, the most predictive and economical framework allowing for perturbative unification.

The three pillars of SUSY GUTs are:

- gauge coupling unification at $M_G \sim 3 \times 10^{16}$ GeV;
- low-energy supersymmetry [with a large SUSY desert], and
- nucleon decay.

The first prediction has already been verified (see Fig. Fig. 15.1). Perhaps the next two will soon appear. Whether or not Yukawa couplings unify is more model dependent. Nevertheless, the “digital” 16 dimensional representation of quarks and leptons in $SO(10)$ is very compelling and may yet lead to an understanding of fermion masses and mixing angles.

In any event, the experimental verification of the first three pillars of SUSY GUTs would forever change our view of Nature. Moreover, the concomitant evidence for a vast SUSY desert would expose a huge lever arm for discovery. For then it would become clear that experiments probing the TeV scale could reveal physics at the GUT scale and perhaps beyond. Of course, some questions will still remain: Why do we have three families of quarks and leptons? How is the grand unified symmetry and possible family symmetries chosen by Nature? At what scale might stringy physics become relevant? Etc.

16. HEAVY-QUARK AND SOFT-COLLINEAR EFFECTIVE THEORY

Written August 2011 by C.W. Bauer (LBNL) and M. Neubert (U. Mainz).

16.1. Effective Field Theories

Quantum field theories represent the most precise computational tool for describing physics at the highest energies. One of their characteristic features is that they almost inevitably involve multiple length scales. When trying to determine the value of an observable, quantum field theory demands that all possible virtual states and hence all particles be included in the calculation. Since these particles have widely different masses, the final prediction is sensitive to many scales. This fact represents a formidable challenge from a practical point of view. No realistic quantum field theories can be solved exactly, so that one has to resort to approximation schemes; these, however, are typically most straightforward when only a single scale is involved at a time.

Effective field theories (EFTs) provide a general theoretical framework to deal with the multi-scale problems of realistic quantum field theories. This framework aims to reduce such problems to a combination of separate and simpler single-scale problems; simultaneously, however, it provides an organizational scheme whereby the other scales are not omitted but allowed to play their role in a separate step of the computation. The philosophy and basic principles of this approach are very generic, and correspondingly EFTs represent a widely used method in many different areas of high-energy physics, from the low energy scales of atomic and nuclear physics to the high energy scales of (partly yet unknown) elementary particle physics. EFTs can play a role both within analytic perturbative computations and in the context of non-perturbative numerical simulations; see [1–3] for some early references. One of the simplest applications of EFTs to particle physics is to describe an underlying theory that is only probed at energy scales $E < \Lambda$. Any particle with mass $m > \Lambda$ cannot be produced as a real state and therefore only leads to short-distance virtual effects. Thus, one can construct an effective theory in which the quantum fluctuations of such heavy particles are “integrated out” from the generating functional integral for Green functions. This results in a simpler theory containing only those degrees of freedom that are relevant to the energy scales under consideration. In fact, the standard model of particle physics itself is widely viewed as an EFT of some yet unknown, more fundamental theory.

The development of any effective theory starts by identifying the degrees of freedom that are relevant to describe the physics at a given energy (or length) scale, and constructing the Lagrangian describing the interactions among these fields. Short-distance quantum fluctuations associated with much smaller length scales are absorbed into the coefficients of the various operators in the effective Lagrangian. These coefficients are determined in a matching procedure, by requiring that the EFT reproduces the matrix elements of the full theory up to power corrections. In many cases the effective Lagrangian exhibits enhanced symmetries compared with the fundamental theory, allowing for simple and sometimes striking predictions relating different observables.

16.2. Heavy-Quark Effective Theory

Heavy-quark systems provide prime examples for applications of the EFT technology, because the hierarchy $m_Q \gg \Lambda_{\text{QCD}}$ (with $Q = b, c$) provides a natural separation of scales. Physics at the scale m_Q is of a short-distance nature and can be treated perturbatively, while for heavy-quark systems there is always also some hadronic physics governed by the confinement scale Λ_{QCD} . Being able to separate the short-distance and long-distance effects associated with these two scales is crucial for any quantitative description in heavy-quark physics. For instance, if the long-distance hadronic matrix elements are obtained from lattice QCD, then it is necessary to analytically compute the short-distance effects, which come from short-wavelength modes that do not fit on present-day lattices. In many other instances, the long-distance hadronic physics can be encoded in a small number of universal parameters.

16.2.1. General idea and derivation of the effective

Lagrangian: The simplest effective theory for heavy-quark systems is the heavy-quark effective theory (HQET) [4–7] (see [8,9] for detailed discussions). It provides a simplified description of the soft interactions of a single heavy quark interacting with soft, light partons. This includes the interactions that bind the heavy quark with other light partons inside heavy mesons (B, B^*, \dots) and baryons ($\Lambda_b, \Sigma_b, \dots$).

A softly interacting heavy quark is nearly on-shell. Its momentum may be decomposed as $p_Q = m_Q v + k$, where v is the 4-velocity of the hadron containing the heavy quark, and the “residual momentum” $k \sim \Lambda_{\text{QCD}}$ results from the soft interactions of the heavy quark with its environment. In the limit $m_Q \gg \Lambda_{\text{QCD}}$, the soft interactions do not change the 4-velocity of the heavy quark, which is therefore a conserved quantum number that is often used as a label on the effective heavy-quark fields. A nearly on-shell Dirac spinor has two large and two small components. We define

$$Q(x) = e^{-im_Q v \cdot x} [h_v(x) + H_v(x)], \quad (16.1)$$

where

$$h_v(x) = e^{im_Q v \cdot x} \frac{1 + \not{v}}{2} Q(x), \quad H_v(x) = e^{im_Q v \cdot x} \frac{1 - \not{v}}{2} Q(x) \quad (16.2)$$

are the large (“upper”) and small (“lower”) components of the Dirac spinor, respectively. The extraction of the phase factor in Eq. (16.1) implies that the fields h_v and H_v carry the residual momentum k . These fields obey the projection relations $\not{v} h_v = h_v$ and $\not{v} H_v = -H_v$. Inserting these definitions into the Dirac Lagrangian yields

$$\mathcal{L}_Q = \bar{h}_v i v \cdot D h_v + \bar{H}_v (-i v \cdot D - 2m_Q) H_v + \bar{h}_v i \overleftrightarrow{D} H_v + \bar{H}_v i \overleftrightarrow{D} h_v, \quad (16.3)$$

where $i \overleftrightarrow{D}^\mu = i D^\mu - v^\mu i v \cdot D$ is the “spatial” covariant derivative (note that $v^\mu = (1, \vec{0})$ in the heavy-hadron rest frame). The interpretation of Eq. (16.3) is that the field h_v describes a massless fermion, while H_v describes a heavy fermion with mass $2m_Q$. Both modes are coupled to each other via the last two terms. Soft interactions cannot excite the heavy fermion, so we integrate it out from the generating functional of the theory. The light field which remains describes the fluctuations of the heavy quark about its mass shell. Solving the classical equation of motion for the field H_v yields

$$H_v = \frac{1}{2m_Q + i v \cdot D} i \overleftrightarrow{D} h_v = \frac{1}{2m_Q} \sum_{n=0}^{\infty} \left(-\frac{i v \cdot D}{2m_Q} \right)^n i \overleftrightarrow{D} h_v, \quad (16.4)$$

which implies $H_v = O(\Lambda_{\text{QCD}}/m_Q) h_v$, provided the residual momenta are small. The effective Lagrangian of HQET is obtained by inserting this result into Eq. (16.3). At subleading order in $1/m_Q$ one finds

$$\mathcal{L}_{\text{HQET}} = \bar{h}_v i v \cdot D_s h_v + \frac{1}{2m_Q} \times \left[\bar{h}_v (i \overleftrightarrow{D}_s)^2 h_v + C_{\text{mag}}(\mu) \frac{g}{2} \bar{h}_v \sigma_{\mu\nu} G_s^{\mu\nu} h_v \right] + \dots \quad (16.5)$$

Note that the covariant derivative $i D_s^\mu = i \partial^\mu + g A_s^\mu$ contains only the soft gluon field. Hard gluons have been integrated out, and their effects are contained in the Wilson coefficients of the various operators in the effective Lagrangian. From the leading operator one derives the Feynman rules of HQET. The new operators entering at subleading order are referred to as the “kinetic energy” and “chromo-magnetic interaction”. The kinetic-energy operator corresponds to the first correction term in the Taylor expansion of the relativistic energy $E = m_Q + \vec{p}^2/2m_Q + \dots$. Lorentz invariance, which is encoded as a reparametrization invariance of the effective Lagrangian [10], ensures that its Wilson coefficient is not renormalized ($C_{\text{kin}} \equiv 1$). The coefficient of the chromo-magnetic operator, $C_{\text{mag}}(\mu) = 1 + \mathcal{O}(\alpha_s)$, receives corrections starting at one-loop order.

16.2.2. Spin-flavor symmetry and applications in spectroscopy : The leading term in the HQET Lagrangian exhibits a global spin-flavor symmetry. Its physical meaning is that, in the infinite mass limit, the properties of hadronic systems containing a single heavy quark are insensitive to the spin and flavor of the heavy quark [11,12]. The spin symmetry results from the fact that there appear no Dirac matrices in the leading term in the effective Lagrangian Eq. (16.5), implying that the interactions of the heavy quark with soft gluons leave its spin unchanged. The flavor symmetry arises since the mass of the heavy quark does not appear at leading order. When there are n_Q heavy quarks moving at the same velocity, one can simply extend Eq. (16.5) by summing over n_Q identical terms for heavy-quark fields h_v^i . The result is invariant under rotations in flavor space. When combined with the spin symmetry, the symmetry group becomes promoted to $SU(2n_Q)$. The flavor symmetry is broken by the operators arising at order $1/m_Q$ and higher. However, at first order only the chromo-magnetic operator breaks the spin symmetry.

The spin-flavor symmetry leads to many interesting relations between the properties of hadrons containing a heavy quark. The most direct consequences concern the spectroscopy of such states [13]. In the heavy-quark limit, the spin of the heavy quark and the total angular momentum j of the light degrees of freedom are separately conserved by the strong interactions. Because of heavy-quark symmetry, the dynamics is independent of the spin and mass of the heavy quark. Hadronic states can thus be classified by the quantum numbers (flavor, spin, parity, etc.) of the light degrees of freedom. The spin symmetry predicts that, for fixed $j \neq 0$, there is a doublet of degenerate states with total spin $J = j \pm 1/2$. The flavor symmetry relates the properties of states with different heavy quark flavor. In the case of the ground-state mesons containing a heavy quark, the light degrees of freedom have the quantum numbers of an antiquark, and the degenerate states are the pseudoscalar ($J = 0$) and vector ($J = 1$) mesons. Their masses are split by hyperfine corrections of order $1/m_Q$, such that one expects $m_{B^*} - m_B = O(1/m_b)$ and $m_{D^*} - m_D = O(1/m_c)$. It follows that $m_{B^*}^2 - m_B^2 \simeq m_{D^*}^2 - m_D^2 \simeq \text{const}$. The data are compatible with this result: $m_{B^*}^2 - m_B^2 \simeq 0.49 \text{ GeV}^2$ and $m_{D^*}^2 - m_D^2 \simeq 0.55 \text{ GeV}^2$.

16.2.3. Weak decay form factors : Of particular interest are the relations between the weak decay form factors of heavy mesons, which parametrize hadronic matrix elements of currents between two meson states containing a heavy quark. These relations have been derived by Isgur and Wise [12], generalizing ideas developed by Nussinov and Wetzel [14] and Voloshin and Shifman [15]. For the purpose of this discussion, it is convenient to work with a mass-independent normalization of meson states and use velocity rather than momentum variables.

Consider the elastic scattering of a pseudoscalar meson, $P(v) \rightarrow P(v')$, induced by an external vector current coupled to the heavy quark contained in P , which acts as a color source moving with the meson's velocity v . The action of the current is to replace instantaneously the color source by one moving at velocity v' . Soft gluons need to be exchanged in order to rearrange the light degrees of freedom and build the final state meson moving at velocity v' . This rearrangement leads to a form factor suppression. The important observation is that, in the $m_Q \rightarrow \infty$ limit, the form factor can only depend on the Lorentz boost $\gamma = v \cdot v'$ connecting the rest frames of the initial and final-state mesons (as long as $\gamma = \mathcal{O}(1)$). In the effective theory, which provides the appropriate framework to consider the limit $m_Q \rightarrow \infty$ with the quark velocities kept fixed, the hadronic matrix element describing the scattering process can be written as

$$\langle P(v') | \bar{h}_{v'} \gamma^\mu h_v | P(v) \rangle = \xi(v \cdot v') (v + v')^\mu, \quad (16.6)$$

with a form factor $\xi(v \cdot v')$ that is real and does not depend on m_Q . By flavor symmetry, the form factor remains identical when one replaces the heavy quark Q in one of the meson states by a heavy quark Q' of a different flavor, thereby turning P into another pseudoscalar meson P' . At the same time, the current becomes a flavor-changing vector current. This universal form factor is called the Isgur-Wise function [12]. For equal velocities the vector current $J^\mu = \bar{h}_v \gamma^\mu h_v$ is conserved in the effective theory, irrespective of the

flavor of the heavy quarks. The corresponding conserved charges are the generators of the flavor symmetry. It follows that the Isgur-Wise function is normalized at the point of equal velocities: $\xi(1) = 1$. Since $E_{\text{recoil}} = m_{P'}(v \cdot v' - 1)$ is the recoil energy of the daughter meson P' in the rest frame of the parent meson P , the point $v \cdot v' = 1$ is referred to as the zero recoil limit. The heavy-quark spin symmetry leads to additional relations among weak decay form factors. It can be used to relate matrix elements involving vector mesons to those involving pseudoscalar mesons, which once again can be described completely in terms of the universal Isgur-Wise function.

These form factor relations imposed by heavy-quark symmetry describe the semileptonic decay processes $\bar{B} \rightarrow D \ell \bar{\nu}$ and $\bar{B} \rightarrow D^* \ell \bar{\nu}$ in the limit of infinite heavy-quark masses. They are model-independent consequences of QCD. The known normalization of the Isgur-Wise function at zero recoil can be used to obtain a model-independent measurement of the element $|V_{cb}|$ of the Cabibbo-Kobayashi-Maskawa (CKM) matrix. The semileptonic decay $\bar{B} \rightarrow D^* \ell \bar{\nu}$ is ideally suited for this purpose [16]. Experimentally, this is a particularly clean mode, since the reconstruction of the D^* meson mass provides a powerful rejection against background. From the theoretical point of view, it is ideal since the decay rate at zero recoil is protected by Luke's theorem against first-order power corrections in $1/m_Q$ [17]. This is described in more detail in Section 11 of the PDG Book.

16.2.4. Decoupling transformation : At leading order in $1/m_Q$, the couplings of soft gluons to heavy quarks in the effective Lagrangian Eq. (16.5) can be removed by the field redefinition $h_v(x) = Y_v(x) h_v^{(0)}(x)$, where $Y_v(x)$ denotes a time-like Wilson line along the direction of v , extending from minus infinity to the point x . In terms of the new fields, the HQET Lagrangian becomes

$$\mathcal{L}_{\text{HQET}} = \bar{h}_v^{(0)} i v \cdot \partial h_v^{(0)} + O(1/m_Q). \quad (16.7)$$

At leading order in $1/m_Q$, this is a free theory as far as the strong interactions of heavy quarks are concerned. However, the theory is nevertheless non-trivial in the presence of external sources. Consider, e.g., the case of a weak-interaction heavy-quark current

$$\bar{h}_{v'} \gamma^\mu (1 - \gamma_5) h_v = \bar{h}_{v'}^{(0)} \gamma^\mu (1 - \gamma_5) Y_{v'}^\dagger Y_v h_v^{(0)}, \quad (16.8)$$

where v and v' are the velocities of the heavy mesons containing the heavy quarks. Unless the two velocities are equal, the object $Y_{v'}^\dagger Y_v$ is non-trivial, and hence the soft gluons do not decouple from the heavy quarks inside the current operator. One may interpret $Y_{v'}^\dagger Y_v$ as a Wilson loop with a cusp at the point x , where the two paths parallel to the different velocity vectors intersect. The presence of the cusp leads to non-trivial ultra-violet behavior (for $v \neq v'$), which is described by a cusp anomalous dimension $\Gamma_c(v \cdot v')$ that was calculated at two-loop order in [18]. It coincides with the velocity-dependent anomalous dimension of heavy-quark currents, which was rediscovered later in the context of HQET [19]. The interpretation of heavy quarks as Wilson lines is a useful tool, which was put forward in some of the very first papers on the subject [4]. This technology will be useful in the study of the interactions of heavy quarks with collinear degrees of freedom discussed later in this review.

16.2.5. Heavy-quark expansion for inclusive decays : The theoretical description of inclusive decays of hadrons containing a heavy quark exploits two observations [20–24]: bound-state effects related to the initial state can be calculated using the heavy-quark expansion, and the fact that the final state consists of a sum over many hadronic channels eliminates the sensitivity to the properties of individual final-state hadrons. The second feature rests on the hypothesis of quark-hadron duality, i.e. the assumption that decay rates are calculable in QCD after a smearing procedure has been applied [25]. In semileptonic decays, the integration over the lepton spectrum provides a smearing over the invariant hadronic mass of the final state (global duality). For nonleptonic decays, where the total hadronic mass is fixed, the summation over many hadronic final states provides an averaging (local duality).

Using the optical theorem, the inclusive decay width of a hadron H_b containing a b quark can be written in the form

$$\Gamma(H_b) = \frac{1}{M_{H_b}} \text{Im} \langle H_b | i \int d^4x T \{ \mathcal{H}_{\text{eff}}(x), \mathcal{H}_{\text{eff}}(0) \} | H_b \rangle. \quad (16.9)$$

The effective weak Hamiltonian for b -quark decays consists of dimension-6 four-fermion operators and dipole operators [80]. It follows that the leading contributions to the inclusive decay rate in Eq. (16.9) arise from two-loop diagrams. Because of the large mass of the b quark, the momenta flowing through the internal propagators are large. It is thus possible to construct an operator-product expansion (OPE) for the transition operator, in which it is represented as a series of local operators containing two b -quark fields. The operator with the lowest dimension is $\bar{b}b$. The next non-trivial operator has dimension 5 and contains the gluon field. It arises from diagrams in which a soft gluon is emitted from one of the internal lines of the two-loop diagrams. From dimension 6 on, an increasing number of operators appears. For dimensional reasons, the matrix elements of higher-dimensional operators are suppressed by inverse powers of the b -quark mass. Thus, the total inclusive decay rate of a hadron H_b can be written as [21,47]

$$\Gamma(H_b) = \frac{G_F^2 m_b^5 |V_{cb}|^2}{192\pi^3} \times \left\{ c_3 \langle \bar{b}b \rangle + c_5 \frac{\langle \bar{b} g \sigma_{\mu\nu} G^{\mu\nu} b \rangle}{m_b^2} + \sum_n c_6^{(n)} \frac{\langle O_6^{(n)} \rangle}{m_b^3} + \dots \right\}, \quad (16.10)$$

where the prefactor arises from the loop integrations, c_i are calculable coefficient functions, and $\langle O_i \rangle$ are the (normalized) forward matrix elements between H_b states. These matrix elements can be systematically expanded in powers of $1/m_b$ using HQET. The result is [21,47]

$$\langle \bar{b}b \rangle = 1 - \frac{\mu_\pi^2(H_b) - \mu_G^2(H_b)}{2m_b^2} + \dots, \quad \langle \bar{b} g \sigma_{\mu\nu} G^{\mu\nu} b \rangle = \frac{2\mu_G^2(H_b)}{m_b^2} + \dots, \quad (16.11)$$

where $\mu_\pi^2(H_b)$ and $\mu_G^2(H_b)$ are the matrix elements of the heavy-quark kinetic energy and chromomagnetic interaction inside the hadron H_b , respectively [27]. For the ground-state heavy mesons and baryons, one can extract $\mu_G^2(B) = 3(m_{B^*}^2 - m_B^2)/4 \simeq 0.36 \text{ GeV}^2$ and $\mu_G^2(\Lambda_b) = 0$ from spectroscopy.

From the fully inclusive width Eq. (16.10) one can obtain the lifetime of a heavy hadron via $\tau(H_b) = 1/\Gamma(H_b)$. Due to the universality of the leading term in the heavy-quark expansion, lifetime ratios such as $\tau(B^-)/\tau(\bar{B}^0)$, $\tau(B_s^0)/\tau(\bar{B}^0)$, and $\tau(\Lambda_b)/\tau(\bar{B}^0)$ are particularly sensitive to the hadronic parameters determining the power corrections in the expansion. In order to understand these ratios theoretically, it is necessary to include phase-space enhanced power corrections of order $(\Lambda_{\text{QCD}}/m_b)^3$ as well as short-distance perturbative effects in the calculation [28,29].

A formula analogous to Eq. (16.10) can be derived for differential distributions in specific inclusive decay processes, assuming that these distributions are integrated over sufficiently large portions of phase space to ensure quark-hadron duality. Important examples are the distributions in lepton energy ($d\Gamma/dE_\ell$) or lepton invariant mass ($d\Gamma/dq^2$), as well as moments of the invariant hadronic mass distribution, in the semileptonic processes $\bar{B} \rightarrow X_u \ell \bar{\nu}$ and $\bar{B} \rightarrow X_c \ell \bar{\nu}$, as well as the photon energy spectrum ($d\Gamma/dE_\gamma$) in the radiative process $\bar{B} \rightarrow X_s \gamma$. While the latter process is primarily used to test the Standard Model and search for hints of new physics, an analysis of decay distributions in the semileptonic processes can be employed to perform a global fit determining the CKM matrix elements $|V_{ub}|$ and $|V_{cb}|$ along with heavy-quark parameters such as the masses m_b , m_c and the hadronic parameters $\mu_\pi^2(B)$, $\mu_G^2(B)$. These determinations provide some of the most accurate values for these parameters [30].

16.2.6. Shape functions and non-local power corrections : In certain regions of phase space, in which the hadronic final state in an inclusive heavy-hadron decay is made up of light energetic partons, the local OPE for inclusive decays must be replaced by a more complicated expansion involving hadronic matrix elements of non-local light-ray operators [52,53]. Prominent examples are the radiative decay $\bar{B} \rightarrow X_s \gamma$ for large photon energy E_γ near $m_B/2$, and the semileptonic decay $\bar{B} \rightarrow X_u \ell \bar{\nu}$ at large lepton energy or small hadronic invariant mass. In these cases, the differential decay rates at leading order in the heavy-quark expansion can be written in the factorized form $d\Gamma \propto H J \otimes S$ [33], where the hard function H and the jet function J are calculable in perturbation theory. The characteristic scales for these functions are set by m_b and $(m_b \Lambda_{\text{QCD}})^{1/2}$, respectively. The soft function

$$S(\omega) = \int \frac{dt}{4\pi} e^{-i\omega t} \langle \bar{B}(v) | \bar{h}_v(tn) Y_n(tn) Y_n^\dagger(0) h_v(0) | \bar{B}(v) \rangle \quad (16.12)$$

is a genuinely non-perturbative object, called the shape function [52,53]. Here Y_n are soft Wilson lines along a light-like direction n aligned with the momentum of the hadronic final-state jet. The jet function and the shape function share a common variable $\omega \sim \Lambda_{\text{QCD}}$, and the symbol \otimes denotes a convolution in this variable.

While the hard function is different for the two decays, the jet and soft functions are identical at leading order in Λ_{QCD}/m_Q . This is particularly important for the soft function. It is this shape function that introduces non-perturbative physics into the theoretical predictions for the cross sections of $\bar{B} \rightarrow X_s \gamma$ and $\bar{B} \rightarrow X_u \ell \bar{\nu}$ in the regions of experimental interest. The fact that both decays depend on the same non-perturbative function made it possible to determine this non-perturbative information from the measured shape of the photon spectrum in $\bar{B} \rightarrow X_s \gamma$, allowing for a better understanding of the process used to determine the CKM element $|V_{ub}|$. In higher orders of the heavy-quark expansion, an increasing number of subleading jet and soft functions is required to describe the decay distributions [34]. These have been analyzed in detail at order $1/m_b$ [35–37]. The technology for deriving the corresponding factorization theorems relies on SCET, which is discussed below.

16.3. Soft-Collinear Effective Theory

As discussed in the previous section, soft gluons that bind a heavy quark inside a heavy meson cannot change the virtuality of that heavy quark by a significant amount. The ratio of Λ_{QCD}/m_Q provided the expansion parameter in HQET, which is a small parameter since $m_Q \gg \Lambda_{\text{QCD}}$. This obviously does not work when considering light quarks. However, if the energy Q of the quarks is large, the ratio Λ_{QCD}/Q provides a small parameter which can be used to construct an effective theory. One major difference to HQET is that light energetic quarks cannot only emit soft gluons, but they can also emit collinear gluons (an energetic gluon in the same direction as the original quark), without parametrically changing their virtuality. Thus, to fully reproduce the long-distance physics of energetic quarks requires that one includes their interactions with both soft and collinear particles. The resulting effective theory is therefore called soft-collinear effective theory (SCET) [38–40].

SCET is applicable for processes containing particles with energy much in excess of their mass, and it has therefore a wide range of applications. In this brief review we will outline the main features of this effective theory and mention a few selected applications.

16.3.1. General idea of the expansion : Consider a quark with energy Q and virtuality $m \ll Q$, moving along the direction \vec{n} . It is convenient to parameterize the momentum p_n of this particle in terms of its light-cone components, defined by $(p_n^-, p_n^+, p_n^\perp) = (\vec{n} \cdot p_n, n \cdot p_n, p_n^\perp)$, where $n^\mu = (1, \vec{n})$ and $\bar{n}^\mu = (1, -\vec{n})$ are light-like 4-vectors, and $n \cdot p_\perp = \bar{n} \cdot p_\perp = 0$. A subscript n has been added to the momentum to identify it as a collinear particle in direction n (more precisely, a particle with energy much larger than its virtuality moving along a direction \vec{n}). In terms of these light-cone components, the virtuality satisfies $m^2 = p_n^+ p_n^- + p_n^{\perp 2}$. The individual components of the momentum satisfy

$$(p_n^-, p_n^+, p_n^\perp) \sim (Q, m^2/Q, m) \equiv Q(1, \lambda^2, \lambda), \quad (16.13)$$

where $\lambda = m/Q$ is the expansion parameter of SCET.

The virtuality of such an energetic particle remains parametrically unchanged if it interacts with energetic particles in the same direction n , or with soft particles with momentum scaling as

$$(p_s^-, p_s^+, p_s^\perp) \sim Q(\lambda^2, \lambda^2, \lambda^2). \quad (16.14)$$

Thus, it is the interactions of collinear and soft degrees of freedom that give rise to the long-distance physics. SCET, which is constructed to reproduce this long-distance dynamics, is therefore an effective theory describing the interactions of collinear and soft particles.

The above power counting treats the soft momentum to be of order m^2/Q , where m denotes the mass of a collinear system. If the mass of the collinear system is of order Λ_{QCD} , as would be the case for a single energetic hadron, this power counting is no longer applicable, since Λ_{QCD} provides a natural cutoff to QCD and the soft momentum cannot be below this scale. To describe such systems requires a modified version of SCET, called SCET_{II}, in which the scaling of the soft modes is $Q(\lambda, \lambda, \lambda)$. In this review we will focus only on SCET with the scaling discussed before, which is sometimes called SCET_I.

16.3.2. Leading-order Lagrangian : The derivation of the SCET Lagrangian follows similar steps as the derivation of the HQET Lagrangian in Section 16.2.1, but care has to be taken to properly account for the interactions of collinear fields with one another. We begin by deriving the Lagrangian for a theory containing only a single type of collinear degrees of freedom. We are interested in the interactions of fermion fields $q_n(x)$ with gluon fields $A_n(x)$, which have collinear momentum in the same light-like direction n . Similar to HQET, one can separate the full QCD field into two components, $q_n(x) = \psi_n(x) + \Xi_n(x)$, where

$$\psi_n(x) = \frac{\not{n}\not{\bar{n}}}{4} q_n(x), \quad \Xi_n(x) = \frac{\not{n}\not{\bar{n}}}{4} q_n(x).$$

In terms of these fields, the QCD Lagrangian is

$$\begin{aligned} \mathcal{L}_n = & \bar{\psi}_n(x) \frac{\not{n}}{2} i n \cdot D_n \psi_n(x) + \bar{\Xi}_n(x) \frac{\not{n}}{2} i \bar{n} \cdot D_n \Xi_n(x) \\ & + \bar{\psi}_n(x) i \not{D}_n^\perp \Xi_n(x) + \bar{\Xi}_n(x) i \not{D}_n^\perp \psi_n(x), \end{aligned} \quad (16.15)$$

where we have defined the transverse derivative $D_n^{\perp\mu} = D_n^\mu - \frac{n^\mu}{2} \bar{n} \cdot D_n - \frac{\bar{n}^\mu}{2} n \cdot D_n$. Since $\bar{n} \cdot p_n \gg 1$ the field $\Xi_n(x)$ has no pole in its propagator, similar to the field $H_v(x)$ in Eq. (16.3). It can therefore be integrated out using its equation of motion. Inserting this back into Eq. (16.15), we find

$$\mathcal{L}_n = \bar{\psi}_n(x) \left[i n \cdot D_n + i \not{D}_n^\perp \frac{1}{i \bar{n} \cdot D_n} i \not{D}_n^\perp \right] \frac{\not{n}}{2} \psi_n(x). \quad (16.16)$$

While this Lagrangian leads to the correct Feynman rules of SCET, there is one feature that warrants extra discussion. In contrast to the Lagrangian of HQET given in Eq. (16.5), where the derivative scales like the residual momentum k of the heavy quark, the derivatives in Eq. (16.16) pick up both the large momentum components of order Q and $Q\lambda$, as well as the residual momentum of order $Q\lambda^2$. One can separate the large and residual momentum components using a procedure similar to the HQET case. Separating the collinear momentum into a ‘‘label’’ and a residual component, $p^\mu = P^\mu + k^\mu$, and performing a phase redefinition on the collinear fields $\psi_n(x) = e^{iP \cdot x} \xi_n(x)$, derivatives acting on the fields $\xi_n(x)$ now only pick out the residual momentum. Since the label momentum in SCET is not conserved as in HQET, one defines a label operator \mathcal{P}^μ acting as $\mathcal{P}^\mu \xi_n(x) = P^\mu \xi_n(x)$ [39], as well as a corresponding covariant label operator $i \mathcal{D}_n^\mu = \mathcal{P}^\mu + g A_n(x)$.

The final step to complete the Lagrangian of SCET is to include the interactions of collinear fields with soft fields. These interactions can be included by adding the soft gluons to the covariant derivatives, while preserving the power counting. This leads to the final SCET Lagrangian [39–41]

$$\mathcal{L}_n = \bar{\xi}_n(x) \left[i n \cdot D_n + g n \cdot A_s + i \not{D}_n^\perp \frac{1}{i \bar{n} \cdot D_n} i \not{D}_n^\perp \right] \frac{\not{n}}{2} \xi_n(x). \quad (16.17)$$

The leading-order Lagrangian describing collinear fields in different light-like directions is simply given by the sum of the Lagrangians for each direction n separately, i.e. $\mathcal{L} = \sum_n \mathcal{L}_n$. The soft gluons are the same in each individual Lagrangian. An alternative way to understand the separation between large and small momentum components is to derive the Lagrangian of SCET in position space. In this case no label operators are required to describe interactions in SCET, and the dependence on short-distance effects is contained in non-localities at short distances. An important difference between SCET and HQET is that the SCET Lagrangian is not corrected by short distance fluctuations [42].

16.3.3. Collinear gauge invariance and Wilson lines : An important aspect of SCET is the gauge structure of the theory. Because the effective field operators in SCET describe modes with certain momentum scalings, the effective Lagrangian respects only residual gauge symmetries. One of them satisfies the collinear scaling

$$(\bar{n} \cdot \partial_n, n \cdot \partial_n, \partial_n^\perp) U_n(x) \sim Q(1, \lambda^2, \lambda) U_n(x), \quad (16.18)$$

and one the soft scaling

$$(\bar{n} \cdot \partial_n, n \cdot \partial_n, \partial_n^\perp) U_s(x) \sim Q(\lambda^2, \lambda^2, \lambda^2) U_s(x). \quad (16.19)$$

The fact that collinear fields in different directions do not transform under the same gauge transformations implies that each collinear sector, containing particles with large momenta along a certain direction, has to be separately gauge invariant. This is achieved by the introduction of collinear Wilson lines [39]

$$W_n(x) = P \exp \left[-ig \int_{-\infty}^0 ds \bar{n} \cdot A_n(s \bar{n} + x) \right], \quad (16.20)$$

which transform under collinear gauge transformations according to $W_n \rightarrow U_n W_n$. Thus, the combination $\chi_n \equiv W_n^\dagger \psi_n$ is gauge invariant. In a similar manner, one can define the gauge-invariant gluon field $B_n^\mu = g^{-1} W_n^\dagger i D_n^\mu W_n$ [43]. Operators in SCET are typically constructed from such gauge-invariant collinear fields.

16.3.4. Decoupling of soft gluons : Soft gluons in SCET couple to collinear quarks only through the term $\bar{\xi}_n g n \cdot A_s \frac{\not{n}}{2} \xi_n$ in the effective Lagrangian in Eq. (16.17). This coupling is similar to the coupling of soft gluons to heavy quarks in HQET, and soft gluons in SCET can be decoupled from collinear fields in a way similar as explained in Section 16.2.4. Written in terms of the redefined fields

$$\psi_n(x) = Y_n(x) \psi_n^{(0)}(x), \quad A_n(x) = Y_n(x) A_n^{(0)}(x) Y_n^\dagger(x), \quad (16.21)$$

the soft gluons decouple from the SCET Lagrangian [40]. This fact greatly facilitates proofs of factorization theorems in SCET.

16.3.5. Factorization Theorems : One of the important applications of SCET is to understand how to factorize cross sections involving energetic particles in different directions into simpler pieces that can either be calculated perturbatively or determined from data. Factorization theorems have been around for much longer than SCET. For a review on the subject, see [44]. However, the effective theory allows for a conceptually simpler understanding of certain classes of factorization theorems [45], since most simplifications happen already at the level of the Lagrangian. The discussion in this section is valid to leading order in the power counting of the effective theory.

As discussed in the previous section, the Lagrangian of SCET does not involve any couplings between collinear degrees of freedom in different light-like directions, or between soft and collinear degrees of freedom after the field redefinition Eq. (16.21) has been performed. An operator describing the scattering and production of collinear partons at short distances can thus be written as

$$\langle O(x) \rangle \simeq C_O(\mu) \times$$

$$\left\langle \mathcal{C}_{n_a}^{(0)}(x) \mathcal{C}_{n_b}^{(0)}(x) \mathcal{C}_{n_1}^{(0)}(x) \dots \mathcal{C}_{n_N}^{(0)}(x) [\mathcal{Y}_{n_a} \mathcal{Y}_{n_b} \mathcal{Y}_{n_1} \dots \mathcal{Y}_{n_N}](x) \right\rangle_\mu. \quad (16.22)$$

Here $\mathcal{C}_n(x)$ denotes a gauge-invariant combination of collinear fields (either quark or gluon fields) in the direction n , and the matching coefficient accounting for short-distance effects is denoted by C_O . The soft Wilson lines can either be in a color triplet or color octet representation, and are collectively denoted by \mathcal{Y}_n . Both the matrix elements and the coefficient C_O depend on the renormalization scale μ .

Having defined the operator mediating a given process, one can calculate the cross section by squaring the operator, taking the forward matrix element and integrating over the phase space of all final-state particles. The absence of interactions between collinear degrees of freedom moving along different directions or soft degrees of freedom implies that the forward matrix element of the operator can be factorized as

$$\begin{aligned} \langle \text{in} | O(x) O^\dagger(0) | \text{in} \rangle &= \langle \text{in}_a | \mathcal{C}_{n_a}(x) \mathcal{C}_{n_a}^\dagger(0) | \text{in}_a \rangle \langle \text{in}_b | \mathcal{C}_{n_b}(x) \mathcal{C}_{n_b}^\dagger(0) | \text{in}_b \rangle \\ &\times \langle 0 | \mathcal{C}_{n_1}(x) \mathcal{C}_{n_1}^\dagger(0) | 0 \rangle \cdots \langle 0 | \mathcal{C}_{n_N}(x) \mathcal{C}_{n_N}^\dagger(0) | 0 \rangle \\ &\times \langle 0 | [\mathcal{Y}_{n_a} \cdots \mathcal{Y}_{n_N}](x) [\mathcal{Y}_{n_a} \cdots \mathcal{Y}_{n_N}]^\dagger(0) | 0 \rangle. \end{aligned} \quad (16.23)$$

Thus, the matrix element required for the differential cross section has factorized into a product of simpler structures, each of which can be evaluated separately.

For most applications the matrix elements of incoming collinear fields are non-perturbative objects given in terms of the well-known parton distribution functions, while the matrix elements of outgoing collinear fields are determined by perturbatively calculable jet functions $J_i(\mu)$. Finally, the vacuum matrix element of the soft Wilson lines defines a so-called soft function, commonly denoted by $S(\mu)$. The common dependence on x in the above equation implies that in momentum space the various components of the factorization theorem are convoluted with one another. Deriving this convolution requires a careful treatment of the phase-space integration, in particular treating the large and residual components of each momentum appropriately.

Putting all information together, the differential cross section can be written as

$$d\sigma \sim H(\mu) \otimes [f_{p_1/P}(\mu) f_{p_2/P}(\mu)] \otimes [J_1(\mu) \cdots J_N(\mu)] \otimes S(\mu). \quad (16.24)$$

The hard coefficient is equal to the square of the matching coefficient, $H(\mu) = |C_O(\mu)|^2$. It should be mentioned that the most difficult part of traditional factorization proofs involves showing that so-called Glauber gluons do not spoil the above factorization theorem. This question has not yet been fully addressed in the context of SCET.

16.3.6. Resummation of large logarithms: SCET can be used to sum the large logarithmic terms that arise in perturbative calculations. In general, perturbation theory will generate a logarithmic dependence on any ratio of scales r in a problem, and for processes that involve initial or final states with energy much in excess of their mass there are two powers of logarithms for every power of the strong coupling constant. Thus, for widely separated scales these large logarithms can spoil fixed-order perturbation theory, and a much better convergence is achieved by expanding in α_s , but holding $\alpha_s \log^2 r$ fixed, such that the first term in the new expansion resums powers of $\alpha_s \log^2 r$ to all orders. More precisely, a proper resummation requires to sum logarithms of the form $\alpha_s^n \log^m r$ with $m \leq n + 1$ in the logarithm of a cross-section.

The important ingredient in achieving this resummation is the fact that SCET factorizes a given cross section into simpler pieces, as discussed in the previous section. Each of the ingredients of the factorization theorem depends on a single physical scale, and the only dependence on that scale can arise through logarithms of its ratio with the renormalization scale μ . Thus, for each of the components in the factorization theorem one can choose a renormalization scale μ for which the large logarithmic terms are absent.

Of course, the factorization formula requires a common renormalization scale μ in all its components, and one therefore has to use the RG to evolve the various component functions from their preferred

scale to the common scale μ . For example, for the hard coefficient $H(\mu)$, the RG equation can be written as

$$\mu \frac{d}{d\mu} H(\mu) = \gamma_H(\mu) H(\mu). \quad (16.25)$$

In general, the anomalous dimension is of the form $\gamma_H(\mu) = c_H \Gamma_{\text{cusp}}(\alpha_s) \log(Q/\mu) + \gamma(\alpha_s)$, where c_H is a process-dependent coefficient and Γ_{cusp} denotes the so-called cusp anomalous dimension [18,46]. The non-cusp part of the anomalous dimension γ is again process dependent. The presence of a logarithm of the hard scale Q in the anomalous dimension is characteristic of Sudakov problems and arises since the perturbative series contains double logarithms of scale ratios. The anomalous dimension γ_H is known at two-loop order for arbitrary n -parton amplitudes containing massless or massive external partons [47–50]. Solving the RG equation yields

$$H(\mu) = U_H(\mu, \mu_h) H(\mu_h), \quad (16.26)$$

which can be used to write the hard function at a scale $\mu_h \sim Q$, where its perturbative expression does not contain any large logarithms, in terms of the common renormalization scale μ . The RG evolution factor $U_H(\mu, \mu_h)$ sums logarithms of the form μ/μ_h . By calculating the anomalous dimension $\gamma_H(\mu)$ to higher and higher orders in perturbation theory, one can resum more and more logarithms in the evolution kernel. The RG equations for the jet and soft functions are more complicated, since they involve convolutions over the relevant momentum variables.

16.3.7. Applications: Most of the applications of SCET are either in flavor physics, where the decay of a heavy B meson can give rise to energetic light partons, or in collider physics, where the presence of jets naturally leads to collimated sets of energetic particles. For several of these applications alternative approaches existed before the invention of SCET, but the effective theory has opened up alternative ways to understand the physics of these processes. There are, however, many examples for which SCET has allowed new insights that were not available or possible without the effective theory. In particular, it has provided a field-theoretic basis for the QCD factorization approach to exclusive, non-leptonic decays of B mesons [51]. Using SCET methods, proofs of factorization were derived for the color-allowed decay $\bar{B}^0 \rightarrow D^+ \pi^-$ [52], the color-suppressed decay $\bar{B}^0 \rightarrow D^0 \pi^0$ [53], and the radiative decay $\bar{B} \rightarrow K^* \gamma$ [54]. Further examples are factorization theorems and the resummation of endpoint logarithms for quarkonia production [55], factorization theorems for cross sections defined through jet algorithms [56], the resummation of large logarithmic terms for the thrust [57] and jet broadening [58] distributions in e^+e^- annihilation beyond NLL order, the development of new factorizable observables to veto extra jets [59], all-orders factorization theorems for processes containing electroweak Sudakov logarithms [60], as well as the resummation of threshold (soft gluon) logarithms for several important processes at hadron colliders [61,62]. We describe two of these applications in more detail.

Event-shape distributions, in particular the thrust distribution, have been measured to high accuracy at LEP [63]. Comparing these data to precise theoretical predictions allows for a determination of the strong coupling constant α_s . For small values of $\tau \equiv 1 - T$, the distribution can be factorized into the form [64,65]

$$\frac{1}{Q\sigma_0} \frac{d\sigma}{d\tau} = H(\mu) \int ds \int dk J(s, \mu) S(Q\tau - s/Q - k, \mu). \quad (16.27)$$

Here Q denotes the center-of-mass energy of the collision, σ_0 is the total hadronic cross section, and H , J and S are the hard, jet and soft functions in SCET. Large logarithms of the form $(\alpha_s^n \ln^{2n-1} \tau)/\tau$ become important and have to be resummed. Furthermore, for $\tau \sim \Lambda_{\text{QCD}}/Q$ non-perturbative effects in the soft function become important. Using SCET the resummation of these large logarithms has been performed to N^3LL , which is two orders beyond what was previously available [57]. The factorization in the effective theory has also allowed to include the non-perturbative physics through a shape function, very similar to the B -physics case discussed above.

The known perturbative effects for large values of τ can be included by matching the SCET result to the known two-loop spectrum [66,67]. Comparing the predicted to the measured thrust distribution allows for a precise determination of the strong coupling constant α_s [68].

For quarkonium produced in e^+e^- annihilation or photo-production, large logarithms arise in the region of phase space where the energy of the produced $Q\bar{Q}$ state is close to its maximum value. In this region the quarkonium is predominantly produced in a color-octet configuration and recoils against a collinear hadronic system. Then logarithms of the form $\log(1 - E_\Psi/E_{\max})$ as well as non-perturbative effects become important and should be included in attempts to describe the data. While some of these issues had been addressed without the use of an effective theory (see [69] and references therein), a complete treatment of the endpoint region has only been achieved using SCET [55]. It was shown that including both effects consistently, theory and data can be brought into better agreement.

16.4. Open issues and perspectives

HQET has successfully passed many experimental tests, and there are not too many open questions that still need to be addressed. One issue that has not been derived from first principles is quark-hadron duality. The validity of global duality (at energies even lower than those relevant in B decays) has been tested experimentally using high-precision data on semileptonic B decays and on hadronic τ decays, and there has been good agreement between theory and data. However, assigning a theoretical uncertainty to possible duality violations is difficult. Another known issue is that the measured value of the CKM element $|V_{cb}|$ is different depending of whether one uses inclusive or exclusive B decays to derive it (see the relevant section in the Particle Data Book). Both measurements rely on the heavy-quark limit, and the uncertainties quoted include the effects from power corrections arising from the finite b -quark mass.

SCET, on the other hand, is still an active field of research, and there are several open questions that need to be answered. In this review we have not discussed any issues having to do with SCET_{II}, which is the appropriate effective theory describing the interactions of collinear particles with soft particles having momentum scaling as $Q(\lambda, \lambda, \lambda)$. This is important, for example, to describe exclusive decays of B mesons into light, energetic mesons, or in collider-physics applications such as the p_T resummation for Drell-Yan production. There are still open issues in how to properly formulate SCET_{II}, which are under active investigation. They include the treatment of endpoint singularities of convolution integrals, double counting between overlapping momentum regions, and the breakdown of the naive factorization of soft and collinear modes due to quantum effects. Glauber gluons are known to affect factorization theorems, but how to properly include them in SCET is still an open question.

17. LATTICE QUANTUM CHROMODYNAMICS

Written September 2011 by S. Hashimoto (KEK), J. Laiho (University of Glasgow) and S.R. Sharpe (University of Washington).

17.1. Lattice regularization of QCD

Gauge theories form the building blocks of the Standard Model. While the SU(2) and U(1) parts have weak couplings and can be studied accurately with perturbative methods, the SU(3) component—QCD—is only amenable to a perturbative treatment at high energies. The growth of the coupling constant in the infrared—the flip-side of asymptotic freedom—requires the use of non-perturbative methods to determine the low energy properties of QCD. Lattice gauge theory, proposed by K. Wilson in 1974 [1], provides such a method, for it gives a non-perturbative definition of vector-like gauge field theories like QCD. In lattice regularized QCD—commonly called lattice QCD or LQCD—Euclidean space-time is discretized, usually on a hypercubic lattice with lattice spacing a , with quark fields placed on sites and gauge fields on the links between sites. The lattice spacing plays the role of the ultraviolet regulator, rendering the quantum field theory finite. The continuum theory is recovered by taking the limit of vanishing lattice spacing, which can be reached by tuning the bare coupling constant to zero according to the renormalization group.

Unlike dimensional regularization, which is commonly used in continuum QCD calculations, the definition of LQCD does not rely on the perturbative expansion. Indeed, LQCD allows non-perturbative calculations by numerical evaluation of the path integral that defines the theory.

Practical LQCD calculations are limited by the availability of computational resources and the efficiency of algorithms. Because of this, LQCD results come with both statistical and systematic errors, the former arising from the use of Monte-Carlo integration, the latter, for example, from the use of non-zero values of a . There are also different ways in which the QCD action can be discretized, and all must give consistent results in the continuum limit. It is the purpose of this review to provide an outline of the methods of LQCD, with particular focus on applications to particle physics, and an overview of the various sources of error. This should allow the reader to better understand the LQCD results that are presented in other sections for a variety of quantities (quark masses, the hadron spectrum and several electroweak matrix elements). For more extensive explanations the reader should consult the available text books, the most up-to-date of which are Refs. [2,3,4].

17.1.1. Gauge invariance, gluon fields and the gluon action :

A key feature of the lattice formulation of QCD is that it preserves gauge invariance. This is in contrast to perturbative calculations, where gauge fixing is an essential step. The preservation of gauge invariance leads to considerable simplifications, e.g. restricting the form of operators that can mix under renormalization.

The gauge transformations of lattice quark fields are just as in the continuum: $q(x) \rightarrow V(x)q(x)$ and $\bar{q}(x) \rightarrow \bar{q}(x)V^\dagger(x)$, with $V(x)$ an arbitrary element of SU(3). The only difference is that the Euclidean space-time positions x are restricted to lie on the sites of the lattice, i.e. $x = a(n_1, n_2, n_3, n_4)$ for a hypercubic lattice, with the n_j being integers. Quark bilinears involving different lattice points can be made gauge invariant by introducing the gluon field $U_\mu(x)$. For example, for adjacent points the bilinear is $\bar{q}(x)U_\mu(x)q(x+a\hat{\mu})$, with $\hat{\mu}$ the unit vector in the μ 'th direction. (This form is used in the construction of the lattice covariant derivative.) The gluon field (or “gauge link”) is an element of the group, SU(3), in contrast to the continuum field A_μ which takes values in the Lie algebra. The bilinear is invariant if U_μ transforms as $U_\mu(x) \rightarrow V(x)U_\mu(x)V^\dagger(x+a\hat{\mu})$. The lattice gluon field is naturally associated with the link joining x and $x+a\hat{\mu}$, and corresponds in the continuum to a Wilson line connecting these two points, $P \exp(i \int_x^{x+a\hat{\mu}} dx_\mu A_\mu^{\text{cont}}(x))$ (where P indicates a path-ordered integral, and the superscript on A_μ indicates that it is a continuum field). The trace of a product of the $U_\mu(x)$ around any closed loop is easily seen to be gauge invariant and is the lattice version of a Wilson loop.

The simplest possible gauge action, usually called the Wilson gauge action, is given by the product of gauge links around elementary

plaquettes:

$$S_g = \beta \sum_{x,\mu\nu} [1 - \text{ReTr}[U_\mu(x)U_\nu(x+a\hat{\mu})U_\mu^\dagger(x+a\hat{\nu})U_\nu^\dagger(x)]/3]. \quad (17.1)$$

For small a , assuming that the fields are slowly varying, one can expand the action in powers of a using $U_\mu(x) = \exp(iaA_\mu(x))$. Keeping only the leading non-vanishing term, and replacing the sum with an integral, one finds the continuum form,

$$S_g \rightarrow \int d^4x \frac{1}{4g_{\text{lat}}^2} \text{Tr}[F_{\mu\nu}^2(x)], \quad (F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + i[A_\mu, A_\nu]) \quad (17.2)$$

as long as one chooses $\beta = 6/g_{\text{lat}}^2$ for the lattice coupling. In this expression, g_{lat} is the bare coupling constant in the lattice scheme, which can be related (by combining continuum and lattice perturbation theory) to a more conventional coupling constant such as that in the $\overline{\text{MS}}$ scheme (see Sec. 17.3.4 below).

In practice, the lattice spacing a is non-zero, leading to discretization errors. In particular, the lattice breaks Euclidean rotational invariance (which is the Euclidean version of Lorentz invariance) down to a discrete hypercubic subgroup. One wants to reduce discretization errors as much as possible. A very useful tool in this regard is the Symanzik effective action: the interactions of quarks and gluons with momenta low compared to the lattice cutoff ($|p| \ll 1/a$) are described by a continuum action consisting of the standard continuum terms (e.g. the gauge action given in Eq. (17.2)) augmented by higher dimensional operators suppressed by powers of a [5]. For the Wilson lattice gauge action, the leading correction comes in at $\mathcal{O}(a^2)$. It takes the form $\sum_j a^2 \mathcal{O}_6^{(j)}$, with the sum running over all dimension-six operators $\mathcal{O}_6^{(j)}$ allowed by the lattice symmetries. Some of these operators violate Euclidean invariance, and all of them lead to discretization errors proportional to a^2 . These errors can, however, be reduced by adding corresponding operators to the lattice action and tuning their coefficients to eliminate the dimension-six operators in the effective action to a given order in perturbation theory. This is the idea of the Symanzik improvement program [5]. In the case of the gauge action, one adds loops involving six gauge links (as opposed to the four links needed for the original plaquette action, Eq. (17.1)) to define the $\mathcal{O}(a^2)$ improved (or “Symanzik”) action [6]. In practical implementations, the improvement is either at tree-level (so that residual errors are proportional to $\alpha_s a^2$, where the coupling is evaluated at a scale $\sim 1/a$), or at one loop order (errors proportional to $\alpha_s^2 a^2$). Another popular choice is motivated by studies of renormalization group (RG) flow. It has the same terms as the $\mathcal{O}(a^2)$ improved action but with different coefficients, and is called the RG-improved or “Iwasaki” action [7].

17.1.2. Lattice fermions :

Naive discretization of the continuum fermion action $S_f = \int d^4x \bar{q}[i\partial_\mu \gamma_\mu + m]q$, in which one replaces the derivative $\partial_\mu q$ by a discrete difference $[q(x+a\hat{\mu}) - q(x-a\hat{\mu})]/2a$, leads to the fermion doubling problem—the resulting action describes 2^d equivalent fermion fields in the continuum limit in d dimensions. The appearance of the extra “doubler” fermions is related to the deeper theoretical problem of formulating chirally symmetric fermions on the lattice. This is encapsulated by the Nielsen-Ninomiya theorem [8]: one cannot define lattice fermions having exact, continuum-like chiral symmetry without producing doublers. Naive lattice fermions do have chiral symmetry but at the cost of introducing 15 unwanted doublers (for $d = 4$).

The doubling problem has been addressed in various ways, each coming with different pros and cons. Wilson fermions [1] add a term proportional to $a\bar{q}\Delta q$ to the fermion action (the “Wilson term”—in which Δ is a covariant lattice Laplacian). This gives a mass of $\mathcal{O}(1/a)$ to the doublers, so that they decouple in the continuum limit. The Wilson term, however, violates chiral symmetry, and also introduces discretization errors linear in a . A commonly used variant that eliminates the $\mathcal{O}(a)$ discretization error is the $\mathcal{O}(a)$ -improved Wilson (or “clover”) fermion [9]. In this application of Symanzik improvement, methods have been developed to remove $\mathcal{O}(a)$ terms to all orders in perturbation theory using auxiliary simulations to tune parameters (“non-perturbative improvement”) [10].

The advantages of Wilson fermions are their theoretical simplicity and relatively small computational cost. The disadvantage is their lack of chiral symmetry, which makes them difficult to use in cases where mixing with wrong chirality operators can occur, particularly if this involves divergences proportional to powers of $1/a$. A related problem is potential numerical instabilities due to spurious near-zero modes. Ongoing work has, however, been successful at ameliorating these problems and increasing the range of quantities for which Wilson fermions can be used.

Twisted-mass fermions [11] are a variant of Wilson fermions which remove the numerical instability problem by treating two flavors of fermions together and adding an isospin-breaking mass term (the “twisted mass” term). Another advantage of this approach is that all errors linear in a are automatically removed (without the need for tuning of parameters) by a clever choice of twisted mass and operators.

Staggered fermions are a reduced version of naive fermions in which there is only a single fermion Dirac component on each lattice site, with the full Dirac structure built up from neighboring sites [12]. They have the advantages of being somewhat faster to simulate than Wilson-like fermions, of preserving some chiral symmetry, and of having discretization errors of $\mathcal{O}(a^2)$. Their disadvantage is that they retain some of the doublers (3 for $d = 4$). The action thus describes four degenerate fermions in the continuum limit. The resulting SU(4) flavor symmetry is usually called “taste symmetry”, and the preserved chiral symmetry in this formulation has non-singlet taste. Practical applications usually introduce one staggered fermion for each physical flavor, and remove contributions from the unwanted tastes by taking the fourth-root of the fermion determinant appearing in the path integral. The validity of this “rooting” procedure is not obvious because taste symmetry is violated for non-zero lattice spacing. Theoretical arguments, supported by numerical evidence, suggest that the procedure is valid as long as one takes the continuum limit before approaching the light quark mass region [13].

Just as for Wilson fermions, the staggered action can be improved, so as to reduce discretization errors. The widely used “asqtad” action [14] removes tree-level $\mathcal{O}(a^2)$ errors, and leads to substantial reduction in the breaking of taste symmetry. More recently, a highly improved staggered quark (“HISQ”) action has been introduced [15], which further reduces taste symmetry-breaking and can also be used for heavy quarks such as charm.

There is an important class of lattice fermions that possess a continuum-like chiral symmetry without introducing unwanted doublers. The Dirac operator D for these fermions satisfies the Ginsparg-Wilson relation $D\gamma_5 + \gamma_5 D = aD\gamma_5 D$ [16]. In the continuum, the right-hand-side vanishes due to chiral symmetry. On the lattice, it is non-vanishing, but with a particular form (with two factors of D) that restricts the violations of chiral symmetry in Ward-Takahashi identities to short-distance terms that do not contribute to physical matrix elements. In fact, one can define a modified chiral transformation on the lattice (by including dependence on the gauge fields) such that “Ginsparg-Wilson fermions” have an exact chiral symmetry [17]. The net result is that such fermions essentially have the same properties under chiral transformations as do continuum fermions. Their leading discretization errors are of $\mathcal{O}(a^2)$.

Two types of Ginsparg-Wilson fermions are being used in large-scale projects. The first are Domain-wall fermions (DWF). These are defined on a five-dimensional space, in which the fifth dimension is fictitious [18]. The action is chosen so that the low-lying modes are chiral, with left- and right-handed modes localized on opposite four-dimensional surfaces. For an infinite fifth dimension, these fermions satisfy the Ginsparg-Wilson relation. In practice, the fifth dimension is kept finite, and there remains a small, controllable violation of chiral symmetry. The second type are Overlap fermions. These appeared from a completely different context and have an explicit form that exactly satisfies the Ginsparg-Wilson relation [19]. Their numerical implementation requires an approximation of the matrix sign function of a Wilson-like fermion operator, which is costly, instead of treating five-dimensional fields in the case of DWF.

As noted above, each fermion formulation has its own advantages and disadvantages. For instance, domain-wall and overlap fermions are

theoretically preferred as they have chiral symmetry without doublers, but their computational cost is at least an order of magnitude greater than for other choices. If the physics application of interest does not require near-exact chiral symmetry, there is no strong motivation to use these expensive formulations. On the other hand, there is a class of applications (including the calculation of the $\Delta I = 1/2$ amplitude for $K \rightarrow \pi\pi$ decays and the S-parameter [20]) where chiral symmetry plays an essential role and for which the use of Ginsparg-Wilson fermions is strongly favored.

17.1.3. Heavy quarks on the lattice :

The fermion formulations described in the previous subsection are useful only for quarks whose masses are small compared to the lattice cutoff, $m \lesssim 1/a$. This is because there are discretization errors proportional to powers of am , and if $am \gtrsim 1$ these errors are large and uncontrolled. Present LQCD simulations typically have cutoffs in the range of $1/a = 2 - 4$ GeV (corresponding to $a \approx 0.1 - 0.05$ fm), so that bottom quarks (with $m_b \approx 4.5$ GeV) require alternative discretizations while charm quarks ($m_c \approx 1.5$ GeV) are a borderline case.

For the charm quark, a straightforward approach is to simultaneously reduce the lattice spacing and to improve the fermion action so as to reduce the size of errors proportional to powers of am_c . This approach has, for example, been followed successfully by the HPQCD collaboration using the HISQ action [15]. It is important to note, however, that reducing a increases the computational cost because an increased number of lattice points are needed for the same physical volume. One cannot reduce the spatial size below $2 - 3$ fm without introducing finite volume errors. Present lattices have sizes up to $\sim 64^3 \times 144$ (with the long direction being Euclidean time), and thus allow a lattice cutoff up to $1/a \sim 4$ GeV.

Other choices for the heavy quark action are motivated by effective field theories. For a bottom quark in heavy-light hadrons, one can use Heavy Quark Effective Theory (HQET) to expand about the infinite quark-mass limit, in which the bottom quark is a static color source [21]. Corrections, proportional to powers of $1/m_b$, can be introduced as operator insertions, with coefficients that can be determined non-perturbatively using existing techniques [22].

Another way of introducing the $1/m_b$ corrections is to include the relevant terms in the effective action. This leads to a non-relativistic QCD (NRQCD) action, in which the heavy quark is described by a two-component spinor [23]. This approach has the advantage over HQET that it can also be used for heavy-heavy systems, such as the Upsilon states. A disadvantage is that some of the parameters in this effective theory are determined perturbatively (in practice at tree-level, or in some cases at one-loop), which limits the precision of the final results. Although discretization effects can be controlled within NRQCD, at fine enough lattice spacings the NRQCD effective theory no longer applies since power divergent terms become important, and taking the continuum limit would require fine-tuning a large number of couplings non-perturbatively.

This problem can be avoided if one uses HQET power counting to reduce heavy-quark discretization effects. This can be accomplished by tuning the parameters of an improved Wilson quark action so that the leading HQET corrections to the static quark limit are correctly accounted for. As the lattice spacing becomes finer, the action smoothly goes over to that of a light Wilson quark action, where the continuum limit can be taken as usual. In principle, one can improve the action in the heavy quark regime up to arbitrarily high orders using HQET, but so far large-scale simulations have typically used clover improved Wilson quarks, where tuning the parameters of the action corresponds to including all corrections through next-to-leading order in HQET. Three different methods for tuning the parameters of the clover action are being used: the Fermilab [24], Tsukuba [25] and Columbia [26] approaches. An advantage of this HQET approach is that the c and b quarks can be treated on the same footing. On the other hand, as in NRQCD the tuning of the parameters in the effective action is typically done perturbatively, though a first attempt to tune them non-perturbatively has been made [27].

17.1.4. Basic inputs for lattice calculations :

Since LQCD is a regularization of QCD, the number of input parameters is the same as for continuum QCD—the strong coupling constant $\alpha_s = g^2/(4\pi)$, the quark masses for each flavor, and the CP violating phase θ . The θ parameter is usually assumed to be zero, while the other parameters must be determined using experimental inputs.

17.1.4.1. Lattice spacing: In QCD, the coupling constant is a function of scale. With lattice regularization, this scale is the inverse lattice spacing $1/a$, and choosing the bare coupling constant is equivalent to fixing the lattice spacing.

In principle, a can be determined using any dimensionful quantity measured by experiments. For example, using the mass of hadron H one has $a = (am_H)^{\text{lat}}/m_H^{\text{exp}}$. (Of course, one must first tune the quark masses to their physical values, as discussed below.) In practice, one chooses quantities that can be calculated accurately on the lattice, and that are only weakly dependent on the light quark masses. The latter property minimizes errors from extrapolating to the physical light quark masses or from mistuning of these masses. Two commonly used choices are the spin-averaged 1S-1P or 1S-2S splittings in the Upsilon system, and the mass of the Ω^- baryon. The former has the advantage that it is insensitive to the b -quark mass, but the disadvantage that it requires a discretized heavy quark action.

The determination of a using quantities involving light (up and down) quarks—such as the nucleon mass or the pion decay constant—is more challenging. Most current lattice simulations are done using light quark masses heavier than those in nature. One thus has to extrapolate the lattice data towards the physical quark masses. This “chiral extrapolation” is non-trivial because the quark mass dependence may involve non-analytic terms due to the loops of nearly massless pions, as predicted by Chiral Perturbation Theory (ChPT) [28].

17.1.4.2. Light quark masses: In LQCD simulations, the up, down and strange quarks are usually referred to as the light quarks, in the sense that $m_q < \Lambda_{\text{QCD}}$. (The standard definition of Λ_{QCD} is given in the “Quantum Chromodynamics” review; in this review we are using it only to indicate the approximate non-perturbative scale of QCD.) This condition is stronger than that used above to distinguish quarks with small discretization errors, $m_q < 1/a$. Loop effects from light quarks must be included in the simulations to accurately represent QCD. At present, most simulations are done in the isospin symmetric limit $m_u = m_d \equiv m_\ell$, and are often referred to as “ $N_f = 2 + 1$ ” simulations. Precision is now reaching the point where isospin breaking effects, as well as those of electromagnetism (EM) must be included. This can be done approximately using ChPT and other theoretical input, but ultimately one needs to simulate directly with $m_u \neq m_d$ and including QED corrections. Such work is now beginning.

To tune m_ℓ and m_s to their physical values, the most commonly used quantities are, respectively, m_π and m_K . If the scale is being set by m_Ω , then one adjusts the lattice light quark masses until the ratios m_π/m_Ω and m_K/m_Ω take their physical values. At leading order in ChPT, one has the Gell-Mann-Oakes-Renner relations $m_{\pi_0}^2 \propto (m_u + m_d)$ and $m_{K^0}^2 \propto (m_d + m_s)$, which shows the sensitivity of these quantities to the quark masses. In practice one uses higher order ChPT (or other fit functions) to extrapolate or interpolate the lattice results so as to match the desired ratios, correcting for the (small) effects of isospin breaking and electromagnetic corrections. Most present calculations need to extrapolate to the physical value of m_ℓ , while simulating directly at or near to the physical value of m_s .

17.1.4.3. Heavy quark masses: Heavy quarks (c and b) are usually treated only as valence quarks, with no loop effects included. Generically, the errors introduced by this approximation are $\sim \alpha_s(m_c)\Lambda_{\text{QCD}}^2/m_c^2$ and are small. For high precision, however, dynamical charm quarks may be necessary, and simulations are beginning to include them.

The heavy quark masses can be tuned by setting heavy-heavy or heavy-light meson masses to their experimental values. For the charm quark, for example, one could use the J/ψ or the D_s meson.

Consistency between these two determinations provides an important check on the lattice formulation used for the heavy quark [29].

17.1.5. Sources of systematic error :

Lattice results have statistical and systematic errors that must be quantified for any calculation in order for the result to be a useful input to phenomenology. The statistical error is due to the use of Monte Carlo importance sampling to evaluate the path integral (a method discussed below) and is the most straightforward error to estimate. There are, in addition, a number of systematic errors that are always present to some degree in lattice calculations, although the size of any given error depends on the particular quantity under consideration and the parameters of the lattices being used. The most common lattice errors are reviewed below.

17.1.5.1. Continuum limit: Physical results are obtained in the limit that the lattice spacing a goes to zero. The Symanzik effective theory determines the scaling of lattice errors with a . Most lattice calculations use improved actions with leading discretization errors of $\mathcal{O}(a^2\Lambda^2)$ or $\mathcal{O}(\alpha_s a\Lambda)$, where Λ is a typical momentum scale in the system. Knowledge of the scaling of the leading discretization errors allows controlled extrapolation to $a = 0$ when multiple lattice spacings are available, as in current state-of-the-art calculations. Residual errors arise from the exclusion of subleading a dependence from the fits.

For many quantities the typical momentum scale in the system is $\sim \Lambda_{\text{QCD}} \approx 300$ MeV. Discretization errors are expected to be larger for quantities involving larger scales, for example form factors or decays involving particles with momenta larger than Λ_{QCD} .

17.1.5.2. Infinite volume limit: LQCD calculations are necessarily carried out in finite space-time boxes, leading to departures of physical quantities (masses, decay constants, etc.) from their measured, infinite volume values. These finite-volume shifts are an important systematic that must be estimated and minimized.

Typical lattices are asymmetric, with N_s points in the three spatial directions and N_t in the (Euclidean) temporal direction. The spatial and temporal sizes in physical units are thus $L_s = aN_s$ and $L_t = aN_t$, respectively. (Anisotropic lattice spacings are also sometimes used, as discussed below in Sec. 17.3.1.) Typically, $L_t \geq 2L_s$, so that the dominant impact of using finite volume is from the presence of a finite spatial box.

At present, high-precision LQCD calculations are of quantities involving no more than a single particle in initial and final states. For such quantities, once the volume exceeds about 2 fm (so that the particle is not “squeezed”), the dominant finite-volume effect comes from virtual pions wrapping around the lattice in the spatial directions. This effect is exponentially suppressed as the volume becomes large, roughly as $\sim \exp(-m_\pi L_s)$, and has been estimated using ChPT [30] or other methods [31]. The estimates suggest that finite volume shifts are sub-percent effects when $m_\pi L_s \gtrsim 4$, and most large-scale simulations use lattices satisfying this condition. This becomes challenging as one approaches the physical pion mass, for which $L_s \gtrsim 5$ fm is required. At present, this can only be achieved by using relatively coarse lattices, $a \gtrsim 0.07$ fm.

Finite volume errors are usually determined by repeating the simulations on two or more different volumes (with other parameters fixed). If different volumes are not available, the ChPT estimate can be used, often inflated to account for the fact that the ChPT calculation is truncated at some order.

In the future, LQCD calculations involving more than a single hadron will become increasingly precise. Examples include the calculation of resonance parameters and $K \rightarrow \pi\pi$ amplitudes. Finite volume effects are much larger in these cases, with power-law terms (e.g. $1/L_s^3$) in addition to exponential dependence. Indeed, as will be discussed in Sec. 17.2.4, one can use the volume dependence to indirectly extract infinite-volume quantities such as scattering lengths. Doing so, however, requires a set of lattice volumes satisfying $m_\pi L_s \gtrsim 4$ and is thus more challenging than for single-particle quantities.

17.1.5.3. Chiral extrapolation: An important source of systematic error in most LQCD calculations is the need to extrapolate in m_u and m_d (or, equivalently, in m_π). To do this, one needs a functional form that is, at least approximately, valid for pion masses ranging from the unphysical values used in simulations down to the physical value. A theoretically favored choice is to use the predictions of SU(3) or SU(2) ChPT. This is a valid description of QCD for $m_q \ll \Lambda_{QCD}$ (or $m_\pi \ll m_\rho$), but it is not known *a priori* the extent to which it applies at larger pion masses. This concern is exacerbated in practice since one must truncate the ChPT expressions, typically at one-loop or two-loop order. Experience to date suggests that one-loop expressions are not sufficiently accurate if $m_\pi \gtrsim 400$ MeV [32].

Another choice of fit function is based on the observation that one does not need to extrapolate to the chiral limit, but only to the physical, non-zero, value of m_π , and thus an analytic description might suffice. In practice, of course, one must truncate the analytic form at low order, and a concern is whether the curvature from known non-analytic terms is adequately reproduced.

In either approach, extrapolation errors are estimated by varying the fit function and the number of data points included. We also note that, in many calculations, additional input to the chiral extrapolation is obtained from “partially quenched” results in which the valence and sea-quark masses differ [33].

Very recently, simulations with physical light quark masses (except that $m_u = m_d = (m_u^{\text{phys}} + m_d^{\text{phys}})/2$) have been undertaken [34]. This is a major step forward as it removes the need for chiral extrapolation. As noted above, such simulations require large boxes, and thus very large lattices, and to date the results have been used to compute a limited number of observables. In the future, however, such simulations will play an increasingly important role in the determination of physical quantities.

17.1.5.4. Operator matching: Many of the quantities that LQCD can calculate precisely involve hadronic matrix elements of operators from the electroweak Hamiltonian. Examples include the pion and kaon decay constants, semileptonic form factors and the kaon mixing parameter B_K (the latter defined in Eq. (17.12)). The operators in the lattice matrix elements are defined in the lattice regularization scheme. To be used in tests of the Standard Model, however, they must be matched to the continuum regularization scheme in which the corresponding Wilson coefficients have been calculated. The only case in which such matching is not needed is if the operator is a conserved or partially conserved current. Similar matching is also needed for the conversion of lattice bare quark masses to those in the continuum $\overline{\text{MS}}$ scheme.

Three methods are used to calculate the matching factors: perturbation theory (usually to one- or two-loop order), non-perturbative renormalization (NPR) using Landau-gauge quark and gluon propagators [35], and NPR using gauge-invariant methods based on the Schrödinger functional [36]. The NPR methods replace truncation errors (which can only be approximately estimated) by statistical and systematic errors which can be determined reliably and systematically reduced.

A common issue that arises in many such calculations (e.g. for quark masses and B_K) is that, using NPR, one ends up with operators regularized in a MOM-like (or Schrödinger functional) scheme, rather than the $\overline{\text{MS}}$ scheme mostly used for calculating the Wilson coefficients. To make contact with this scheme requires a purely continuum perturbative matching calculation. The resultant truncation error can, however, be minimized by pushing up the momentum scale at which the matching is done using step-scaling techniques as part of the NPR calculation [37]. It should also be noted that this final step in the conversion to the $\overline{\text{MS}}$ scheme could be avoided if continuum calculations used a MOM-like scheme.

17.2. Methods and status

Once the lattice action is chosen, it is straightforward to define the quantum theory using the path integral formulation. The Euclidean-space partition function is

$$Z = \int [dU] \prod_f [dq_f][d\bar{q}_f] e^{-S_g[U] - \sum_f \bar{q}_f (D[U] + m_f) q_f}, \quad (17.3)$$

where link variables are integrated over the SU(3) manifold, q_f and \bar{q}_f are Grassmann (anticommuting) quark and antiquark fields of flavor f , and $D[U]$ is the chosen lattice Dirac operator with m_f the quark mass in lattice units. Integrating out the quark and antiquark fields, one arrives at a form suitable for simulation:

$$Z = \int [dU] e^{-S_g[U]} \prod_f \det(D[U] + m_f). \quad (17.4)$$

The building blocks for calculations are expectation values of multi-local gauge-invariant operators,

$$\begin{aligned} \langle \mathcal{O}(U, q, \bar{q}) \rangle &= \\ (1/Z) \int [dU] \prod_f [dq_f][d\bar{q}_f] \mathcal{O}(U, q, \bar{q}) e^{-S_g[U] - \sum_f \bar{q}_f (D[U] + m_f) q_f}. \end{aligned} \quad (17.5)$$

If the operators depend on the (anti-)quark fields q_f and \bar{q}_f , then integrating these fields out leads not only to the fermion determinant but also, through Wick’s theorem, a series of quark “propagators”, $(D[U] + m_f)^{-1}$, connecting the positions of the fields.

17.2.1. Monte-Carlo method:

Since the number of integration variables U is huge ($N_s^3 \times N_t \times 4 \times 9$), direct numerical integration is impractical and one has to use Monte-Carlo techniques. In this method, one generates a Markov chain of gauge configurations (a “configuration” being the set of U ’s on all links) distributed according to the probability measure $[dU] e^{-S_g[U]} \prod_f \det(D[U] + m_f)$. Once the configurations are generated, expectation values $\langle \mathcal{O}(U, q, \bar{q}) \rangle$ are calculated by averaging over those configurations. In this way the configurations can be used repeatedly for many different calculations, and there are several large collections of ensembles of configurations (with a range of values of a , lattice sizes and quark masses) that are generally available. As the number of the configurations, N , is increased, the error decreases as $1/\sqrt{N}$, as long as the configurations are statistically independent.

The most challenging part of the generation of gauge configurations is the need to include the fermion determinant. Direct evaluation of the determinant is not feasible, as it requires $\mathcal{O}((N_s^3 \times N_t)^3)$ computations. Instead, one rewrites it in terms of “pseudofermion” fields ϕ (auxiliary fermion fields with bosonic statistics). For example, for two degenerate quarks one has

$$\det(D[U] + m_f)^2 = \int [d\phi] e^{-\phi^\dagger (D[U] + m_f)^{-2} \phi}. \quad (17.6)$$

By treating the pseudofermions as additional integration variables in the path integral, one obtains a totally bosonic representation. The price one pays is that the pseudofermion effective action is highly non-local since it includes the inverse Dirac operator $(D[U] + m_f)^{-1}$. Thus, the large sparse matrix $(D[U] + m)$ has to be inverted every time one needs an evaluation of the effective action.

Present simulations generate gauge configurations using the Hybrid Monte Carlo (HMC) algorithm [38], or variants thereof. This algorithm combines molecular dynamics (MD) evolution in a fictitious time (which is also discretized) with a Metropolis “accept-reject” step. It makes a global update of the configuration, and is made exact by the Metropolis step. In its original form it can be used only for two degenerate flavors, but extensions (particularly the rational HMC [39]) are available for single flavors. Considerable speed-up of the algorithms has been achieved over the last two decades using a variety of techniques.

All these algorithms spend the bulk of their computational time on the repeated inversion of $(D[U] + m)$ acting on a source (which

is required at every step of the MD evolution). Inversions are done using iterative algorithms such as the conjugate gradient algorithm and its generalizations. In this class of algorithms, computational cost is proportional to the condition number of the matrix, which is the ratio of maximum and minimum eigenvalues. For $(D[U] + m)$ the smallest eigenvalue is $\approx m$, so the condition number and cost are inversely proportional to the quark mass. This is a major reason why simulations at the physical quark mass are challenging. Recent algorithmic improvements, however, promise to significantly reduce or remove this problem.

A practical concern is the inevitable presence of correlations between configurations in the Markov chain. These are characterized by an autocorrelation length in the fictitious MD time. One aims to use configurations separated in MD time by greater than this autocorrelation length. In practice, it is difficult to measure this length accurately, and this leads to some uncertainty in the resulting statistical errors.

For most of the applications of LQCD discussed in this review, the cost of generating gauge configurations is larger than that of performing the “measurements” on those configurations. The computational cost of the HMC and related algorithms grows with the lattice volume, $V_{\text{lat}} = N_s^3 N_t$, as $V_{\text{lat}}^{5/4}$ [40]. This provides a (time-dependent) limit on the largest lattice volumes that can be simulated. At present, the largest lattices being used have $N_s = 64$ and $N_t = 144$. Typically one aims to create an ensemble of $\sim 10^3$ statistically independent configurations at each choice of parameters (a , m_q and V_{lat}). For most physical quantities of interest, this is sufficient to make the resulting statistical errors smaller than or comparable to the systematic errors.

17.2.2. Two-point functions :

One can extract properties of stable hadrons using two-point correlation functions, $\langle O_X(x)O_Y^\dagger(0) \rangle$. Here $O_{X,Y}(x)$ are operators that have non-zero overlaps with the hadronic state of interest $|H\rangle$, *i.e.* $\langle 0|O_{X,Y}(x)|H\rangle \neq 0$. One usually Fourier-transforms in the spatial directions and considers correlators as a function of Euclidean time:

$$C_{XY}(t; \vec{p}) = \sum_{\vec{x}} \langle O_X(t, \vec{x})O_Y^\dagger(0) \rangle e^{-i\vec{p}\cdot\vec{x}}. \quad (17.7)$$

(Here and throughout this section all quantities are expressed in dimensionless lattice units, so that, for example, $\vec{p} = a\vec{p}_{\text{phys}}$.) By inserting a complete set of states having spatial momentum \vec{p} , the two-point function can be written as

$$C_{XY}(t; \vec{p}) = \sum_{i=0}^{\infty} \frac{1}{2E_i(\vec{p})} \langle 0|O_X(0)|H_i(\vec{p}) \rangle \langle H_i(\vec{p})|O_Y^\dagger(0)|0 \rangle e^{-E_i(\vec{p})t}, \quad (17.8)$$

where the energy of the i -th state $E_i(\vec{p})$ appears as an eigenvalue of the time evolution operator e^{-Ht} in the Euclidean time direction. The factor of $1/[2E_i(\vec{p})]$ is due to the relativistic normalization used for the states. For large enough t , the dominant contribution is that of the lowest energy state $|H_0(\vec{p})\rangle$:

$$C_{XY}(t) \xrightarrow{t \rightarrow \infty} \frac{1}{2E_0(\vec{p})} \langle 0|O_X(0)|H_0(\vec{p}) \rangle \langle H_0(\vec{p})|O_Y^\dagger(0)|0 \rangle e^{-E_0(\vec{p})t}. \quad (17.9)$$

One can thus obtain the energy $E_0(\vec{p})$, which equals the hadron mass m_H when $\vec{p} = 0$, and the product of matrix elements $\langle 0|O_X(0)|H_i(\vec{p}) \rangle \langle H_i(\vec{p})|O_Y^\dagger(0)|0 \rangle$.

This method can be used to determine the masses of all the stable mesons and baryons by making appropriate choices of operators. For example, if one uses the axial current, $O_X = O_Y = A_\mu = \bar{d}\gamma_\mu\gamma_5 u$, then one can determine m_{π^+} from the rate of exponential fall-off, and in addition the decay constant f_π from the coefficient of the exponential. A complication arises for states with high spins ($j \geq 4$ for bosons) because the spatial rotation group on the lattice is a discrete subgroup of the continuum group $\text{SO}(3)$. This implies that lattice operators, even when chosen to lie in irreducible representations of the lattice rotation group, have overlap with states that have a number of values of j in the continuum limit [41]. For example $j = 0$ operators can

also create mesons with $j = 4$. A method to overcome this problem has recently been introduced [42].

The expression given above for the correlator $C_{XY}(t; \vec{p})$ shows how, in principle, one can determine the energies of the excited hadron states having the same quantum numbers as the operators $O_{X,Y}$, by fitting the correlation function to a sum of exponentials. In practice, this usually requires using a large basis of operators and adopting the variational approach such as that of Ref. [43]. One can also use an anisotropic lattice in which a_t , the lattice spacing in the time direction, is smaller than its spatial counterpart a_s . This allows better separation of the different exponentials. Using a combination of these and other technical improvements extensive excited-state spectra have recently been obtained [42,44].

17.2.3. Three-point functions :

Weak matrix elements needed to calculate semileptonic form factors and neutral meson mixing amplitudes can be computed from three-point correlation functions. We discuss here, as a representative example, the $D \rightarrow K$ amplitude. As in the case of two-point correlation functions one constructs operators O_D and O_K having overlap, respectively, with the D and K mesons. We are interested in calculating the matrix element $\langle K|V_\mu|D \rangle$, with $V_\mu = \bar{c}\gamma_\mu s$ the vector current. To obtain this, we use the three-point correlator

$$C_{KV_\mu D}(t_x, t_y; \vec{p}) = \sum_{\vec{x}, \vec{y}} \langle O_K(t_x, \vec{x})V_\mu(0)O_D^\dagger(t_y, \vec{y}) \rangle e^{-i\vec{p}\cdot\vec{x}}, \quad (17.10)$$

and focus on the limit $t_x \rightarrow \infty$, $t_y \rightarrow -\infty$. In this example we set the D -meson at rest while the kaon carries three-momentum \vec{p} . Momentum conservation then implies that the weak operator V_μ inserts three-momentum $-\vec{p}$. Inserting a pair of complete sets of states between each pair of operators, we find

$$C_{KV_\mu D}(t_x, t_y; \vec{p}) = \sum_{i,j} \frac{1}{2m_{D_i} 2E_{K_j}(\vec{p})} e^{-m_{D_i}t_x - E_{K_j}(\vec{p})|t_y|} \times \\ \times \langle 0|O_K(t_x, \vec{x})|K_i(\vec{p}) \rangle \langle K_i(\vec{p})|V_\mu(0)|D_j(\vec{0}) \rangle \langle D_j(\vec{0})|O_D^\dagger(0)|0 \rangle. \quad (17.11)$$

The matrix element $\langle K_i(\vec{p})|V_\mu(0)|D_j(\vec{0}) \rangle$ can then be extracted, since all other quantities in this expression can be obtained from two-point correlation functions. Typically one is interested in the weak matrix elements of ground states, such as the lightest pseudoscalar mesons. In the limit of large separation between the three operators in Euclidean time, the three-point correlation function yields the weak matrix element of the transition between ground states.

17.2.4. Scattering amplitudes and resonances :

The methods described thus far yield matrix elements involving single, stable particles (where by stable here we mean absolutely stable to strong interaction decays). Most of the particles listed in the Review of Particle Properties are, however, unstable—they are resonances decaying into final states consisting of multiple strongly interacting particles. LQCD simulations cannot directly calculate resonance properties, but methods have been developed to do so indirectly for resonances coupled to two-particle final states in the elastic regime [45].

The difficulty faced by LQCD calculations is that, to obtain resonance properties, or, more generally, scattering phase-shifts, one must calculate multiparticle scattering amplitudes in momentum space and put the external particles on their mass-shells. This requires analytically continuing from Euclidean to Minkowski momenta. Although it is straightforward in LQCD to generalize the methods described above to calculate four- and higher-point correlation functions, one necessarily obtains them at a discrete and finite set of Euclidean momenta. Analytic continuation to $p_E^2 = -m^2$ is then an ill-posed and numerically unstable problem. The same problem arises for single-particle states, but can be overcome by picking out the exponential fall-off of the Euclidean correlator, as described above. With a multi-particle state, however, there is no corresponding trick, except for two particles at threshold [46].

What LQCD can calculate are the energies of the eigenstates of the QCD Hamiltonian in a finite box. The energies of states containing two stable particles, e.g. two pions, clearly depend on the interactions between the particles. It is possible to invert this dependence and, with plausible assumptions, determine the scattering phase-shifts at a discrete set of momenta from a calculation of the two-particle energy levels for a variety of spatial volumes [45]. This is a challenging calculation, but it has recently been carried through for pions with $m_\pi \sim 300 - 400$ MeV for the $I = 2$ $\pi\pi$ system (where there is no resonance) [47] and for the $I = 1$ system, where the parameters of the ρ resonance can be determined from the phase shifts (ignoring the small inelasticity) [48,49]. Extensions to nucleon interactions are also being actively studied [50].

It is also possible to extend the methodology to calculate electroweak decay amplitudes to two particles below the inelastic threshold, e.g. $\Gamma(K \rightarrow \pi\pi)$ [51]. First results using this methodology are now appearing. An extension to decays above the elastic threshold, e.g. hadronic B decays, has yet to be formulated.

17.2.5. Status of LQCD simulations :

Until the 1990s, most large-scale lattice simulations were limited to the “quenched” approximation, wherein the fermion determinant is omitted from the path integral. While much of the basic methodology was developed in this era, the results obtained had uncontrolled systematic errors and were not suitable for use in placing precision constraints on the Standard Model. During the 1990s, more extensive simulations including the fermion determinant (also known as simulations with “dynamical” fermions) were begun, but with unphysically high quark masses ($m_\ell \sim 50 - 100$ MeV), such that the extrapolation to the physical light quark masses was a source of large systematic errors [52]. In the last 5-10 years, advances in both algorithms and computers have allowed simulations to reach much smaller quark masses ($m_\ell \sim 10 - 20$ MeV) and even, as noted above, to work at the physical light quark mass [34]. The net effect is that LQCD calculations of selected quantities now have all sources of error controlled and small, such that they can be used effectively in phenomenological analyses.

On a more qualitative level, analytic and numerical results from LQCD have demonstrated that QCD confines color and spontaneously breaks chiral symmetry. Confinement can be seen as a linearly rising potential between heavy quark and anti-quark in the absence of quark loops. Analytically, this can be shown in the strong coupling limit $g_{\text{lat}} \rightarrow \infty$ [1]. At weaker couplings there are precise numerical calculations of the potential that clearly show that this behavior persists in the continuum limit [2,3,4].

Chiral symmetry breaking was also demonstrated in the strong coupling limit on the lattice [12,53], and there have been a number of numerical studies showing that this holds also in the continuum limit. The accumulation of low-lying modes of the Dirac operator, which is the analog of Cooper pair condensation in superconductors, has been observed, yielding a determination of the chiral condensate [54]. Many relations among physical quantities that can be derived under the assumption of broken chiral symmetry have been confirmed by a number of lattice groups.

17.3. Physics applications

In this section we describe the main applications of LQCD that are both computationally mature and relevant for the determination of particle properties.

A general feature to keep in mind is that, since there are many different choices for lattice actions, all of which lead to the same continuum theory, a crucial test is that results for any given quantity are consistent. In many cases, different lattice calculations are completely independent and often have very different systematic errors. Thus final agreement, if found, is a highly non-trivial check, just as it is for different experimental measurements.

Figure 17.1: Results for f_K/f_π from simulations with $N_f = 2 + 1$. These are from the HPQCD/UKQCD [29], ALV [58], BMW [60], RBC/UKQCD [61] and MILC [62] collaborations. The resulting average is 1.1931 ± 0.0053 .

17.3.1. Spectrum :

The most basic prediction of LQCD is of the hadron spectrum. Once the input parameters are fixed as described in Sec. 17.1.4, the masses or resonance parameters of all other states can be predicted. This includes hadrons composed of light (u , d and s) quarks, as well as heavy-light and heavy-heavy hadrons. It also includes quark-model exotics (e.g. $J^{PC} = 1^{-+}$ mesons) and glueballs. Thus, in principle, LQCD calculations should be able to reproduce many of the experimental results compiled in the Review of Particle Properties. Doing so would test both that the error budgets of LQCD calculations are accurate and that QCD indeed describes the strong interactions in the low-energy domain. The importance of the latter test can hardly be overstated.

What is the status of this fundamental test? As discussed in Sec. 17.2, LQCD calculations are most straightforward for stable, low-lying hadrons. Resonances which can decay into only two particles are more challenging, though ultimately tractable, while those with decays to more than two particles are not yet accessible. It is also more challenging to calculate masses of flavor singlet states (which can annihilate into purely gluonic intermediate states) than those of flavor non-singlets. The present status for light hadrons is that fully controlled results are available for the masses of the octet light baryons, while results with less than complete control are available for the decuplet baryon resonances, the vector meson resonances and the η and η' . There are more extensive results for heavy-light (D and B systems) and heavy-heavy (J/ψ and Υ systems). All present results, which are discussed in the “Quark Model” review, are consistent with experimental values.

17.3.2. Decay constants and bag parameters :

The pseudoscalar decay constants can be determined from two point correlation functions involving the axial-vector current, as discussed in Sec. 17.2.2. The decay constant f_P of a meson P is extracted from the weak matrix element involving the axial-vector current using the relation $\langle 0 | A_\mu(x) | P(\vec{p}) \rangle = f_P p_\mu \exp(-ip \cdot x)$, where p_μ is the momentum of P and $A_\mu(x)$ is the axial-vector current. For the pion and kaon decay constants, this calculation is by now straightforward. The ratio f_K/f_π is especially important for the extraction of $|V_{us}|/|V_{ud}|$ from experiment, and many of the systematic errors in the lattice calculation cancel or are significantly reduced when forming the ratio. A number of lattice groups have calculated this ratio with precision at the percent level or better; all the results are in good agreement, with sub-percent precision in the world average [55,56]. A recent summary from Ref. [57] is shown in Fig. 17.1.

The heavy-light decay constants f_D and f_{D_s} involve a charm valence quark, which requires special treatment because of the relatively large charm quark mass. The different approaches in use have been discussed in Sec. 17.1.3. The HISQ action allows the charm quark to be treated in the same way as the light quarks, and has enabled HPQCD to quote precise values for the charm decay constants [29]. Calculations using less improved quark actions give consistent results, but with larger errors [59,63].

The bottom meson decay constants f_B and f_{B_s} require a valence b quark. Lattice calculations of these quantities are available using the Fermilab formulation or NRQCD to treat the bottom quark (from Refs. [64] and [65], respectively), or using an interpolation between results from around m_c to infinite quark mass [66].

The kaon bag parameter B_K is needed to turn the precise measurement of CP-violation in kaon mixing into a constraint on the Standard Model. It is defined by

$$\frac{8}{3}m_K^2 f_K^2 B_K(\mu) = \langle \bar{K}^0 | Q_{\Delta S=2}(\mu) | K^0 \rangle, \quad (17.12)$$

where m_K is the kaon mass, f_K is the kaon decay constant, $Q_{\Delta S=2} = \bar{s}\gamma_\mu(1-\gamma_5)d\bar{s}\gamma_\mu(1-\gamma_5)d$ is the four-quark operator of the effective electroweak Hamiltonian and μ is the renormalization scale. The short distance contribution to the electroweak Hamiltonian can be calculated perturbatively, but the long-distance matrix element parameterized by B_K must be computed using non-perturbative methods. In order to be of use to phenomenology, the renormalization factor of the four-quark operator must be matched to a continuum renormalization scheme, e.g. to \overline{MS} , as described in Sec. 17.1.5.4. Determinations with percent-level precision using different fermion actions are now available with DWF [67], staggered fermions [68], DWF valence on staggered sea quarks [69], twisted mass fermions [70] and Wilson fermions [71]. The results are all consistent.

The bag parameters for B and B_s meson mixing are defined analogously to that of kaon mixing. The B and B_s mesons contain a valence b -quark so that calculations of these quantities must use one of the methods for heavy quarks described above. These quantities have been calculated by HPQCD using NRQCD for the b -quark [65]. The ratio $\xi = f_{B_s}\sqrt{B_{B_s}}/(f_B\sqrt{B_B})$ is especially useful in CKM studies because many of the lattice systematic uncertainties cancel in the ratio, including most of the operator matching needed to convert to a continuum scheme. The dominant error in the ratio is the error associated with the chiral extrapolation of the light quark masses. The ratio ξ has been calculated in unquenched LQCD using different treatments for the b -quark [65,72], with results that are consistent.

The results discussed in this section are used in the reviews “The CKM Quark-Mixing Matrix,” “ V_{ud}, V_{us} , the Cabibbo Angle and CKM Unitarity,” and “ $B_0 - \bar{B}_0$ Mixing.”

17.3.3. Form factors ($K \rightarrow \pi\ell\nu$, $D \rightarrow K\ell\nu$, $B \rightarrow \pi\ell\nu$, $B \rightarrow D^{(*)}\ell\nu$):

Semileptonic decay rates can be used to extract CKM matrix elements once the semileptonic form factors are known from lattice calculations. For example, the matrix element of a pseudoscalar meson P undergoing semileptonic decay to another pseudoscalar meson D is mediated by the vector current, and can be written in terms of form factors as

$$\langle D(p_D) | V_\mu | P(p_P) \rangle = f_+(q^2)(p_D + p_P - \Delta)_\mu + f_0(q^2)\Delta_\mu, \quad (17.13)$$

where $q = p_D - p_P$, $\Delta_\mu = (m_D^2 - m_P^2)q_\mu/q^2$ and V_μ is the quark vector current. The shape of the form factor is typically well determined by experiment, and the value of $f_+(q^2)$ at some reference value of q^2 is needed from the lattice in order to extract CKM matrix elements. Typically $f_+(q^2)$ dominates the decay rate, since the contribution from $f_0(q^2)$ is suppressed when the final state lepton is light.

The form factor $f_+(0)$ for $K \rightarrow \pi\ell\nu$ decays is highly constrained by the Ademollo-Gatto theorem [73] and chiral symmetry. Old estimates using chiral perturbation theory combined with quark models quote sub-percent precision [74], though they suffer from some model dependence. The lattice has now matched this precision while also

eliminating the model dependence; good agreement with the old estimate is found [75,76].

Charm meson semileptonic decays have been calculated by different groups using methods similar to those used for charm decay constants, and results are steadily improving in precision [77,78,79]. For semileptonic decays involving a bottom quark, one uses HQET or NRQCD to control the discretization errors of the bottom quark. The form factors for the semileptonic decay $B \rightarrow \pi\ell\nu$ have been calculated in unquenched lattice QCD by two groups: HPQCD [80] and the Fermilab/MILC Collaborations [81]. These B semileptonic form factors are difficult to calculate at low q^2 , i.e. when the momentum transfer to the leptons is small and the pion carries significant momentum. The low q^2 region has large discretization errors and very large statistical errors, while the high q^2 region is much more accessible to the lattice. For experiment, the opposite is true. To combine lattice and experimental results it has proved helpful to use the z -parameter expansion [82]. This provides a theoretically constrained parameterization of the entire q^2 range, and allows one to obtain $|V_{ub}|$ with minimal model dependence [83,81].

The semileptonic decays $B \rightarrow D\ell\nu$ and $B \rightarrow D^*\ell\nu$ can be used to extract $|V_{cb}|$ once the corresponding form factors are known. At present only one unquenched calculation exists for the $B \rightarrow D^*\ell\nu$ form factor, where the Fermilab formulation of the heavy quark was adopted [84]. This calculation is done at zero-recoil because that is where the lattice systematic errors are smallest. Calculations of the necessary form factors for both processes at non-zero recoil have been done in the quenched approximation [85]. Using a step-scaling approach for the heavy quarks. Lattice calculations at non-zero recoil are needed in order to decrease the error associated with the extrapolation of the experimental data to the zero-recoil point.

The results discussed in this section are used in the reviews “The CKM Quark-Mixing Matrix,” “ V_{ud}, V_{us} , the Cabibbo Angle and CKM Unitarity,” and “ V_{cb} and V_{ub} CKM Matrix Elements.”

17.3.4. Strong coupling constant:

As explained in Sec. 17.1.4.1, for a given lattice action, the choice of bare lattice coupling constant, g_{lat} , determines the lattice spacing a . If one then calculates a as described in Sec. 17.1.4.1, one knows the strong coupling constant in the bare lattice scheme at the scale $1/a$, $\alpha_{\text{lat}} = g_{\text{lat}}^2/(4\pi)$. This is not, however, useful for comparing to results for α_s obtained from experiment. This is because the latter results give α_s in the \overline{MS} scheme, and the conversion factor between these two schemes is known to converge extremely poorly in perturbation theory. Instead one must use a method which directly determines α_s in a scheme closer to \overline{MS} .

Several such methods have been used, all following a similar strategy. One calculates a short-distance quantity K both perturbatively (K^{PT}) and non-perturbatively (K^{NP}) on the lattice, and requires equality: $K^{\text{NP}} = K^{\text{PT}} = \sum_{i=0}^n c_i \alpha_s^i$. Solving this equation one obtains α_s at a scale related to the quantity being used. Often, α_s thus obtained is not defined in the conventional \overline{MS} scheme, and one has to convert among the different schemes using perturbation theory. Unlike for the bare lattice scheme, the required conversion factors are reasonably convergent. As a final step, one uses the renormalization group to run the resulting coupling to a canonical scale (such as M_Z).

In the work of the HPQCD collaboration [86], the short-distance quantities are Wilson loops of several sizes and their ratios, which are perturbatively calculated to $\mathcal{O}(\alpha_s^3)$ using the V -scheme defined through the heavy quark potential. The coefficients of even higher orders are estimated with the lattice data at various values of a .

Another choice of short-distance quantities are current-current correlators. Appropriate moments of these correlators are ultraviolet finite, and by matching lattice results to the *continuum* perturbative predictions, one can directly extract the \overline{MS} coupling. The JLQCD collaboration [87] uses this approach with light overlap fermions, while the HPQCD collaboration uses charm-quark correlators and HISQ fermions [88].

With a definition of α_s given using the Schrödinger functional, one can non-perturbatively control the evolution of α_s to high-energy scales, such as 100 GeV, where the perturbative expansion converges

very well. This method developed by the ALPHA collaboration [37] has been applied to 2+1-flavor QCD by the PACS-CS collaboration [89].

Results are summarized in the review of “Quantum Chromodynamics”.

17.3.5. Quark masses :

Once the quark mass parameters are tuned in the lattice action, the remaining task is to convert them to those of the conventional definition. Since the quarks do not appear as asymptotic states due to confinement, the pole mass of the quark propagator is not a physical quantity. Instead, one defines the quark mass after subtracting the ultra-violet divergences in some particular way. The conventional choice is again the $\overline{\text{MS}}$ scheme at a canonical scale such as 2 or 3 GeV.

As discussed in Sec. 17.1.5.4, one must convert the lattice bare quark mass to that in the $\overline{\text{MS}}$ scheme. The most common approaches used for doing so are perturbation theory and the NPR method, the latter using an RI/MOM intermediate scheme.

Alternatively, one can use a definition based on the Schrödinger functional, which allows one to evolve the quark mass to a high scale non-perturbatively [90]. In practice, one can reach scales as high as ~ 100 GeV, at which matching to the $\overline{\text{MS}}$ scheme can be reliably calculated in perturbation theory.

Another approach available for heavy quarks is to match current-current correlators at short distances calculated on the lattice to those obtained in continuum perturbation theory in the $\overline{\text{MS}}$ scheme. This has allowed an accurate determination of $m_c(\overline{\text{MS}})$ [91].

Results are summarized in the review of “Quark Masses”.

17.3.6. Other applications :

In this review we have concentrated on applications of LQCD that are relevant to the quantities discussed in the Review of Particle Properties. We have not discussed at all several other applications which are being actively pursued by simulations. Here we list the major such applications. The reader can consult the texts [2,3,4] for further details.

LQCD can be used, in principle, to simulate QCD at non-zero temperature and density, and in particular to study how confinement and chiral-symmetry breaking are lost as T and μ (the chemical potential) are increased. This is of relevance to heavy-ion collisions, the early Universe and neutron-star structure. In practice, finite temperature simulations are computationally tractable and relatively mature, while simulations at finite μ suffer from a “sign problem” and are at a rudimentary stage.

Another topic under active investigation is nucleon structure (generalized structure functions) and inter-nucleon interactions.

Finally, we note that there is much recent interest in studying QCD-like theories with more fermions, possibly in other representations of the gauge group. The main interest is to find nearly conformal theories which might be candidates for “walking technicolor” models.

17.4. Outlook

While LQCD calculations have made major strides in the last decade, and are now playing an important role in constraining the Standard Model, there are many calculations that could be done in principle but are not yet mature due to limitations in computational resources. As we move to exascale resources (e.g. 10^{18} floating point operations per second), the list of mature calculations will grow. Examples that we expect to mature in the next few years are results for excited hadrons, including quark-model exotics; $\langle N|\bar{s}s|N\rangle$ and related matrix elements (needed for dark-matter searches); results for moments of structure functions; $K \rightarrow \pi\pi$ amplitudes (allowing a prediction of ϵ'/ϵ from the Standard Model); $\bar{K} \leftrightarrow K$ and $\bar{B} \leftrightarrow B$ mixing amplitudes from operators arising in models of new physics (allowing one to constrain these models in a manner complementary to the direct searches at the LHC); hadronic vacuum polarization contributions to muon $g-2$, the running of α_{EM} and α_s ; $\pi \rightarrow \gamma\gamma$ and related amplitudes; and perhaps the long-distance contribution to $\bar{K} \leftrightarrow K$ mixing and the light-by-light contribution to muon $g-2$. There will also be steady improvement in the precision attained

for the mature quantities discussed above. As already noted, this will ultimately require simulations with $m_u \neq m_d$ and including electromagnetic effects.

18. STRUCTURE FUNCTIONS

Updated July 2011 by B. Foster (University of Hamburg/DESY), A.D. Martin (University of Durham), and M.G. Vincter (Carleton University).

18.1. Deep inelastic scattering

High-energy lepton-nucleon scattering (deep inelastic scattering) plays a key role in determining the partonic structure of the proton. The process $\ell N \rightarrow \ell' X$ is illustrated in Fig. 18.1. The filled circle in this figure represents the internal structure of the proton which can be expressed in terms of structure functions.

Figure 18.1: Kinematic quantities for the description of deep inelastic scattering. The quantities k and k' are the four-momenta of the incoming and outgoing leptons, P is the four-momentum of a nucleon with mass M , and W is the mass of the recoiling system X . The exchanged particle is a γ , W^\pm , or Z ; it transfers four-momentum $q = k - k'$ to the nucleon.

Invariant quantities:

$\nu = \frac{q \cdot P}{M} = E - E'$ is the lepton's energy loss in the nucleon rest frame (in earlier literature sometimes $\nu = q \cdot P$). Here, E and E' are the initial and final lepton energies in the nucleon rest frame.

$Q^2 = -q^2 = 2(E E' - \vec{k} \cdot \vec{k}') - m_\ell^2 - m_{\ell'}^2$ where $m_\ell(m_{\ell'})$ is the initial (final) lepton mass. If $E E' \sin^2(\theta/2) \gg m_\ell^2, m_{\ell'}^2$, then $\approx 4E E' \sin^2(\theta/2)$, where θ is the lepton's scattering angle with respect to the lepton beam direction.

$x = \frac{Q^2}{2M\nu}$ where, in the parton model, x is the fraction of the nucleon's momentum carried by the struck quark.

$y = \frac{q \cdot P}{k \cdot P} = \frac{\nu}{E}$ is the fraction of the lepton's energy lost in the nucleon rest frame.

$W^2 = (P + q)^2 = M^2 + 2M\nu - Q^2$ is the mass squared of the system X recoiling against the scattered lepton.

$s = (k + P)^2 = \frac{Q^2}{xy} + M^2 + m_\ell^2$ is the center-of-mass energy squared of the lepton-nucleon system.

The process in Fig. 18.1 is called deep ($Q^2 \gg M^2$) inelastic ($W^2 \gg M^2$) scattering (DIS). In what follows, the masses of the initial and scattered leptons, m_ℓ and $m_{\ell'}$, are neglected.

18.1.1. DIS cross sections :

$$\frac{d^2\sigma}{dx dy} = x(s - M^2) \frac{d^2\sigma}{dx dQ^2} = \frac{2\pi M\nu}{E'} \frac{d^2\sigma}{d\Omega_{N\text{rest}} dE'} . \quad (18.1)$$

In lowest-order perturbation theory, the cross section for the scattering of polarized leptons on polarized nucleons can be expressed in terms of the products of leptonic and hadronic tensors associated with the coupling of the exchanged bosons at the upper and lower vertices in Fig. 18.1 (see Refs. 1–4)

$$\frac{d^2\sigma}{dx dy} = \frac{2\pi y \alpha^2}{Q^4} \sum_j \eta_j L_j^{\mu\nu} W_{\mu\nu}^j . \quad (18.2)$$

For neutral-current processes, the summation is over $j = \gamma, Z$ and γZ representing photon and Z exchange and the interference between

them, whereas for charged-current interactions there is only W exchange, $j = W$. (For transverse nucleon polarization, there is a dependence on the azimuthal angle of the scattered lepton.) $L_{\mu\nu}$ is the lepton tensor associated with the coupling of the exchange boson to the leptons. For incoming leptons of charge $e = \pm 1$ and helicity $\lambda = \pm 1$,

$$\begin{aligned} L_{\mu\nu}^\gamma &= 2 \left(k_\mu k'_\nu + k'_\mu k_\nu - k \cdot k' g_{\mu\nu} - i\lambda \varepsilon_{\mu\nu\alpha\beta} k^\alpha k'^\beta \right), \\ L_{\mu\nu}^{\gamma Z} &= (g_V^e + e\lambda g_A^e) L_{\mu\nu}^\gamma, \quad L_{\mu\nu}^Z = (g_V^e + e\lambda g_A^e)^2 L_{\mu\nu}^\gamma, \\ L_{\mu\nu}^W &= (1 + e\lambda)^2 L_{\mu\nu}^\gamma, \end{aligned} \quad (18.3)$$

where $g_V^e = -\frac{1}{2} + 2\sin^2\theta_W$, $g_A^e = -\frac{1}{2}$.

Although here the helicity formalism is adopted, an alternative approach is to express the tensors in Eq. (18.3) in terms of the polarization of the lepton.

The factors η_j in Eq. (18.2) denote the ratios of the corresponding propagators and couplings to the photon propagator and coupling squared

$$\begin{aligned} \eta_\gamma &= 1 \quad ; \quad \eta_{\gamma Z} = \left(\frac{G_F M_Z^2}{2\sqrt{2}\pi\alpha} \right) \left(\frac{Q^2}{Q^2 + M_Z^2} \right); \\ \eta_Z &= \eta_{\gamma Z}^2 \quad ; \quad \eta_W = \frac{1}{2} \left(\frac{G_F M_W^2}{4\pi\alpha} \frac{Q^2}{Q^2 + M_W^2} \right)^2 . \end{aligned} \quad (18.4)$$

The hadronic tensor, which describes the interaction of the appropriate electroweak currents with the target nucleon, is given by

$$W_{\mu\nu} = \frac{1}{4\pi} \int d^4z e^{iq \cdot z} \langle P, S | [J_\mu^\dagger(z), J_\nu(0)] | P, S \rangle, \quad (18.5)$$

where S denotes the nucleon-spin 4-vector, with $S^2 = -M^2$ and $S \cdot P = 0$.

18.2. Structure functions of the proton

The structure functions are defined in terms of the hadronic tensor (see Refs. 1–3)

$$\begin{aligned} W_{\mu\nu} &= \left(-g_{\mu\nu} + \frac{q_\mu q_\nu}{q^2} \right) F_1(x, Q^2) + \frac{\hat{P}_\mu \hat{P}_\nu}{P \cdot q} F_2(x, Q^2) \\ &\quad - i\varepsilon_{\mu\nu\alpha\beta} \frac{q^\alpha P^\beta}{2P \cdot q} F_3(x, Q^2) \\ &\quad + i\varepsilon_{\mu\nu\alpha\beta} \frac{q^\alpha}{P \cdot q} \left[S^\beta g_1(x, Q^2) + \left(S^\beta - \frac{S \cdot q}{P \cdot q} P^\beta \right) g_2(x, Q^2) \right] \\ &\quad + \frac{1}{P \cdot q} \left[\frac{1}{2} (\hat{P}_\mu \hat{S}_\nu + \hat{S}_\mu \hat{P}_\nu) - \frac{S \cdot q}{P \cdot q} \hat{P}_\mu \hat{P}_\nu \right] g_3(x, Q^2) \\ &\quad + \frac{S \cdot q}{P \cdot q} \left[\frac{\hat{P}_\mu \hat{P}_\nu}{P \cdot q} g_4(x, Q^2) + \left(-g_{\mu\nu} + \frac{q_\mu q_\nu}{q^2} \right) g_5(x, Q^2) \right] \end{aligned} \quad (18.6)$$

where

$$\hat{P}_\mu = P_\mu - \frac{P \cdot q}{q^2} q_\mu, \quad \hat{S}_\mu = S_\mu - \frac{S \cdot q}{q^2} q_\mu . \quad (18.7)$$

In Ref. 2, the definition of $W_{\mu\nu}$ with $\mu \leftrightarrow \nu$ is adopted, which changes the sign of the $\varepsilon_{\mu\nu\alpha\beta}$ terms in Eq. (18.6), although the formulae given here below are unchanged. Ref. 1 tabulates the relation between the structure functions defined in Eq. (18.6) and other choices available in the literature.

The cross sections for neutral- and charged-current deep inelastic scattering on unpolarized nucleons can be written in terms of the structure functions in the generic form

$$\begin{aligned} \frac{d^2\sigma^i}{dx dy} &= \frac{4\pi\alpha^2}{xyQ^2} \eta^i \left\{ \left(1 - y - \frac{x^2 y^2 M^2}{Q^2} \right) F_2^i \right. \\ &\quad \left. + y^2 x F_1^i \mp \left(y - \frac{y^2}{2} \right) x F_3^i \right\}, \end{aligned} \quad (18.8)$$

where $i = \text{NC}, \text{CC}$ corresponds to neutral-current ($eN \rightarrow eX$) or charged-current ($eN \rightarrow \nu X$ or $\nu N \rightarrow eX$) processes, respectively. For incoming neutrinos, $L_{\mu\nu}^W$ of Eq. (18.3) is still true, but with e, λ corresponding to the outgoing charged lepton. In the last term of Eq. (18.8), the $-$ sign is taken for an incoming e^+ or $\bar{\nu}$ and the $+$ sign for an incoming e^- or ν . The factor $\eta^{\text{NC}} = 1$ for unpolarized e^\pm beams, whereas*

$$\eta^{\text{CC}} = (1 \pm \lambda)^2 \eta_W \quad (18.9)$$

with \pm for ℓ^\pm ; and where λ is the helicity of the incoming lepton and η_W is defined in Eq. (18.4); for incoming neutrinos $\eta^{\text{CC}} = 4\eta_W$. The CC structure functions, which derive exclusively from W exchange, are

$$F_1^{\text{CC}} = F_1^W, \quad F_2^{\text{CC}} = F_2^W, \quad xF_3^{\text{CC}} = xF_3^W. \quad (18.10)$$

The NC structure functions $F_2^\gamma, F_2^{\gamma Z}, F_2^Z$ are, for $e^\pm N \rightarrow e^\pm X$, given by Ref. 5,

$$F_2^{\text{NC}} = F_2^\gamma - (g_V^e \pm \lambda g_A^e) \eta_{\gamma Z} F_2^{\gamma Z} + (g_V^e + g_A^e \pm 2\lambda g_V^e g_A^e) \eta_Z F_2^Z \quad (18.11)$$

and similarly for F_1^{NC} , whereas

$$xF_3^{\text{NC}} = -(g_A^e \pm \lambda g_V^e) \eta_{\gamma Z} xF_3^{\gamma Z} + [2g_V^e g_A^e \pm \lambda(g_V^e + g_A^e)] \eta_Z xF_3^Z. \quad (18.12)$$

The polarized cross-section difference

$$\Delta\sigma = \sigma(\lambda_n = -1, \lambda_\ell) - \sigma(\lambda_n = 1, \lambda_\ell), \quad (18.13)$$

where λ_ℓ, λ_n are the helicities (± 1) of the incoming lepton and nucleon, respectively, may be expressed in terms of the five structure functions $g_{1,\dots,5}(x, Q^2)$ of Eq. (18.6). Thus,

$$\begin{aligned} \frac{d^2 \Delta\sigma^i}{dx dy} &= \frac{8\pi\alpha^2}{xyQ^2} \eta^i \left\{ -\lambda_\ell y \left(2 - y - 2x^2 y^2 \frac{M^2}{Q^2} \right) x g_1^i + \lambda_\ell 4x^3 y^2 \frac{M^2}{Q^2} g_2^i \right. \\ &+ 2x^2 y \frac{M^2}{Q^2} \left(1 - y - x^2 y^2 \frac{M^2}{Q^2} \right) g_3^i \\ &\left. - \left(1 + 2x^2 y \frac{M^2}{Q^2} \right) \left[\left(1 - y - x^2 y^2 \frac{M^2}{Q^2} \right) g_4^i + x y^2 g_5^i \right] \right\} \quad (18.14) \end{aligned}$$

with $i = \text{NC}$ or CC as before. The Eq. (18.13) corresponds to the difference of antiparallel minus parallel spins of the incoming particles for e^- or ν initiated reactions, but the difference of parallel minus antiparallel for e^+ or $\bar{\nu}$ initiated processes. For longitudinal nucleon polarization, the contributions of g_2 and g_3 are suppressed by powers of M^2/Q^2 . These structure functions give an unsuppressed contribution to the cross section for transverse polarization [1], but in this case the cross-section difference vanishes as $M/Q \rightarrow 0$.

Because the same tensor structure occurs in the spin-dependent and spin-independent parts of the hadronic tensor of Eq. (18.6) in the $M^2/Q^2 \rightarrow 0$ limit, the differential cross-section difference of Eq. (18.14) may be obtained from the differential cross section Eq. (18.8) by replacing

$$F_1 \rightarrow -g_5, \quad F_2 \rightarrow -g_4, \quad F_3 \rightarrow 2g_1, \quad (18.15)$$

and multiplying by two, since the total cross section is the average over the initial-state polarizations. In this limit, Eq. (18.8) and Eq. (18.14) may be written in the form

$$\begin{aligned} \frac{d^2 \sigma^i}{dx dy} &= \frac{2\pi\alpha^2}{xyQ^2} \eta^i \left[Y_+ F_2^i \mp Y_- x F_3^i - y^2 F_L^i \right], \\ \frac{d^2 \Delta\sigma^i}{dx dy} &= \frac{4\pi\alpha^2}{xyQ^2} \eta^i \left[-Y_+ g_4^i \mp Y_- 2x g_1^i + y^2 g_L^i \right], \quad (18.16) \end{aligned}$$

with $i = \text{NC}$ or CC , where $Y_\pm = 1 \pm (1 - y)^2$ and

$$F_L^i = F_2^i - 2x F_1^i, \quad g_L^i = g_4^i - 2x g_5^i. \quad (18.17)$$

In the naive quark-parton model, the analogy with the Callan-Gross relations [6] $F_L^i = 0$, are the Dicus relations [7] $g_L^i = 0$. Therefore, there are only two independent polarized structure functions: g_1 (parity conserving) and g_5 (parity violating), in analogy with the unpolarized structure functions F_1 and F_3 .

18.2.1. Structure functions in the quark-parton model :

In the quark-parton model [8,9], contributions to the structure functions F^i and g^i can be expressed in terms of the quark distribution functions $q(x, Q^2)$ of the proton, where $q = u, \bar{u}, d, \bar{d}$ etc. The quantity $q(x, Q^2) dx$ is the number of quarks (or antiquarks) of designated flavor that carry a momentum fraction between x and $x + dx$ of the proton's momentum in a frame in which the proton momentum is large.

For the neutral-current processes $ep \rightarrow eX$,

$$\begin{aligned} [F_2^\gamma, F_2^{\gamma Z}, F_2^Z] &= x \sum_q [e_q^2, 2e_q g_V^q, g_V^{q2} + g_A^{q2}] (q + \bar{q}), \\ [F_3^\gamma, F_3^{\gamma Z}, F_3^Z] &= \sum_q [0, 2e_q g_A^q, 2g_V^q g_A^q] (q - \bar{q}), \\ [g_1^\gamma, g_1^{\gamma Z}, g_1^Z] &= \frac{1}{2} \sum_q [e_q^2, 2e_q g_V^q, g_V^{q2} + g_A^{q2}] (\Delta q + \Delta \bar{q}), \\ [g_5^\gamma, g_5^{\gamma Z}, g_5^Z] &= \sum_q [0, e_q g_A^q, g_V^q g_A^q] (\Delta q - \Delta \bar{q}), \quad (18.18) \end{aligned}$$

where $g_V^q = \pm \frac{1}{2} - 2e_q \sin^2 \theta_W$ and $g_A^q = \pm \frac{1}{2}$, with \pm according to whether q is a u - or d -type quark respectively. The quantity Δq is the difference $q \uparrow - q \downarrow$ of the distributions with the quark spin parallel and antiparallel to the proton spin.

For the charged-current processes $e^- p \rightarrow \nu X$ and $\bar{\nu} p \rightarrow e^+ X$, the structure functions are:

$$\begin{aligned} F_2^{W^-} &= 2x(u + \bar{d} + \bar{s} + c \dots), \\ F_3^{W^-} &= 2(u - \bar{d} - \bar{s} + c \dots), \\ g_1^{W^-} &= (\Delta u + \Delta \bar{d} + \Delta \bar{s} + \Delta c \dots), \\ g_5^{W^-} &= (-\Delta u + \Delta \bar{d} + \Delta \bar{s} - \Delta c \dots), \quad (18.19) \end{aligned}$$

where only the active flavors are to be kept and where CKM mixing has been neglected. For $e^+ p \rightarrow \bar{\nu} X$ and $\nu p \rightarrow e^- X$, the structure functions F^{W^+}, g^{W^+} are obtained by the flavor interchanges $d \leftrightarrow u, s \leftrightarrow c$ in the expressions for F^{W^-}, g^{W^-} . The structure functions for scattering on a neutron are obtained from those of the proton by the interchange $u \leftrightarrow d$. For both the neutral- and charged-current processes, the quark-parton model predicts $2xF_1^i = F_2^i$ and $g_4^i = 2xg_5^i$.

Neglecting masses, the structure functions g_2 and g_3 contribute only to scattering from transversely polarized nucleons (for which $S \cdot q = 0$), and have no simple interpretation in terms of the quark-parton model. They arise from off-diagonal matrix elements $\langle P, \lambda' | [J_\mu^\dagger(z), J_\nu(0)] | P, \lambda \rangle$, where the proton helicities satisfy $\lambda' \neq \lambda$. In fact, the leading-twist contributions to both g_2 and g_3 are both twist-2 and twist-3, which contribute at the same order of Q^2 . The Wandzura-Wilczek relation [10] expresses the twist-2 part of g_2 in terms of g_1 as

$$g_2^i(x) = -g_1^i(x) + \int_x^1 \frac{dy}{y} g_1^i(y). \quad (18.20)$$

However, the twist-3 component of g_2 is unknown. Similarly, there is a relation expressing the twist-2 part of g_3 in terms of g_4 . A complete set of relations, including M^2/Q^2 effects, can be found in Ref. 11.

18.2.2. Structure functions and QCD :

One of the most striking predictions of the quark-parton model is that the structure functions F_i, g_i scale, i.e., $F_i(x, Q^2) \rightarrow F_i(x)$ in the Bjorken limit that Q^2 and $\nu \rightarrow \infty$ with x fixed [12]. This property is related to the assumption that the transverse momentum of the partons in the infinite-momentum frame of the proton is small. In QCD, however, the radiation of hard gluons from the quarks violates this assumption, leading to logarithmic scaling violations, which are particularly large at small x , see Fig. 18.2. The radiation of gluons produces the evolution of the structure functions. As Q^2 increases, more and more gluons are radiated, which in turn split into $q\bar{q}$ pairs. This process leads both to the softening of the initial quark momentum distributions and to the growth of the gluon density and the $q\bar{q}$ sea as x decreases.

Figure 18.2: The proton structure function F_2^p given at two Q^2 values (3.5 GeV^2 and 90 GeV^2), which exhibit scaling at the ‘pivot’ point $x \sim 0.14$. See the captions in Fig. 18.8 and Fig. 18.10 for the references of the data. The various data sets have been renormalized by the factors shown in brackets in the key to the plot, which were globally determined in the full HERAPDF analysis [46]. In practice, data for the reduced cross section, $F_2(x, Q^2) - (y^2/Y_+)F_L(x, Q^2)$, are fitted, rather than F_2 and F_L separately.

In QCD, the above process is described in terms of scale-dependent parton distributions $f_a(x, \mu^2)$, where $a = g$ or q and, typically, μ is the scale of the probe Q . For $Q^2 \gg M^2$, the structure functions are of the form

$$F_i = \sum_a C_i^a \otimes f_a, \quad (18.21)$$

where \otimes denotes the convolution integral

$$C \otimes f = \int_x^1 \frac{dy}{y} C(y) f\left(\frac{x}{y}\right), \quad (18.22)$$

and where the coefficient functions C_i^a are given as a power series in α_s . The parton distribution f_a corresponds, at a given x , to the density of parton a in the proton integrated over transverse momentum k_t up to μ . Its evolution in μ is described in QCD by a DGLAP equation (see Refs. 14–17) which has the schematic form

$$\frac{\partial f_a}{\partial \ln \mu^2} \sim \frac{\alpha_s(\mu^2)}{2\pi} \sum_b (P_{ab} \otimes f_b), \quad (18.23)$$

where the P_{ab} , which describe the parton splitting $b \rightarrow a$, are also given as a power series in α_s . Although perturbative QCD can predict, via Eq. (18.23), the evolution of the parton distribution functions from a particular scale, μ_0 , these DGLAP equations cannot predict them *a priori* at any particular μ_0 . Thus they must be measured at a starting point μ_0 before the predictions of QCD can be compared to the data at other scales, μ . In general, all observables involving a hard hadronic interaction (such as structure functions) can be expressed as a convolution of calculable, process-dependent coefficient functions and these universal parton distributions, e.g. Eq. (18.21).

It is often convenient to write the evolution equations in terms of the gluon, non-singlet (q^{NS}) and singlet (q^S) quark distributions, such that

$$q^{NS} = q_i - \bar{q}_i \quad (\text{or } q_i - q_j), \quad q^S = \sum_i (q_i + \bar{q}_i). \quad (18.24)$$

The non-singlet distributions have non-zero values of flavor quantum numbers, such as isospin and baryon number. The DGLAP evolution

equations then take the form

$$\frac{\partial q^{NS}}{\partial \ln \mu^2} = \frac{\alpha_s(\mu^2)}{2\pi} P_{qq} \otimes q^{NS},$$

$$\frac{\partial}{\partial \ln \mu^2} \begin{pmatrix} q^S \\ g \end{pmatrix} = \frac{\alpha_s(\mu^2)}{2\pi} \begin{pmatrix} P_{qq} & 2n_f P_{qg} \\ P_{gq} & P_{gg} \end{pmatrix} \otimes \begin{pmatrix} q^S \\ g \end{pmatrix}, \quad (18.25)$$

where P are splitting functions that describe the probability of a given parton splitting into two others, and n_f is the number of (active) quark flavors. The leading-order Altarelli-Parisi [16] splitting functions are

$$P_{qq} = \frac{4}{3} \left[\frac{1+x^2}{(1-x)} \right]_+ = \frac{4}{3} \left[\frac{1+x^2}{(1-x)_+} \right] + 2\delta(1-x), \quad (18.26)$$

$$P_{gq} = \frac{1}{2} \left[x^2 + (1-x)^2 \right], \quad (18.27)$$

$$P_{gq} = \frac{4}{3} \left[\frac{1+(1-x)^2}{x} \right], \quad (18.28)$$

$$P_{gg} = 6 \left[\frac{1-x}{x} + x(1-x) + \frac{x}{(1-x)_+} \right] + \left[\frac{11}{2} - \frac{n_f}{3} \right] \delta(1-x), \quad (18.29)$$

where the notation $[F(x)]_+$ defines a distribution such that for any sufficiently regular test function, $f(x)$,

$$\int_0^1 dx f(x) [F(x)]_+ = \int_0^1 dx (f(x) - f(1)) F(x). \quad (18.30)$$

In general, the splitting functions can be expressed as a power series in α_s . The series contains both terms proportional to $\ln \mu^2$ and to $\ln 1/x$. The leading-order DGLAP evolution sums up the $(\alpha_s \ln \mu^2)^n$ contributions, while at next-to-leading order (NLO) the sum over the $\alpha_s (\alpha_s \ln \mu^2)^{n-1}$ terms is included [18,19]. In fact, the NNLO contributions to the splitting functions and the DIS coefficient functions are now also all known [20–22].

In the kinematic region of very small x , it is essential to sum leading terms in $\ln 1/x$, independent of the value of $\ln \mu^2$. At leading order, LLx, this is done by the BFKL equation for the unintegrated distributions (see Refs. [23,24]). The leading-order $(\alpha_s \ln(1/x))^n$ terms result in a power-like growth, $x^{-\omega}$ with $\omega = (12\alpha_s \ln 2)/\pi$, at asymptotic values of $\ln 1/x$. More recently, the next-to-leading $\ln 1/x$ (NLLx) contributions have become available [25,26]. They are so large (and negative) that the result appears to be perturbatively unstable. Methods, based on a combination of collinear and small x resummations, have been developed which reorganize the perturbative series into a more stable hierarchy [27–30]. There are indications that small x resummations become necessary for real precision for $x \lesssim 10^{-3}$ at low scales. On the other hand, there is no convincing indication that, for $Q^2 \gtrsim 2 \text{ GeV}^2$, we have entered the ‘non-linear’ regime where the gluon density is so high that gluon-gluon recombination effects become significant.

The precision of the contemporary experimental data demands that at least NLO, and preferably NNLO, DGLAP evolution be used in comparisons between QCD theory and experiment. Beyond the leading order, it is necessary to specify, and to use consistently, both a renormalization and a factorization scheme. The renormalization scheme used is almost universally the modified minimal subtraction ($\overline{\text{MS}}$) scheme [31,32]. There are two popular choices for factorization scheme, in which the form of the correction for each structure function is different. The most-used factorization scheme is again $\overline{\text{MS}}$ [33]. However, sometimes the DIS [34] scheme is adopted, in which there are no higher-order corrections to the F_2 structure function. The two schemes differ in how the non-divergent pieces are assimilated in the parton distribution functions.

The u , d , and s quarks are taken to be massless, and the effects of the c and b -quark masses have been studied up to NNLO, for example, in [35–42]. An approach using a ‘general mass variable flavor number scheme’ (GM-VFNS) is now generally adopted, in which evolution

Table 18.1: The main processes relevant to global PDF analyses, ordered in three groups: fixed-target experiments, HERA and the $p\bar{p}$ Tevatron (pp LHC). For each process we give an indication of their dominant partonic subprocesses, the primary partons which are probed and the approximate range of x constrained by the data. The Table is adapted from [13].

Process	Subprocess	Partons	x range
$\ell^\pm \{p, n\} \rightarrow \ell^\pm X$	$\gamma^* q \rightarrow q$	q, \bar{q}, g	$x \gtrsim 0.01$
$\ell^\pm n/p \rightarrow \ell^\pm X$	$\gamma^* d/u \rightarrow d/u$	d/u	$x \gtrsim 0.01$
$pp \rightarrow \mu^+ \mu^- X$	$u\bar{u}, d\bar{d} \rightarrow \gamma^*$	\bar{q}	$0.015 \lesssim x \lesssim 0.35$
$pn/pp \rightarrow \mu^+ \mu^- X$	$(u\bar{d})/(u\bar{u}) \rightarrow \gamma^*$	\bar{d}/\bar{u}	$0.015 \lesssim x \lesssim 0.35$
$\nu(\bar{\nu}) N \rightarrow \mu^-(\mu^+) X$	$W^* q \rightarrow q'$	q, \bar{q}	$0.01 \lesssim x \lesssim 0.5$
$\nu N \rightarrow \mu^- \mu^+ X$	$W^* s \rightarrow c$	s	$0.01 \lesssim x \lesssim 0.2$
$\bar{\nu} N \rightarrow \mu^+ \mu^- X$	$W^* \bar{s} \rightarrow \bar{c}$	\bar{s}	$0.01 \lesssim x \lesssim 0.2$
$e^\pm p \rightarrow e^\pm X$	$\gamma^* q \rightarrow q$	g, q, \bar{q}	$0.0001 \lesssim x \lesssim 0.1$
$e^+ p \rightarrow \bar{\nu} X$	$W^+ \{d, s\} \rightarrow \{u, c\}$	d, s	$x \gtrsim 0.01$
$e^\pm p \rightarrow e^\pm c\bar{c}X, e^\pm b\bar{b}X$	$\gamma^* c \rightarrow c, \gamma^* g \rightarrow c\bar{c}$	c, b, g	$0.0001 \lesssim x \lesssim 0.01$
$e^\pm p \rightarrow \text{jet}+X$	$\gamma^* g \rightarrow q\bar{q}$	g	$0.01 \lesssim x \lesssim 0.1$
$p\bar{p}, pp \rightarrow \text{jet}+X$	$gg, qg, q\bar{q} \rightarrow 2j$	g, q	$0.005 \lesssim x \lesssim 0.5$
$p\bar{p} \rightarrow (W^\pm \rightarrow \ell^\pm \nu) X$	$ud \rightarrow W^+, \bar{u}\bar{d} \rightarrow W^-$	u, d, \bar{u}, \bar{d}	$x \gtrsim 0.05$
$pp \rightarrow (W^\pm \rightarrow \ell^\pm \nu) X$	$u\bar{d} \rightarrow W^+, d\bar{u} \rightarrow W^-$	u, d, \bar{u}, \bar{d}	$x \gtrsim 0.001$
$p\bar{p}(pp) \rightarrow (Z \rightarrow \ell^+ \ell^-) X$	$uu, dd, \dots (u\bar{u}, \dots) \rightarrow Z$	u, d, \dots	$x \gtrsim 0.001$
$pp \rightarrow (\gamma^* \rightarrow \ell^+ \ell^-) X$	$u\bar{u}, d\bar{d}, \dots \rightarrow \gamma^*$	\bar{q}	$x \gtrsim 10^{-5}$
$pp \rightarrow b\bar{b} X$	$gg \rightarrow b\bar{b}$	g	$x \gtrsim 10^{-5}$
$pp \rightarrow \gamma X$	$gq \rightarrow \gamma q, g\bar{q} \rightarrow \gamma\bar{q}$	g	$x \gtrsim 0.005$

with $n_f = 3$ is matched to that with $n_f = 4$ at the charm threshold, with an analogous matching at the bottom threshold.

The discussion above relates to the Q^2 behavior of leading-twist (twist-2) contributions to the structure functions. Higher-twist terms, which involve their own non-perturbative input, exist. These die off as powers of Q ; specifically twist- n terms are damped by $1/Q^{n-2}$. The higher-twist terms appear to be numerically unimportant for Q^2 above a few GeV^2 , except for x close to 1.

18.3. Determination of parton distributions

The parton distribution functions (PDFs) can be determined from data for deep inelastic lepton-nucleon scattering and for related hard-scattering processes initiated by nucleons. Table 18.1 highlights some processes and their primary sensitivity to PDFs. The kinematic ranges of fixed-target and collider experiments are complementary (as is shown in Fig. 18.3), which enables the determination of PDFs over a wide range in x and Q^2 . As precise LHC data for W^\pm , Z , γ , jet, $b\bar{b}$ and $t\bar{t}$ production become available, the kinematic reach of the data will further widen, and tighter constraints on the PDFs are expected.

Recent determinations of the unpolarized PDF's have been made by six groups: MSTW [13], CT(EQ) [43], NNPDF [44,45], HERAPDF [46], ABKM [47] and GJR [48,49]. Distinguishing features of the various analyses have been reviewed in [50,51]. Most groups use input PDFs of the form $x f = x^a(\dots)(1-x)^b$ with 10-25 free parameters in total. Note, however, that NNPDF combine a Monte Carlo representation of the probability measure in the space of PDFs with the use of neural networks to give a set of unbiased input distributions, while GJR generate 'dynamical' PDFs from a valence-like input at some very low starting scale, $Q_0^2 = 0.5 \text{ GeV}^2$. All groups, except CT, present PDFs at NLO and NNLO. The results of one analysis are shown in Fig. 18.4 at scales $\mu^2 = 10$ and 10^4 GeV^2 .

MSTW, CT and NNPDF are 'global' analyses in that they fit to a full range of the types of data that are available (and use GM-VFNS). The most recent determinations of these three groups have converged, so that now a reasonable agreement has been achieved between the resulting PDFs, the value obtained for $\alpha_s(M_Z^2)$, and their predictions for the LHC. The values of α_s found by MSTW [13,52] may be taken

Figure 18.3: Kinematic domains in x and Q^2 probed by fixed-target and collider experiments, shown together with the parton distributions that are most strongly constrained by the indicated regions.

Figure 18.4: Distributions of x times the unpolarized parton distributions $f(x)$ (where $f = u_v, d_v, \bar{u}, \bar{d}, s, c, b, g$) and their associated uncertainties using the NNLO MSTW2008 parameterization [13] at a scale $\mu^2 = 10 \text{ GeV}^2$ and $\mu^2 = 10,000 \text{ GeV}^2$.

as representative of that found in global fits to DIS and related hard scattering data

$$\text{NLO} : \alpha_s(M_Z^2) = 0.1202_{-0.0015}^{+0.0012} \pm 0.003,$$

$$\text{NNLO} : \alpha_s(M_Z^2) = 0.1171 \pm 0.0014 \pm 0.002,$$

where the first error (at 68% C.L.) corresponds to the uncertainties in the data fitted and the second is an estimate of the theory error (that is, the uncertainty which might be expected at higher orders).

The PDFs of the remaining three groups are obtained without including the Tevatron W, Z production data; and the HERAPDF and ABKM groups do not fit to the Tevatron jet data. The importance of carefully including the latter data is discussed in detail in [53], and is shown to be responsible for the anomalously low value of α_s found by ABKM [47].

Spin-dependent (or polarized) PDFs have been obtained through NLO global analyses which include measurements of the g_1 structure function in inclusive polarized DIS, 'flavour-tagged' semi-inclusive DIS data, and results from polarized pp scattering at RHIC. Recent NLO analyses are given in Refs. [54–57]. Improved parton-to-hadron fragmentation functions, needed to describe the semi-inclusive DIS data, can be found in [58–60]. Fig. 18.5 shows several global analyses at a scale of 2.5 GeV^2 along with the data from semi-inclusive DIS.

Comprehensive sets of PDFs are available as program-callable functions from the HepData website [66], which includes comparison graphics of PDFs, and from the LHAPDF library [67], which can be linked directly into a users programme to provide access to recent PDFs in a standard format.

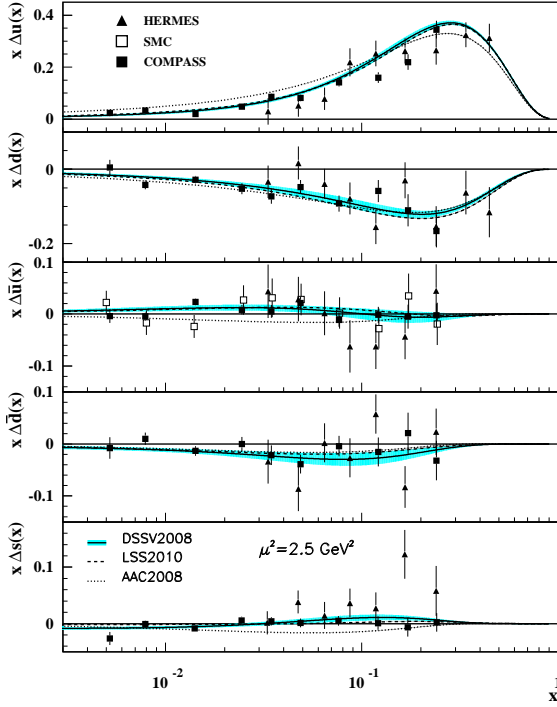

Figure 18.5: Distributions of x times the polarized parton distributions $\Delta q(x)$ (where $q = u, d, \bar{u}, \bar{d}, s$) using the LSS2010 [57], AAC2008 [54], and DSSV2008 [55] parameterizations at a scale $\mu^2 = 2.5 \text{ GeV}^2$, showing the error corridor of the latter set (corresponding to a one-unit increase in χ^2). See also BB2010 [56]. Points represent data from semi-inclusive positron (HERMES [61,62]) and muon (SMC [63] and COMPASS [64,65]) deep inelastic scattering given at $Q^2 = 2.5 \text{ GeV}^2$. SMC results are extracted under the assumption that $\Delta \bar{u}(x) = \Delta \bar{d}(x)$.

18.4. The hadronic structure of the photon

Besides the *direct* interactions of the photon, it is possible for it to fluctuate into a hadronic state via the process $\gamma \rightarrow q\bar{q}$. While in this state, the partonic content of the photon may be *resolved*, for example, through the process $e^+e^- \rightarrow e^+e^-\gamma^* \rightarrow e^+e^-X$, where the virtual photon emitted by the DIS lepton probes the hadronic structure of the quasi-real photon emitted by the other lepton. The perturbative LO contributions, $\gamma \rightarrow q\bar{q}$ followed by $\gamma^*q \rightarrow q$, are subject to QCD corrections due to the coupling of quarks to gluons.

Often the equivalent-photon approximation is used to express the differential cross section for deep inelastic electron–photon scattering in terms of the structure functions of the transverse quasi-real photon times a flux factor N_γ^T (for these incoming quasi-real photons of transverse polarization)

$$\frac{d^2\sigma}{dx dQ^2} = N_\gamma^T \frac{2\pi\alpha^2}{xQ^4} \left[\left(1 + (1-y)^2\right) F_2^\gamma(x, Q^2) - y^2 F_L^\gamma(x, Q^2) \right],$$

where we have used $F_2^\gamma = 2xF_T^\gamma + F_L^\gamma$, not to be confused with F_2^γ of Sec. 18.2. Complete formulae are given, for example, in the comprehensive review of Ref. 68.

The hadronic photon structure function, F_2^γ , evolves with increasing Q^2 from the ‘hadron-like’ behavior, calculable via the vector-meson-dominance model, to the dominating ‘point-like’ behaviour, calculable in perturbative QCD. Due to the point-like coupling, the logarithmic evolution of F_2^γ with Q^2 has a *positive* slope for all values of x , see Fig. 18.15. The ‘loss’ of quarks at large x due to gluon radiation is over-compensated by the ‘creation’ of quarks via the point-like $\gamma \rightarrow q\bar{q}$ coupling. The logarithmic evolution was first predicted in the quark–parton model ($\gamma^*\gamma \rightarrow q\bar{q}$) [69,70], and then in QCD in the limit of large Q^2 [71]. The evolution is now known to NLO [72–74]. NLO data analyses to determine the parton densities of the photon can be found in [75–77].

18.5. Diffractive DIS (DDIS)

Some 10% of DIS events are diffractive, $\gamma^*p \rightarrow X + p$, in which the slightly deflected proton and the cluster X of outgoing hadrons are well-separated in rapidity. Besides x and Q^2 , two extra variables are needed to describe a DDIS event: the fraction x_{IP} of the proton’s momentum transferred across the rapidity gap and t , the square of the 4-momentum transfer of the proton. The DDIS data [78–83] are usually analyzed using two levels of factorization. First, the diffractive structure function F_2^D satisfies *collinear factorization*, and can be expressed as the convolution [84]

$$F_2^D = \sum_{a=q,g} C_2^a \otimes f_{a/p}^D, \quad (18.31)$$

with the same coefficient functions as in DIS (see Eq. (18.21)), and where the diffractive parton distributions $f_{a/p}^D$ ($a = q, g$) satisfy DGLAP evolution. Second, *Regge factorization* is assumed [85],

$$f_{a/p}^D(x_{IP}, t, z, \mu^2) = f_{IP/p}(x_{IP}, t) f_{a/IP}(z, \mu^2), \quad (18.32)$$

where $f_{a/IP}$ are the parton densities of the Pomeron, which itself is treated like a hadron, and $z \in [x/x_{IP}, 1]$ is the fraction of the Pomeron’s momentum carried by the parton entering the hard subprocess. The Pomeron flux factor $f_{IP/p}(x_{IP}, t)$ is taken from Regge phenomenology. There are also secondary Reggeon contributions to Eq. (18.32). A sample of the t -integrated diffractive parton densities, obtained in this way, is shown in Fig. 18.6.

Although collinear factorization holds as $\mu^2 \rightarrow \infty$, there are non-negligible corrections for finite μ^2 and small x_{IP} . Besides the *resolved* interactions of the Pomeron, the perturbative QCD Pomeron may also interact *directly* with the hard subprocess, giving rise to an inhomogeneous evolution equation for the diffractive parton densities analogous to the photon case. The results of the MRW analysis [87], which includes these contributions, are also shown in Fig. 18.6. Unlike the inclusive case, the diffractive parton densities cannot be directly used to calculate diffractive hadron–hadron cross sections, since account must first be taken of ‘soft’ rescattering effects.

18.6. Generalized parton distributions

The parton distributions of the proton of Sec. 18.3 are given by the diagonal matrix elements $\langle P, \lambda | \hat{O} | P, \lambda \rangle$, where P and λ are the 4-momentum and helicity of the proton, and \hat{O} is a twist-2 quark or gluon operator. However, there is new information in the so-called generalised parton distributions (GPDs) defined in terms of the off-diagonal matrix elements $\langle P', \lambda' | \hat{O} | P, \lambda \rangle$; see Refs. 89–93 for reviews. Unlike the diagonal PDFs, the GPDs cannot be regarded as parton densities, but are to be interpreted as probability amplitudes.

The physical significance of GPDs is best seen using light-cone coordinates, $z^\pm = (z^0 \pm z^3)/\sqrt{2}$, and in the light-cone gauge, $A^+ = 0$. It is conventional to define the generalised quark distributions in terms of quark operators at light-like separation

$$\begin{aligned} F_q(x, \xi, t) &= \frac{1}{2} \int \frac{dz^-}{2\pi} e^{ix\bar{P}^+z^-} \langle P' | \bar{\psi}(-z/2) \gamma^+ \psi(z/2) | P \rangle \Big|_{z^+ = z^1 = z^2 = 0} \\ &= \frac{1}{2P^+} \left(H_q(x, \xi, t) \bar{u}(P') \gamma^+ u(P) + E_q(x, \xi, t) \bar{u}(P') \frac{i\sigma^{+\alpha} \Delta_\alpha}{2m} u(P) \right) \end{aligned} \quad (18.34)$$

Figure 18.6: Diffractive parton distributions, $x_{IP} z f_a^D$, obtained from fitting to the ZEUS data with $Q^2 > 5 \text{ GeV}^2$ [86], H1 data with $Q^2 > 8.5 \text{ GeV}^2$ assuming Regge factorization [81], and using a more perturbative QCD approach [87]. Only the Pomeron contributions are shown and not the secondary Reggeon contributions, which are negligible at the value of $x_P = 0.003$ chosen here. The H1 2007 Jets distribution [88] is similar to H1 2006 Fit B.

with $\bar{P} = (P + P')/2$ and $\Delta = P' - P$, and where we have suppressed the helicity labels of the protons and spinors. We now have two extra kinematic variables:

$$t = \Delta^2, \quad \xi = -\Delta^+ / (P + P')^+. \quad (18.35)$$

We see that $-1 \leq \xi \leq 1$. Similarly, we may define GPDs \bar{H}_q and \bar{E}_q with an additional γ_5 between the quark operators in Eq. (18.33); and also an analogous set of gluon GPDs, H_g , E_g , \bar{H}_g and \bar{E}_g . After a Fourier transform with respect to the transverse components of Δ , we are able to describe the spatial distribution of partons in the impact parameter plane in terms of GPDs [94,95].

For $P' = P$, $\lambda' = \lambda$ the matrix elements reduce to the ordinary PDFs of Sec. 18.2.1

$$H_q(x, 0, 0) = q(x), \quad H_q(-x, 0, 0) = -\bar{q}(x), \quad H_g(x, 0, 0) = xg(x), \quad (18.36)$$

$$\bar{H}_q(x, 0, 0) = \Delta q(x), \quad \bar{H}_q(-x, 0, 0) = \Delta \bar{q}(x), \quad \bar{H}_g(x, 0, 0) = x\Delta g(x), \quad (18.37)$$

where $\Delta q = q \uparrow - q \downarrow$ as in Eq. (18.18). No corresponding relations exist for E , \bar{E} as they decouple in the forward limit, $\Delta = 0$.

H_q, E_g are even functions of x , and \bar{H}_g, \bar{E}_g are odd functions of x . We can introduce valence and ‘singlet’ quark distributions which are even and odd functions of x respectively. For example

$$H_q^V(x, \xi, t) \equiv H_q(x, \xi, t) + H_q(-x, \xi, t) = H_q^V(-x, \xi, t), \quad (18.38)$$

$$H_q^S(x, \xi, t) \equiv H_q(x, \xi, t) - H_q(-x, \xi, t) = -H_q^S(-x, \xi, t). \quad (18.39)$$

All the GPDs satisfy relations of the form

$$H(x, -\xi, t) = H(x, \xi, t) \quad \text{and} \quad H(x, -\xi, t)^* = H(x, \xi, t), \quad (18.40)$$

and so are real-valued functions. Moreover, the moments of GPDs, that is the x integrals of $x^n H_q$ etc., are *polynomials* in ξ of order $n + 1$. Another important property of GPDs are Ji’s sum rules [89]

$$\frac{1}{2} \int_{-1}^1 dx x (H_q(x, \xi, t) + E_q(x, \xi, t)) = J_q(t), \quad (18.41)$$

where $J_q(0)$ is the total angular momentum carried by quarks and antiquarks of flavour q , with a similar relation for gluons.

Figure 18.7: Schematic diagrams of the three distinct kinematic regions of (the imaginary part of) H_q . The proton and quark momentum fractions refer to \bar{P}^+ , and x covers the interval $(-1,1)$. In the ERBL domain the GPDs are generalisations of distribution amplitudes which occur in processes such as $p\bar{p} \rightarrow J/\psi$.

To visualize the physical content of H_q , we Fourier expand ψ and $\bar{\psi}$ in terms of quark, antiquark creation (b, d) and annihilation (b^\dagger, d^\dagger) operators, and sketch the result in Fig. 18.7. There are two types of domain: (i) the time-like or ‘annihilation’ domain, with $|x| < |\xi|$, where the GPDs describe the wave functions of a t -channel $q\bar{q}$ (or gluon) pair and evolve according to modified ERBL equations [96,97]; (ii) the space-like or ‘scattering’ domain, with $|x| > |\xi|$, where the GPDs generalise the familiar \bar{q}, q (and gluon) PDFs and describe ‘deeply virtual Compton scattering’ ($\gamma^* p \rightarrow \gamma p$), $\gamma p \rightarrow J/\psi p$, etc., and evolve according to modified DGLAP equations. The splitting functions for the evolution of GPDs are known to NLO [98].

GPDs describe new aspects of proton structure and must be determined from experiment. We can parametrise them in terms of ‘double distributions’ [99,100], which reduce to diagonal PDFs as $\xi \rightarrow 0$. With an additional physically reasonable ‘Regge’ assumption of no extra singularity at $\xi = 0$, GPDs at low ξ are uniquely given in terms of diagonal PDFs to $O(\xi)$, and have been used [101] to describe $\gamma p \rightarrow J/\psi p$ data. Alternatively, flexible $SO(3)$ -based parametrisations have been used to determine GPDs from DVCS data [102].

* The value of η^{CC} deduced from Ref. 1 is found to be a factor of two too small; η^{CC} of Eq. (18.9) agrees with Refs. [2,3].

NOTE: THE FIGURES IN THIS SECTION ARE INTENDED TO SHOW THE REPRESENTATIVE DATA. THEY ARE NOT MEANT TO BE COMPLETE COMPILATIONS OF ALL THE WORLD'S RELIABLE DATA.

Figure 18.8: The proton structure function F_2^p measured in electromagnetic scattering of electrons and positrons on protons (collider experiments H1 and ZEUS for $Q^2 \geq 2 \text{ GeV}^2$), in the kinematic domain of the HERA data (see Fig. 18.10 for data at smaller x and Q^2), and for electrons (SLAC) and muons (BCDMS, E665, NMC) on a fixed target. Statistical and systematic errors added in quadrature are shown. The data are plotted as a function of Q^2 in bins of fixed x . Some points have been slightly offset in Q^2 for clarity. The H1+ZEUS combined binning in x is used in this plot; all other data are rebinned to the x values of these data. For the purpose of plotting, F_2^p has been multiplied by 2^{i_x} , where i_x is the number of the x bin, ranging from $i_x = 1$ ($x = 0.85$) to $i_x = 24$ ($x = 0.00005$). References: **H1 and ZEUS**—F.D. Aaron *et al.*, JHEP **1001**, 109 (2010); **BCDMS**—A.C. Benvenuti *et al.*, Phys. Lett. **B223**, 485 (1989) (as given in [66]); **E665**—M.R. Adams *et al.*, Phys. Rev. **D54**, 3006 (1996); **NMC**—M. Arneodo *et al.*, Nucl. Phys. **B483**, 3 (1997); **SLAC**—L.W. Whitlow *et al.*, Phys. Lett. **B282**, 475 (1992).

Figure 18.9: The deuteron structure function F_2^d measured in electromagnetic scattering of electrons (SLAC) and muons (BCDMS, E665, NMC) on a fixed target, shown as a function of Q^2 for bins of fixed x . Statistical and systematic errors added in quadrature are shown. For the purpose of plotting, F_2^d has been multiplied by 2^{i_x} , where i_x is the number of the x bin, ranging from 1 ($x = 0.85$) to 29 ($x = 0.0009$). References: **BCDMS**—A.C. Benvenuti *et al.*, Phys. Lett. **B237**, 592 (1990). **E665**, **NMC**, **SLAC**—same references as Fig. 18.8.

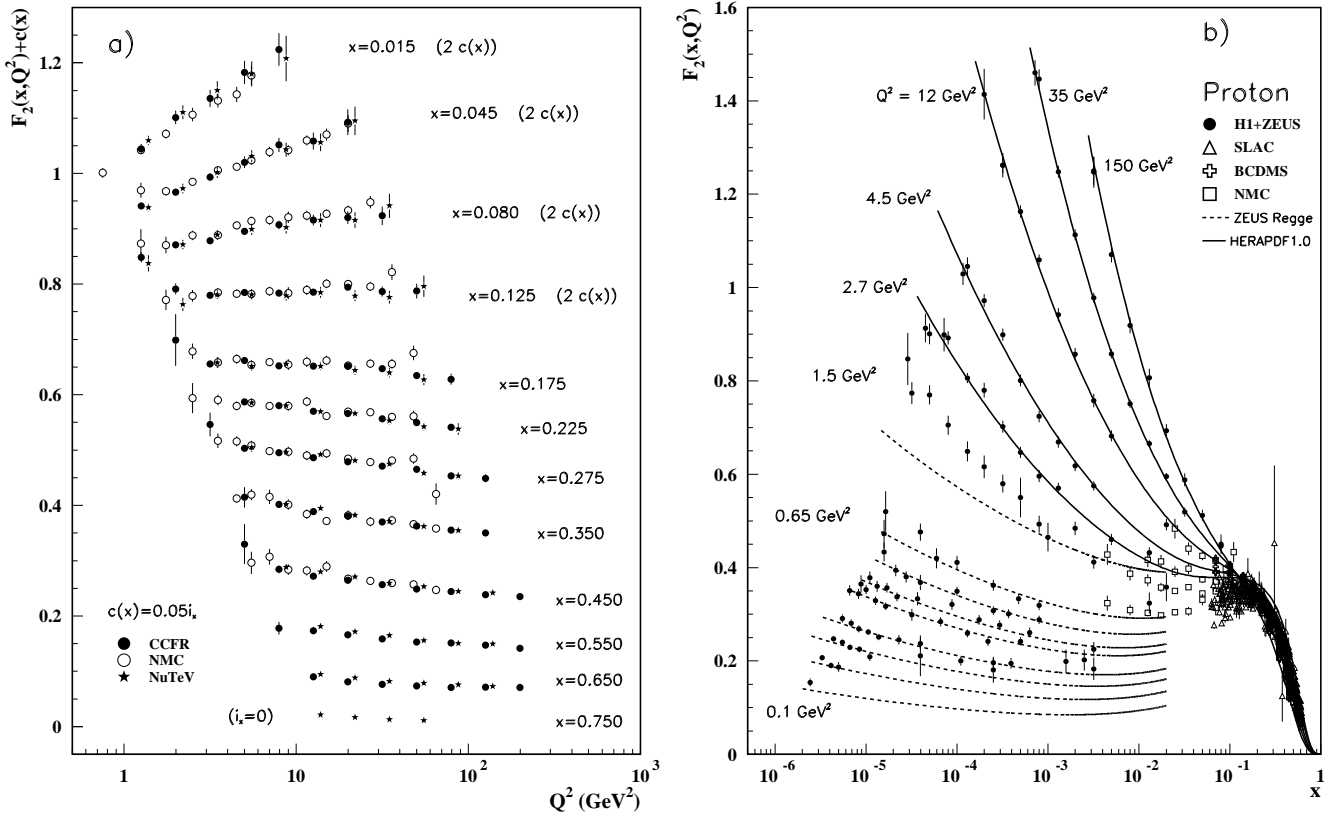

Figure 18.10: a) The deuteron structure function F_2 measured in deep inelastic scattering of muons on a fixed target (NMC) is compared to the structure function F_2 from neutrino-iron scattering (CCFR and NuTeV) using $F_2^\mu = (5/18)F_2^p - x(s + \bar{s})/6$, where heavy-target effects have been taken into account. The data are shown versus Q^2 , for bins of fixed x . The NMC data have been rebinned to CCFR and NuTeV x values. For the purpose of plotting, a constant $c(x) = 0.05i_x$ is added to F_2 , where i_x is the number of the x bin, ranging from 0 ($x = 0.75$) to 7 ($x = 0.175$). For $i_x = 8$ ($x = 0.125$) to 11 ($x = 0.015$), $2c(x)$ has been added. References: NMC—M. Arneodo *et al.*, Nucl. Phys. **B483**, 3 (1997); CCFR/NuTeV—U.K. Yang *et al.*, Phys. Rev. Lett. **86**, 2741 (2001); NuTeV—M. Tzanov *et al.*, Phys. Rev. **D74**, 012008 (2006).

b) The proton structure function F_2^p mostly at small x and Q^2 , measured in electromagnetic scattering of electrons and positrons (H1, ZEUS), electrons (SLAC), and muons (BCDMS, NMC) on protons. Lines are ZEUS Regge and HERAPDF parameterizations for lower and higher Q^2 , respectively. The width of the bins can be up to 10% of the stated Q^2 . Some points have been slightly offset in x for clarity. References: H1 and ZEUS—F.D. Aaron *et al.*, JHEP **1001**, 109 (2010) (for both data and HERAPDF parameterization); ZEUS—J. Breitweg *et al.*, Phys. Lett. **B487**, 53 (2000) (ZEUS Regge parameterization); BCDMS, NMC, SLAC—same references as Fig. 18.8.

Statistical and systematic errors added in quadrature are shown for both plots.

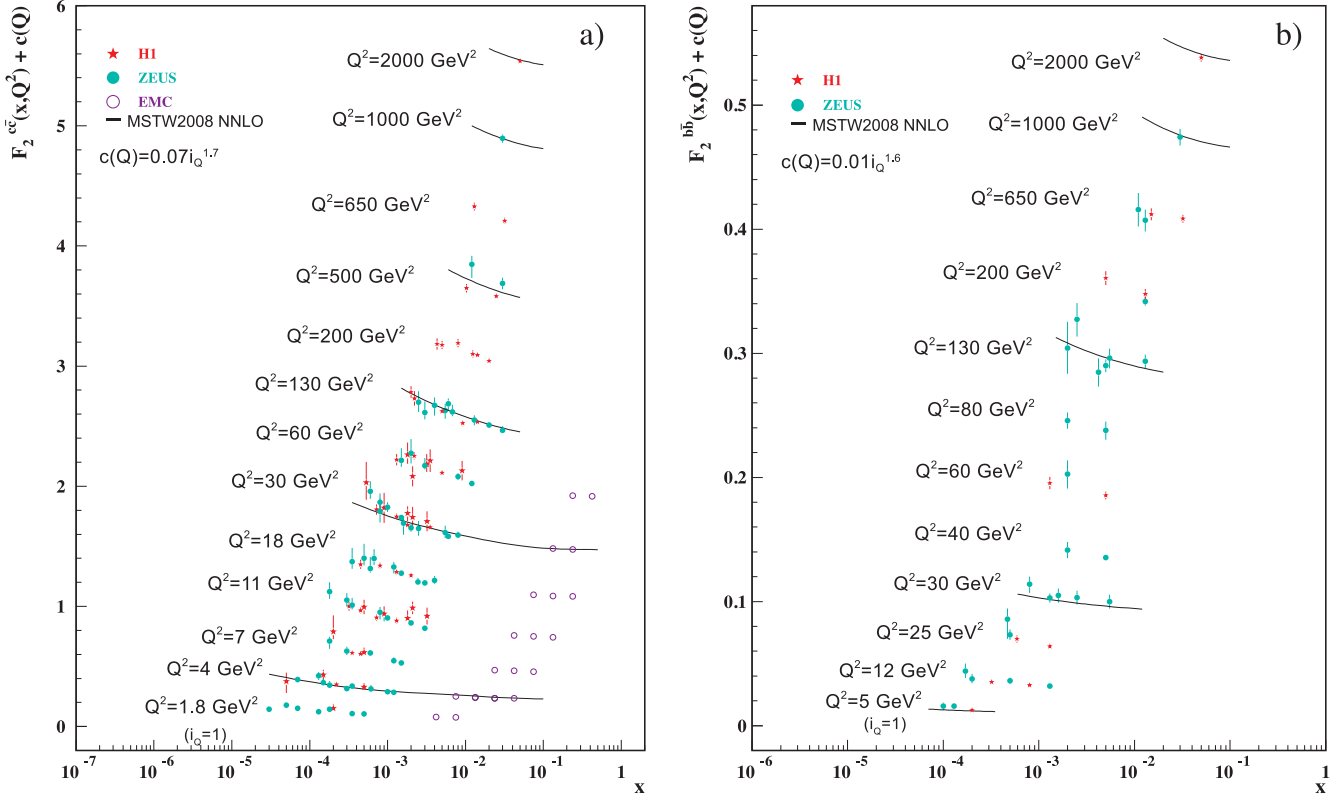

Figure 18.11: a) The charm quark structure function $F_2^{c\bar{c}}(x)$, i.e. that part of the inclusive structure function F_2^p arising from the production of charm quarks, measured in electromagnetic scattering of positrons on protons (H1, ZEUS) and muons on iron (EMC). For the purpose of plotting, a constant $c(Q) = 0.07i_Q^{1.7}$ is added to $F_2^{c\bar{c}}$ where i_Q is the number of the Q^2 bin, ranging from 1 ($Q^2 = 1.8 \text{ GeV}^2$) to 13 ($Q^2 = 2000 \text{ GeV}^2$). References: **ZEUS**—J. Breitweg *et al.*, *Eur. Phys. J.* **C12**, 35 (2000); S. Chekanov *et al.*, *Phys. Rev.* **D69**, 012004 (2004); S. Chekanov *et al.*, *JHEP* **07**, 074 (2007); S. Chekanov *et al.*, *Eur. Phys. J.* **C65**, 65 (2010); **H1**—C. Adloff *et al.*, *Z. Phys.* **C72**, 593 (1996); C. Adloff *et al.*, *Phys. Lett.* **B528**, 199 (2002); F.D. Aaron *et al.*, *Phys. Lett.* **B686**, 91 (2010); F.D. Aaron *et al.*, *Eur. Phys. J.* **C65**, 89 (2010); **EMC**—J.J. Aubert *et al.*, *Nucl. Phys.* **B213**, 31 (1983).

b) The bottom quark structure function $F_2^{b\bar{b}}(x)$. For the purpose of plotting, a constant $c(Q) = 0.01i_Q^{1.6}$ is added to $F_2^{b\bar{b}}$ where i_Q is the number of the Q^2 bin, ranging from 1 ($Q^2 = 5 \text{ GeV}^2$) to 12 ($Q^2 = 2000 \text{ GeV}^2$). References: **ZEUS**—S. Chekanov *et al.*, *Eur. Phys. J.* **C65**, 65 (2010); H. Abramowicz *et al.*, *Eur. Phys. J.* **C69**, 347 (2010); H. Abramowicz *et al.*, *Eur. Phys. J.* **C71**, 1573 (2010); **H1**—F.D. Aaron *et al.*, *Eur. Phys. J.* **C65**, 89 (2010).

For both plots, statistical and systematic errors added in quadrature are shown. The data are given as a function of x in bins of Q^2 . Points may have been slightly offset in x for clarity. Some data have been rebinned to common Q^2 values. Also shown is the MSTW2008 parameterization given at several Q^2 values (A.D. Martin *et al.*, *Eur. Phys. J.* **C63**, 189 (2009)).

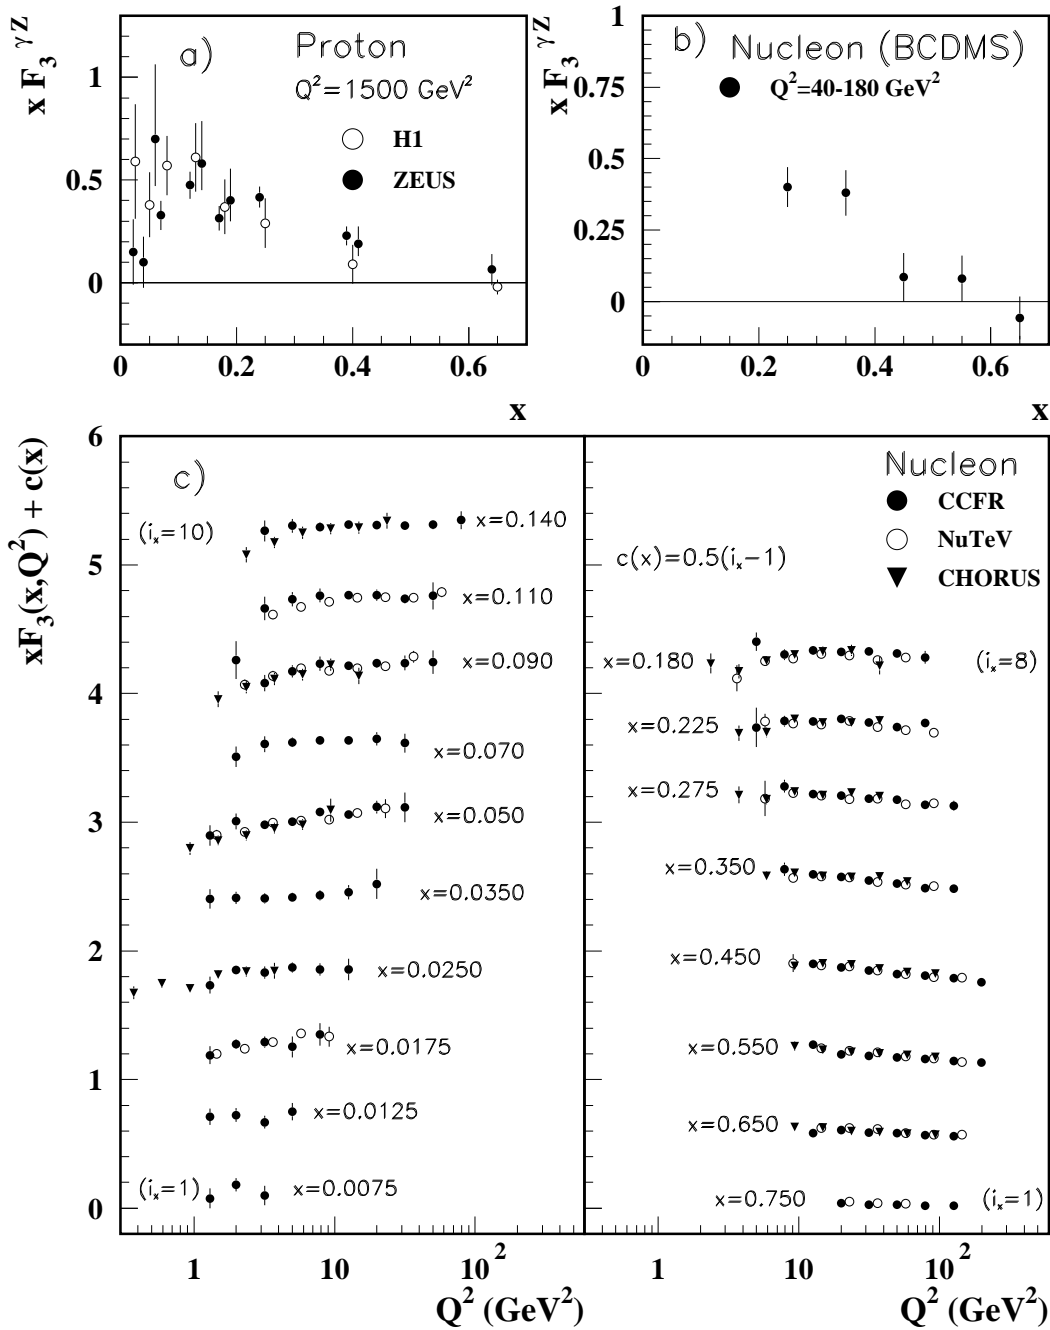

Figure 18.12: The structure function $xF_3^{\gamma Z}$ measured in electroweak scattering of **a)** electrons on protons (H1 and ZEUS) and **b)** muons on carbon (BCDMS). The ZEUS points have been slightly offset in x for clarity. References: **H1**—C. Adloff *et al.*, *Eur. Phys. J. C* **30**, 1 (2003); **ZEUS**—S. Chekanov *et al.*, *Eur. Phys. J. C* **28**, 175 (2003); S. Chekanov *et al.*, *Eur. Phys. J. C* **62**, 625 (2009); **BCDMS**—A. Argento *et al.*, *Phys. Lett. B* **140**, 142 (1984).

c) The structure function xF_3 of the nucleon measured in ν -Fe scattering. The data are plotted as a function of Q^2 in bins of fixed x . For the purpose of plotting, a constant $c(x) = 0.5(i_x - 1)$ is added to xF_3 , where i_x is the number of the x bin as shown in the plot. The NuTeV and CHORUS points have been shifted to the nearest corresponding x bin as given in the plot and slightly offset in Q^2 for clarity. References: **CCFR**—W.G. Seligman *et al.*, *Phys. Rev. Lett.* **79**, 1213 (1997); **NuTeV**—M. Tzanov *et al.*, *Phys. Rev. D* **74**, 012008 (2006); **CHORUS**—G. Önençüt *et al.*, *Phys. Lett. B* **632**, 65 (2006).

Statistical and systematic errors added in quadrature are shown for all plots.

Figure 18.13: Top panel: The longitudinal structure function F_L as a function of x in bins of fixed Q^2 measured on the proton (except for the SLAC data which also contain deuterium data). BCDMS, NMC, and SLAC results are from measurements of R (the ratio of longitudinal to transverse photon absorption cross sections) which are converted to F_L by using the BCDMS parameterization of F_2 (A.C. Benvenuti *et al.*, Phys. Lett. **B223**, 485 (1989)). It is assumed that the Q^2 dependence of the fixed-target data is small within a given Q^2 bin. Some of the other data may have been rebinned to common Q^2 values. Also shown is the MSTW2008 parameterization given at two Q^2 values (A.D. Martin *et al.*, Eur. Phys. J. **C63**, 189 (2009)). References: **H1**—F.D. Aaron *et al.*, Phys. Lett. **B665**, 139 (2008); F.D. Aaron *et al.*, Eur. Phys. J. **C71**, 1579 (2011); **ZEUS**—S. Chekanov *et al.*, Phys. Lett. **B682**, 8 (2009); **BCDMS**—A. Benvenuti *et al.*, Phys. Lett. **B223**, 485 (1989); **NMC**—M. Arneodo *et al.*, Nucl. Phys. **B483**, 3 (1997); **SLAC**—L.W. Whitlow *et al.*, Phys. Lett. **B250**, 193 (1990) and numerical values from the thesis of L.W. Whitlow (SLAC-357).

Bottom panel: Higher Q^2 values of the longitudinal structure function F_L as a function of Q^2 given at the measured x for e^+/e^- -proton scattering. Points have been slightly offset in Q^2 for clarity. References: **H1**—C. Adloff *et al.*, Eur. Phys. J. **C30**, 1 (2003).

The H1 results shown in the bottom plot require the assumption of the validity of the QCD form for the F_2 structure function in order to extract F_L . Statistical and systematic errors added in quadrature are shown for both plots.

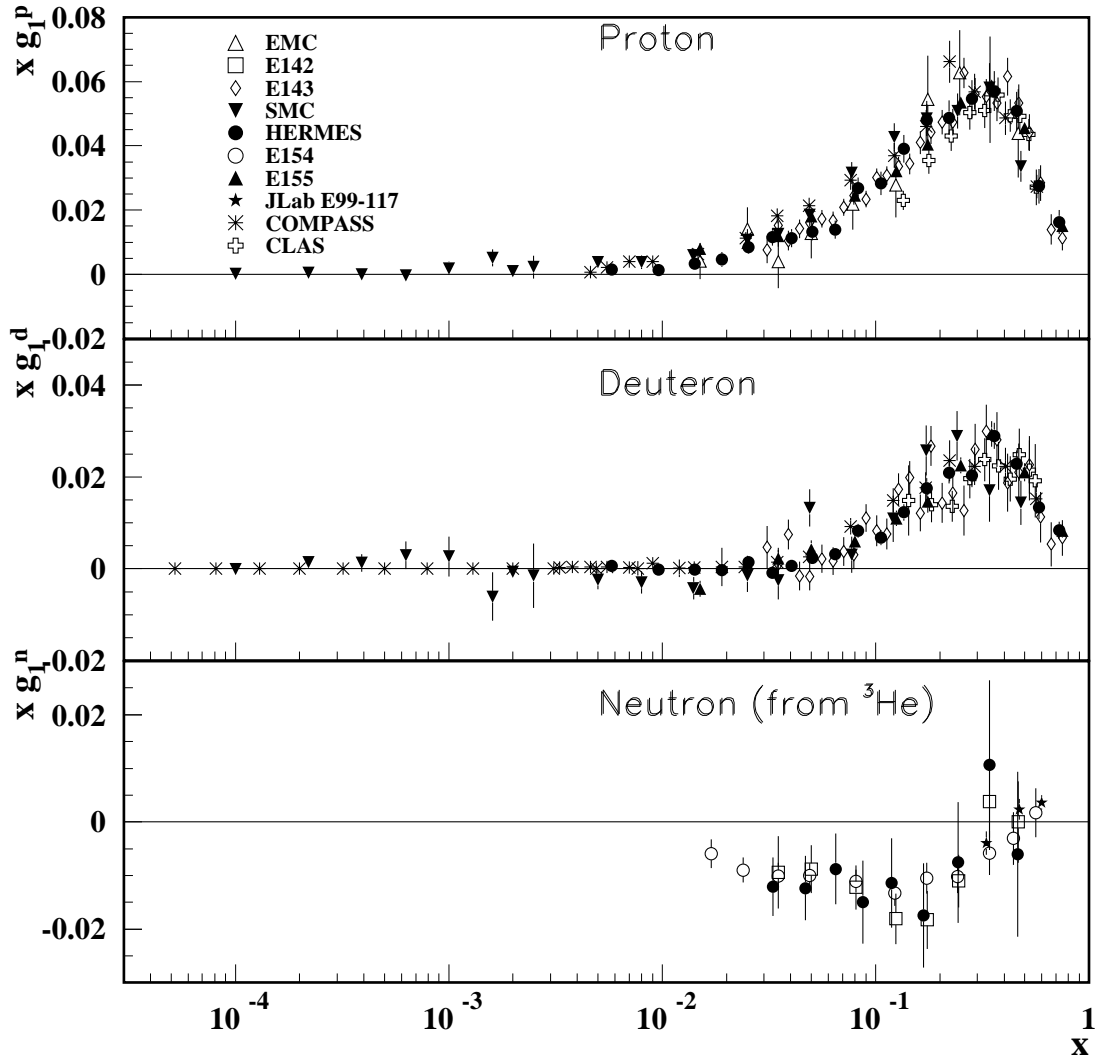

Figure 18.14: The spin-dependent structure function $xg_1(x)$ of the proton, deuteron, and neutron (from ${}^3\text{He}$ target) measured in deep inelastic scattering of polarized electrons/positrons: E142 ($Q^2 \sim 0.3 - 10 \text{ GeV}^2$), E143 ($Q^2 \sim 0.3 - 10 \text{ GeV}^2$), E154 ($Q^2 \sim 1 - 17 \text{ GeV}^2$), E155 ($Q^2 \sim 1 - 40 \text{ GeV}^2$), JLab E99-117 ($Q^2 \sim 2.71 - 4.83 \text{ GeV}^2$), HERMES ($Q^2 \sim 0.18 - 20 \text{ GeV}^2$), CLAS ($Q^2 \sim 1 - 5 \text{ GeV}^2$) and muons: EMC ($Q^2 \sim 1.5 - 100 \text{ GeV}^2$), SMC ($Q^2 \sim 0.01 - 100 \text{ GeV}^2$), COMPASS ($Q^2 \sim 0.001 - 100 \text{ GeV}^2$), shown at the measured Q^2 (except for EMC data given at $Q^2 = 10.7 \text{ GeV}^2$ and E155 data given at $Q^2 = 5 \text{ GeV}^2$). Note that $g_1^n(x)$ may also be extracted by taking the difference between $g_1^d(x)$ and $g_1^p(x)$, but these values have been omitted in the bottom plot for clarity. Statistical and systematic errors added in quadrature are shown. References: **EMC**—J. Ashman *et al.*, Nucl. Phys. **B328**, 1 (1989); **E142**—P.L. Anthony *et al.*, Phys. 19. FRAGMENTATION FUNCTIONS IN e^+e^- , ep AND pp COLLISIONS

Revised August 2011 by O. Biebel (Ludwig-Maximilians-Universität, Munich, Germany), D. de Florian (Dep. de Física, FCEyN-UBA, Buenos Aires, Argentina), D. Milstead (Fysikum, Stockholms Universitet, Sweden), and A. Vogt (Dep. of Mathematical Sciences, University of Liverpool, UK).

19.1. Introduction to fragmentation

The term ‘fragmentation functions’ is widely used for two related if conceptually different sets of functions describing final-state single particle energy distributions in hard scattering processes (see Refs. [1,2] for introductory reviews, and Refs. [3,4] for summaries of recent experimental and theoretical research in this field).

The first are cross-section observables such as the functions $F_{T,L,A}(x,s)$ in semi-inclusive e^+e^- annihilation at center-of-mass (CM) energy \sqrt{s} via an intermediate photon or Z -boson, $e^+e^- \rightarrow \gamma/Z \rightarrow h+X$, given by

$$\frac{1}{\sigma_0} \frac{d^2\sigma^h}{dx d\cos\theta} = \frac{3}{8}(1 + \cos^2\theta)F_T^h + \frac{3}{4}\sin^2\theta F_L^h + \frac{3}{4}\cos\theta F_A^h. \quad (19.1)$$

Here $x = 2E_h/\sqrt{s} \leq 1$ is the scaled energy of the hadron h (in practice the approximation $x \simeq x_p = 2p_h/\sqrt{s}$ is often used), and θ is its angle relative to the electron beam in the CM frame. Eq. (19.1) is the most general form for unpolarized inclusive single-particle production via vector bosons [5]. The transverse and longitudinal fragmentation functions F_T and F_L represent the contributions from γ/Z polarizations transverse or longitudinal with respect to the direction of motion of the hadron. The parity-violating term with the asymmetric fragmentation function F_A arises from the interference between vector and axial-vector contributions. Normalization factors σ_0 used in the literature range from the total cross section σ_{tot} for $e^+e^- \rightarrow$ hadrons, including all weak and QCD contributions, to $\sigma_0 = 4\pi\alpha^2 N_c/3s$ with $N_c = 3$, the lowest-order QED cross section for $e^+e^- \rightarrow \mu^+\mu^-$ times the number of colors N_c . LEP1 measurements of all three fragmentation functions are shown in Fig. 19.1.

Figure 19.1: LEP1 measurements of total transverse (F_T), longitudinal (F_L), and asymmetric (F_A) fragmentation functions [6–8]. Data points with relative errors greater than 100% are omitted.

Integration of Eq. (19.1) over θ yields the total fragmentation function $F^h = F_T^h + F_L^h$,

$$\frac{1}{\sigma_0} \frac{d\sigma^h}{dx} = F^h(x,s) = \sum_i \int_x^1 \frac{dz}{z} C_i(z, \alpha_s(\mu), \frac{s}{\mu^2}) D_i^h(\frac{x}{z}, \mu^2) + \mathcal{O}(\frac{1}{\sqrt{s}}) \quad (19.2)$$

with $i = u, \bar{u}, d, \bar{d}, \dots, g$. Here we have introduced the second set of functions mentioned in the first paragraph, the parton fragmentation functions (or fragmentation densities) D_i^h . These functions are the final-state analogue of the initial-state parton distributions addressed in Section 18 of this *Review*. Due to the different sign of the squared four-momentum q^2 of the intermediate gauge boson these two sets of distributions are also referred to as the timelike (e^+e^- annihilation, $q^2 > 0$) and spacelike (deep-inelastic scattering (DIS), $q^2 < 0$) parton distributions. The function $D_i^h(z, \mu^2)$ encodes the

probability that the parton i fragments into a hadron h carrying a fraction z of the parton’s momentum. Beyond the leading order (LO) of perturbative QCD these universal functions are factorization-scheme dependent, with ‘reasonable’ scheme choices retaining certain quark-parton-model (QPM) constraints such as the momentum sum rule

$$\sum_h \int_0^1 dz z D_i^h(z, \mu^2) = 1. \quad (19.3)$$

The dependence of the functions D_i^h on the factorization (or fragmentation) scale μ^2 (in Eq. (19.2) and below identified with the renormalization scale) is discussed in Section 19.2.

The second ingredient in Eq. (19.2), and analogous expressions for the functions $F_{T,L,A}$, are the observable-dependent coefficient functions C_i . At the zeroth order in the strong coupling α_s the coefficient functions C_g for gluons are zero, while for (anti-)quarks $C_i = g_i(s)\delta(1-z)$ except for F_L , where $g_i(s)$ is the appropriate electroweak coupling. In particular, $g_i(s)$ is proportional to the squared charge of the quark i at $s \ll M_Z^2$, when weak effects can be neglected. The full electroweak prefactors $g_i(s)$ can be found in Ref. [5]. The power corrections in Eq. (19.2) arise from quark and hadron mass terms and from non-perturbative effects.

Measurements of fragmentation in lepton-hadron and hadron-hadron scattering are complementary to those in e^+e^- annihilation. The latter provides a clean environment (no initial-state hadron remnant) and stringent constraints on the combinations $D_{q_i}^h + D_{\bar{q}_i}^h$. However e^+e^- annihilation is far less sensitive to D_g^h and insensitive to the charge asymmetries $D_{q_i}^h - D_{\bar{q}_i}^h$. These quantities are best constrained in proton-(anti-)proton and electron-proton scattering, respectively. Especially the latter provides a more complicated environment with which it is possible to study the influence on the fragmentation process from initial state QCD radiation, the partonic and spin structure of the hadron target, and the target remnant system (see Ref. [9] for a comprehensive review of the measurements and models of fragmentation in lepton-hadron scattering).

Moreover, unlike e^+e^- annihilation where $q^2 = s$ is fixed by the collider energy, lepton-hadron scattering has two independent scales, $Q^2 = -q^2$ and the invariant mass W^2 of the hadronic final state, which both can vary by several orders of magnitudes for a given CM energy, thus allowing the study of fragmentation in different environments by a single experiment. E.g., in photoproduction the exchanged photon is quasi-real ($Q^2 \approx 0$) leading to processes akin to hadron-hadron scattering. In DIS ($Q^2 \gg 1 \text{ GeV}^2$), using the QPM, the hadronic fragments of the struck quark can be directly compared with quark fragmentation in e^+e^- in a suitable frame. Results from lepton-hadron experiments quoted in this report primarily concern fragmentation in the DIS regime. Studies performed by lepton-hadron experiments of fragmentation with photoproduction data containing high transverse momentum jets or particles are also reported, when these are directly comparable to DIS and e^+e^- results.

Fragmentation studies at HERA are usually performed in one of two frames in which the target hadron and the exchanged boson are collinear. The hadronic center-of-mass frame (HCMS) is defined

as the rest system of the exchanged boson and incoming hadron, with the z^* -axis defined along the direction of the exchanged boson. The positive z^* direction defines the so-called current region. Fragmentation measurements performed in the HCMS often use the Feynman- x variable $x_F = 2p_z^*/W$, where p_z^* is the longitudinal momentum of the particle in this frame. As W is the invariant mass of the hadronic final state, x_F ranges between -1 and 1 .

The Breit system [10] is connected to the HCMS by a longitudinal boost such that the time component of q vanishes, i.e., $q = (0, 0, 0, -Q)$. In the QPM, the struck parton then has the longitudinal momentum $Q/2$ which becomes $-Q/2$ after the collision. As compared with the HCMS, the current region of the Breit frame is more closely matched to the partonic scattering process, and is thus appropriate for direct comparisons of fragmentation functions in DIS with those from e^+e^- annihilation. The variable $x_p = 2p^*/Q$ is used at HERA for measurements in the Breit frame, ensuring rather directly comparable DIS and e^+e^- results, where p^* is the particle's momentum in the current region of the Breit frame.

19.2. Scaling violation

The simplest parton-model approach would predict scale-independent x -distributions ('scaling') for both the fragmentation function F^h and the parton fragmentation functions D_i^h . Perturbative QCD corrections lead, after factorization of the final-state collinear singularities for light partons, to logarithmic scaling violations via the evolution equations

$$\frac{\partial}{\partial \ln \mu^2} D_i(x, \mu^2) = \sum_j \int_x^1 \frac{dz}{z} P_{ji}(z, \alpha_s(\mu^2)) D_j\left(\frac{x}{z}, \mu^2\right). \quad (19.4)$$

Usually this system of equations is decomposed into a 2×2 flavour-singlet sector comprising gluon and the sum of all quark and antiquark fragmentation functions, and scalar ('non-singlet') equations for quark-antiquark and flavour differences. Notice that the singlet splitting-function matrix is now P_{ji} , rather than P_{ij} as for the initial-state parton distributions, since D_j represents the fragmentation of the final parton.

The splitting functions in Eq. (19.4) have perturbative expansion of the form

$$P_{ji}(z, \alpha_s) = \frac{\alpha_s}{2\pi} P_{ji}^{(0)}(z) + \left(\frac{\alpha_s}{2\pi}\right)^2 P_{ji}^{(1)}(z) + \left(\frac{\alpha_s}{2\pi}\right)^3 P_{ji}^{(2)}(z) + \dots \quad (19.5)$$

where the leading-order (LO) functions $P^{(0)}(z)$ [11,12] are the same as those for the initial-state parton distributions. The next-to-leading order (NLO) corrections $P^{(1)}(z)$ have been calculated in Refs. [13–17] (there are well-known misprints in the journal version of Ref. [14]). Ref. [17] also includes the spin-dependent case. These functions are different from, but related to their space-like counterparts, see also Ref. [18]. These relations have facilitated recent calculations of the next-to-next-to-leading order (NNLO) quantities $P_{qq}^{(2)}(z)$ and $P_{gg}^{(2)}(z)$ in Eq. (19.5) [19,20]. The corresponding off-diagonal quantities $P_{qg}^{(2)}$ and $P_{gq}^{(2)}$ were recently obtained in Ref. [21] by using similar relations supplemented with constraints from the momentum sum rule Eq. (19.3) [20] and the supersymmetric limit. An uncertainty, which does not affect the logarithmic behaviour at small and large momentum fractions, still remains on the $P_{gg}^{(2)}$ kernel. All these results refer to the standard $\overline{\text{MS}}$ scheme, with the exception of Refs. [16], with a fixed number n_f of light flavours. The NLO treatment of flavour thresholds in the evolution has been addressed in Ref. [22].

The QCD parts of the coefficient functions for $F_{T,L,A}(x, s)$ in Eq. (19.1) and the total fragmentation function $F_2^h \equiv F^h$ in Eq. (19.2) are given by

$$C_{a,i}(z, \alpha_s) = (1 - \delta_{aL}) \delta_{iq} + \frac{\alpha_s}{2\pi} c_{a,i}^{(1)}(z) + \left(\frac{\alpha_s}{2\pi}\right)^2 c_{a,i}^{(2)}(z) + \dots \quad (19.6)$$

The first-order corrections have been calculated a long time ago in Refs. [23], and the second-order terms in [24]. The latter results have recently been verified (and some typos corrected) in Refs. [19,25]. Thus the coefficient functions are known to NNLO except for F_L where the leading contribution is of order α_s .

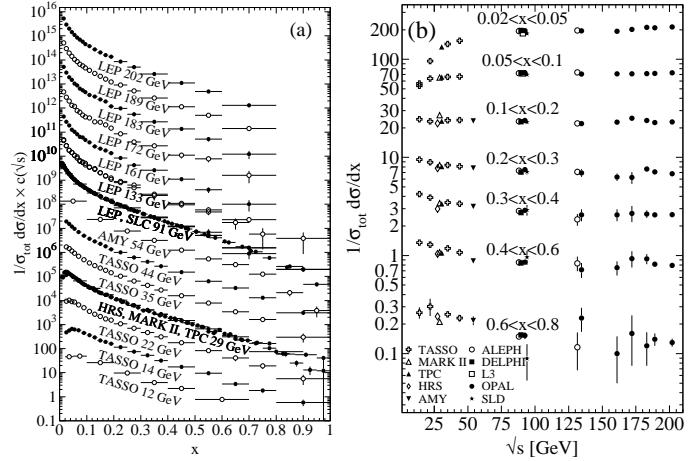

Figure 19.2: The e^+e^- fragmentation function for all charged particles is shown [8, 26–42] (a) for different CM energies \sqrt{s} versus x and (b) for various ranges of x versus \sqrt{s} . For the purpose of plotting (a), the distributions were scaled by $c(\sqrt{s}) = 10^i$ with i ranging from $i = 0$ ($\sqrt{s} = 12$ GeV) to $i = 13$ ($\sqrt{s} = 202$ GeV).

The effect of the evolution is similar in the timelike and spacelike cases: as the scale increases, one observes a scaling violation in which the x -distribution is shifted towards lower values. This can be seen from Fig. 19.2 where a large amount of measurements of the total fragmentation function in e^+e^- annihilation are summarized. QCD analyses of these data are discussed in Section 19.5 below.

Unlike the splitting functions in Eq. (19.5), see Refs. [18–20], the coefficient functions for $F_{2,T,A}$ in Eq. (19.6) show a threshold enhancement with terms up to $\alpha_s^n (1-z)^{-1} \ln^{2n-1}(1-z)$. Such logarithms can be resummed to all orders in α_s using standard soft-gluon techniques [43–45]. Recently this resummation has been extended to the subleading (and for F_L leading) class $\alpha_s^k \ln^k(1-z)$ of large- x logarithms [46,47].

In Refs. [23] the NLO coefficient functions have been calculated also for single hadron production in lepton-proton scattering, $ep \rightarrow e + h + X$. More recently corresponding results have been obtained for the case that a non-vanishing transverse momentum is required in the HCMS frame [48].

Scaling violations in DIS are shown in Fig. 19.3 for both HCMS and Breit frame. In Fig. 1.3(a) the distribution in terms of $x_F = 2p_z^*/W$ shows a steeper slope in ep data than for the lower-energy μp data for $x_F > 0.15$, indicating the scaling violations. At smaller values of x_F in the current jet region, the multiplicity of particles substantially increases with W owing to the increased phase space available for the fragmentation process. The EMC data access both the current region and the region of the fragmenting target remnant system. At higher values of $|x_F|$, due to the extended nature of the remnant, the multiplicity in the target region far exceeds that in the current region. For acceptance reasons the remnant hemisphere of the HCMS is only accessible by the lower-energy fixed-target experiments.

Using hadrons from the current hemisphere in the Breit frame, measurements of fragmentation functions and the production properties of particles in ep scattering have been made by Refs. [53–58]. Fig. 19.3(b) compares results from ep scattering and e^+e^- experiments, the latter results are halved as they cover both event hemispheres. The agreement between the DIS and e^+e^- results is fairly good. However, processes in DIS which are not present in e^+e^- annihilation, such as boson-gluon fusion and initial state QCD radiation, can depopulate the current region. These effects become most prominent at low values of Q and x_p . Hence, when compared with e^+e^- annihilation data at $\sqrt{s} = 5.2, 6.5$ GeV [60] not shown here, the DIS particle rates tend to lie below those from e^+e^- annihilation. A recent ZEUS study [61] finds that the direct comparability of the ep data to e^+e^- results at low scales is improved if twice the energy in the current hemisphere of

Figure 19.3: (a) The distribution $1/N \cdot dN/dx_F$ for all charged particles in DIS lepton-hadron experiments at different values of W , and measured in the HCMS [49–52]. (b) Scaling violations of the fragmentation function for all charged particles in the current region of the Breit frame of DIS [53,58] and in e^+e^- interactions [41,59]. The data are shown as a function of \sqrt{s} for e^+e^- results, and as a function of Q for the DIS results, each within the same indicated intervals of the scaled momentum x_p . The data for the four lowest intervals of x_p are multiplied by factors 50, 10, 5, and 3, respectively for clarity.

the Breit frame, $2E_B^{\text{CF}}$, is used instead of Q as the fragmentation scale.

19.3. Fragmentation functions for small particle momenta

The higher-order timelike splitting functions in Eq. (19.5) are very singular at small x . They show a double-logarithmic (LL) enhancement with leading terms of the form $\alpha_s^n \ln^{2n-2} x$ corresponding to poles $\alpha_s^n (N-1)^{1-2n}$ for the Mellin moments

$$P^{(n)}(N) = \int_0^1 dx x^{N-1} P^{(n)}(x). \quad (19.7)$$

Despite large cancellations between leading and non-leading logarithms at non-asymptotic value of x , the resulting small- x rise in the timelike splitting functions dwarfs that of their spacelike counterparts in the evolution of the parton distributions in Section 18 of this *Review*, see Fig. 1 of Ref. [20]. Consequently the fixed-order approximation to the evolution breaks down orders of magnitude in x earlier in fragmentation than in DIS.

The pattern of the known coefficients and other considerations suggest that the LL terms sum to all-order expressions without any pole at $N=1$ such as [62,63]

$$P_{gg}^{\text{LL}}(N) = -\frac{1}{4}(N-1 - \sqrt{(N-1)^2 - 24\alpha_s/\pi}). \quad (19.8)$$

Keeping the first three terms in the resulting expansion of Eq. (19.4) around $N=1$ yields a Gaussian in the variable $\xi = \ln(1/x)$ for the small- x fragmentation functions,

$$xD(x, s) \propto \exp\left[-\frac{1}{2\sigma^2}(\xi - \xi_p)^2\right], \quad (19.9)$$

with the peak position and width varying with the energy as [64] (see also Ref. [2])

$$\xi_p \simeq \frac{1}{4} \ln\left(\frac{s}{\Lambda^2}\right), \quad \sigma \propto \left[\ln\left(\frac{s}{\Lambda^2}\right)\right]^{3/4}. \quad (19.10)$$

Next-to-leading order corrections to the above predictions have been calculated [65]. In the method of Ref. [66], see also Refs. [67,68], the corrections are included in an analytical form known as the ‘modified leading logarithmic approximation’ (MLLA). Alternatively they can be used to compute higher-moment corrections to the shape in Eq. (19.9) [69]. Double-logarithmic contributions to the gluonic coefficient were derived in the standard $\overline{\text{MS}}$ scheme in Ref. [70]. The resummation of the dominant small x terms for the flavour-singlet splitting kernels and coefficient functions was recently studied in [71].

Fig. 19.4 shows the ξ distribution for charged particles produced in the current region of the Breit frame in DIS and in e^+e^- annihilation. Consistent with Eq. (19.9) (the ‘hump backed plateau’) and Eq. (19.10) the distributions have a Gaussian shape with the peak position and area increasing with the CM energy (e^+e^-) and Q^2 (DIS).

Figure 19.4: Distribution of $\xi = \ln(1/x_p)$ at several CM energies (e^+e^-) [26–28,33–36,41,72–75] and intervals of Q^2 (DIS) [56,57]. At each energy only one representative measurement is displayed. For clarity some measurements at intermediate CM energies (e^+e^-) or Q^2 ranges (DIS) are not shown. The DIS measurements ($*$) have been scaled by a factor of 2 for direct comparability with the e^+e^- results. Fits of simple Gaussian functions are overlaid for illustration.

The predicted energy dependence Eq. (19.10) of the peak in the ξ distribution is explained by soft gluon coherence (angular ordering) which correctly predicts the suppression of hadron production at small x . Of course, a decrease at very small x is expected on purely kinematical grounds, but this would occur at particle energies proportional to their masses, *i.e.*, at $x \propto m/\sqrt{s}$ and hence $\xi \sim \frac{1}{2} \ln s$. Thus, if the suppression were purely kinematic, the peak position ξ_p would vary twice as rapidly with the energy, which is ruled out by the data in Fig. 19.5. The e^+e^- and DIS data agree well with each other, demonstrating the universality of hadronization, and the MLLA prediction. Measurements of the higher moments of the ξ distribution in e^+e^- [41,75–77] and DIS [57] have also been performed and show consistency with each other.

Figure 19.5: Evolution of the peak position, ξ_p , of the ξ distribution with the CM energy \sqrt{s} . The MLLA QCD prediction using $\alpha_s(s = M_Z^2) = 0.118$ is superimposed to the data of Refs. [26,28,29,32–34,36,41,55,56,73,74,77–85].

19.4. Fragmentation models

Although the scaling violation can be calculated perturbatively, the actual form of the parton fragmentation functions is non-perturbative. Perturbative evolution gives rise to a shower of quarks and gluons (partons). Multi-parton final states from leading and higher order matrix element calculations are linked to these parton showers using factorization prescriptions, also called matching schemes, see Ref. [86] for an overview. Phenomenological schemes are then used to model the carry-over of parton momenta and flavor to the hadrons. Two of the very popular models are the *string fragmentation* [87,88], implemented in the JETSET [89], PYTHIA [90] and UCLA [91] Monte Carlo event generation programs, and the *cluster fragmentation* of the HERWIG [92] and SHERPA [93] Monte Carlo event generators. For details see Chap. 38 of this *Review*.

19.5. Quark and gluon fragmentation functions

The fragmentation functions are solutions to the evolution equations Eq. (19.4), but need to be parametrized at some initial scale μ_0^2 (usually around 1 GeV² for light quarks and gluons and m_Q^2 for heavy quarks). A usual parametrization for light hadrons is [94–100]

$$D_i^h(x, \mu_0^2) = N x^\alpha (1-x)^\beta (1 + \gamma(1-x)^\delta), \quad (19.11)$$

where the normalization N , and the parameters α , β , γ and δ in general depend on the energy scale μ_0^2 , and also on the type of the parton, i , and the hadron, h . Frequently the term involving γ and δ is left out [96–99]. Heavy flavor fragmentation into heavy mesons is discussed in Sec. 19.9. The parameters of Eq. (19.11) (see [94–99]) are obtained by performing global fits to data on various hadron types for different combinations of partons and hadrons in e^+e^- , lepton-hadron and hadron-hadron collisions.

Data from e^+e^- annihilation present the cleanest experimental source for the measurement of fragmentation functions, but can not contribute to disentangle quark from antiquark distributions. Since the bulk of the e^+e^- annihilation data is obtained at the mass of the Z -boson, where the electroweak couplings are roughly the same for the different partons, it provides the most precise determination of the flavor-singlet quark fragmentation. Flavor tagged results [101], distinguishing between the light quark, charm and bottom contributions are of particular value for flavor decomposition, even though those measurements can not be unambiguously interpreted in perturbative QCD.

The most relevant source for quark-antiquark (and also flavor) separation is provided by data from semi-inclusive DIS (SIDIS). Semi-inclusive measurements are usually performed at much lower scales than for e^+e^- annihilation. The inclusion of SIDIS data in global fits allows for a wider coverage in the evolution of the fragmentation functions, resulting at the same time in a stringent test of the universality of these distributions. Charged-hadron production data in hadronic collisions also presents a sensitivity on (anti-)quark fragmentation functions.

The gluon fragmentation function $D_g(x)$ can be extracted, in principle, from the longitudinal fragmentation function F_L in Eq. (19.2), as the coefficient functions $C_{L,i}$ for quarks and gluons are comparable at order α_s . However at NLO, *i.e.*, including the $\mathcal{O}(\alpha_s^2)$ coefficient functions $C_{L,i}^{(2)}$ [24], quark fragmentation is dominant in F_L over a large part of the kinematic range, reducing the sensitivity on D_g . This distribution could be determined also analyzing the evolution of the fragmentation functions. This possibility is limited by the lack of sufficiently precise data at energy scales away from the Z -resonance and the dominance of the quark contributions and at medium and large values of x .

D_g can also be deduced from the fragmentation of three-jet events in which the gluon jet is identified, for example, by tagging the other two jets with heavy quark decays. To leading order, the measured distributions of $x = E_{\text{had}}/E_{\text{jet}}$ for particles in gluon jets can be identified directly with the gluon fragmentation functions $D_g(x)$. At higher orders the theoretical interpretation of this observable is ambiguous.

A direct constraint on D_g is provided by $pp, p\bar{p} \rightarrow hX$ data. At variance with e^+e^- annihilation and SIDIS, for this process gluon fragmentation starts to contribute at the lowest order in the coupling constant, introducing a strong sensitivity on D_g . At large $x \gtrsim 0.5$, where information from e^+e^- is sparse, data from hadronic colliders facilitate significantly improved extractions of D_g [94,95].

Figure 19.6: Comparison of up, strange, charm and gluon NLO fragmentation functions for $\pi^+ + \pi^-$ at the mass of the Z . The different lines correspond to the result of the most recent analyses performed in Refs. [94,95,99].

A comparison of recent fits of NLO fragmentation functions for $\pi^+ + \pi^-$ obtained by DSS07 [94], AKK08 [95] and HKNS07 [99] is shown in Fig. 19.6. Differences between the sets are large especially for the gluon fragmentation function over the full range of x and for the quark distribution at large momentum fractions. Those discrepancies can be considered as a first estimate of the present uncertainties involved in the extraction of the fragmentation functions. The differences are even larger for other species of hadrons like kaons and protons [94,95,99].

19.6. Identified particles in e^+e^- and semi-inclusive DIS

A great wealth of measurements of e^+e^- fragmentation into identified particles exists. A collection of references for data on fragmentation into identified particles is given on Table 46.1. Representative of this body of data is Fig. 19.7 which shows fragmentation functions as the scaled momentum spectra of charged particles at several CM energies.

Quantitative results of studies of scaling violation in e^+e^- fragmentation have been reported in [6,39,103,104]. The values of α_s obtained are consistent with the world average (see review on QCD in Section 9 of this *Review*).

Many studies have been made of identified particles produced in lepton-hadron scattering, although fewer particle species have been measured than in e^+e^- collisions. References [105–110] and [111–117] are representative of the data from fixed target and ep collider experiments, respectively.

QCD calculations performed at NLO provide an overall good description of the HERA data [52,53,57,112,118,119] for both SIDIS [120] and the hadron transverse momentum distribution [48] in the kinematic regions in which the calculations are predictive.

Fig. 19.8(a) compares lower-energy fixed-target and HERA data on strangeness production, showing that the HERA spectra have substantially increased multiplicities, albeit with insufficient statistical precision to study scaling violations. The fixed-target data show that the Λ rate substantially exceeds the $\bar{\Lambda}$ rate in the remnant region, owing to the conserved baryon number from the baryon target. Fig. 19.8(b) shows neutral and charged pion fragmentation functions $1/N \cdot dn/dz$, where z is defined as the ratio of the pion energy to that of the exchanged boson, both measured in the laboratory frame. Results are shown from HERMES and the EMC experiments, where HERMES data have been evolved with NLO QCD to $\langle Q^2 \rangle = 25$ GeV² in order to be consistent with the EMC. Each of the experiments uses various kinematic cuts to ensure that the measured particles lie in

Figure 19.7: Scaled momentum spectra of (a) π^\pm , (b) K^\pm , and (c) p/\bar{p} at $\sqrt{s} = 10, 29, \text{ and } 91 \text{ GeV}$ [38,42,82,102].

the region which is expected to be associated with the struck quark. In the DIS kinematic regime accessed at these experiments, and over the range in z shown in Fig. 19.8, the z and x_F variables have similar values [49]. The precision data on identified particles can be used in the study of the quark flavor content of the proton [121].

Data on identified particle production can aid the investigation of the universality of jet fragmentation in e^+e^- and DIS. The strangeness suppression factor γ_s , as derived principally from tuning the Lund string model [88] within JETSET [89], is typically found to be around 0.3 in e^+e^- experiments [72], although values closer to 0.2 [122] have also been obtained. A number of measurements of so-called V^0 -particles (K^0, Λ^0) and the relative rates of V^0 's and inclusively produced charged particles have been performed at HERA [111,113,117] and fixed target experiments [105]. These typically favour a stronger suppression ($\gamma_s \approx 0.2$) than usually obtained from e^+e^- data although values close to 0.3 have also been obtained [123,124].

However, when comparing the description of QCD-based models for lepton-hadron interactions and e^+e^- collisions, it is important to note that the overall description by event generators of inclusively produced hadronic final states is more accurate in e^+e^- collisions than lepton-hadron interactions [125]. Predictions of particle rates in lepton-hadron scattering are affected by uncertainties in the modelling of the parton composition of the proton and photon, the extended target remnant, and initial and final state QCD radiation. Furthermore, the tuning of event generators for e^+e^- collisions is typically based on a larger set of parameters and uses more observables [72] than are used when optimizing models for lepton-hadron data [126].

Figure 19.8: (a) $1/N \cdot dn/dx_F$ for identified strange particles in DIS at various values of W [105,108,111]. (b) $1/N \cdot dn/dz$ for measurements of pions from fixed-target DIS experiment [106,109,110].

19.7. Fragmentation in hadron-hadron collisions

An extensive set on high-transverse momentum (p_T) single-inclusive hadron data has been collected in $h_1 h_2 \rightarrow hX$ scattering processes, both at high energy colliders and fixed-target experiments [127–145]. Only the transverse momentum p_T is considered in hadron-hadron collisions because of lack of knowledge of the longitudinal momentum of the hard subprocess. Fig. 19.9 shows a compilation of neutral pion and charged hadron production data for energies in the range $\sqrt{s} \approx 23 - 800 \text{ GeV}$.

The differential cross-section for high-transverse momentum distributions has been computed to next-to-leading order accuracy in perturbative QCD [146]. NLO calculations yield a good description of the collider data, but significantly under-predict the cross-section for several fixed-target energy data sets [147,148]. Data collected at high energy colliders are either included in global fit analyses or used as a test for the universality of fragmentation functions.

Different strategies have been developed to ameliorate the theoretical description at fixed-target energies. A possible phenomenological approach involves the introduction of a non-perturbative intrinsic partonic transverse momentum [145,149,150]. From the perturbative side, the resummation of the dominant higher order corrections at

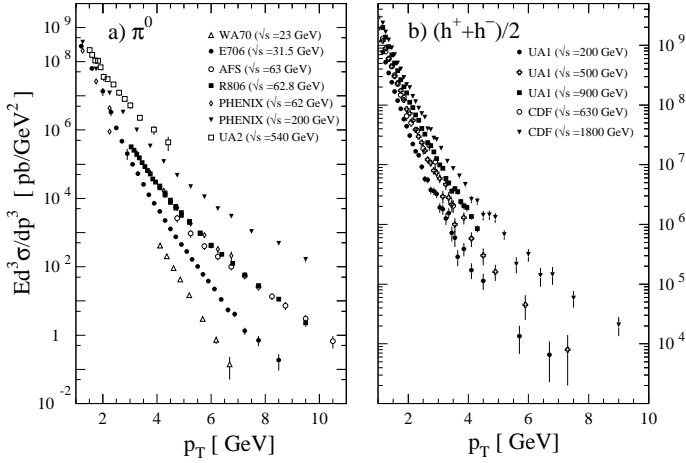

Figure 19.9: Selection of inclusive (a) π^0 and (b) charged-hadron production data from pp [135,142–145] and $p\bar{p}$ [127,130,133] collisions.

threshold produces an enhancement of the theoretical calculation that significantly improves the description of the data [151,152].

Measurements of hadron production in longitudinally polarized pp collisions are used mainly in the determination of the polarized gluon distribution in the proton [153,154].

Hadron production provides a critical observable for probing the high energy-density matter produced in heavy-ion collisions. Measurements at colliders show a suppression of inclusive hadron yields at high transverse momentum for AA collisions compared to pp scattering, indicating the formation of a dense medium opaque to quark and gluons, see e.g. [155].

19.8. Spin-dependent fragmentation

Measurements of charged-hadron production in unpolarized lepton-hadron scattering provide a unique tool to perform a flavor-separation determination of polarized parton densities from DIS interactions with longitudinally polarized targets [156–160].

Polarized scattering presents the possibility to measure the spin transfer from the struck quark to the final hadron, and thus develop spin-dependent fragmentation functions [161,162]. Early measurements of the longitudinal spin transfer to Lambda hyperons have been presented in [163,164]. This process is also useful in the study of the quark transversity distribution [165], which describes the probability of finding a transversely polarized quark with its spin aligned or anti-aligned with the spin of a transversely polarized nucleon. The transversity function is chiral-odd, and therefore not accessible through measurements of inclusive lepton-hadron scattering. Semi-inclusive DIS, in which another chiral-odd observable may be involved, provides a valuable tool to probe transversity. The Collins fragmentation function [166] relates the transverse polarization of the quark to that of the final hadron. It is chiral-odd and naive T-odd, leading to a characteristic single spin asymmetry in the azimuthal angular distribution of the produced hadron in the hadron scattering plane. Azimuthal angular distributions in semi-inclusive DIS can also be produced by other processes requiring non-polarized fragmentation functions, like the Sivers mechanism [167].

A number of experiments have measured these asymmetries [168–178]. Collins and Sivers asymmetries have been shown experimentally to be non zero by the HERMES measurements on transversely polarized proton targets [169–171]. Independent information on the Collins function has been provided by the BELLE Collaboration [172–173]. Measurements performed by the COMPASS collaboration on deuteron targets show results compatible with zero for both asymmetries [174–176].

19.9. Heavy quark fragmentation

It was recognized very early [179] that a heavy flavored meson should retain a large fraction of the momentum of the primordial heavy quark, and therefore its fragmentation function should be much harder than that of a light hadron. In the limit of a very heavy quark, one expects the fragmentation function for a heavy quark to go into any heavy hadron to be peaked near $x = 1$.

When the heavy quark is produced at a momentum much larger than its mass, one expects important perturbative effects, enhanced by powers of the logarithm of the transverse momentum over the heavy quark mass, to intervene and modify the shape of the fragmentation function. In leading logarithmic order (*i.e.*, including all powers of $\alpha_s \log m_Q/p_T$), the total (*i.e.*, summed over all hadron types) perturbative fragmentation function is simply obtained by solving the leading evolution equation for fragmentation functions, Eq. (19.4), with the initial condition at a scale $\mu^2 = m_Q^2$ given by $D_Q(z, m_Q^2) = \delta(1-z)$ and $D_i(z, m_Q^2) = 0$ for $i \neq Q$ (here $D_i(z)$, stands for the probability to produce a heavy quark Q from parton i with a fraction z of the parton momentum).

Several extensions of the leading logarithmic result have appeared in the literature. Next-to-leading-log (NLL) order results for the perturbative heavy quark fragmentation function have been obtained in [180]. The resummation of the dominant logarithmic contributions at large z was performed in [43] to next-to-leading-log accuracy. Fixed-order calculations of the fragmentation function at order α_s^2 in e^+e^- annihilation have appeared in [181] while the initial condition for the perturbative heavy quark fragmentation function has been extended to NNLO in [182].

Inclusion of non-perturbative effects in the calculation of the heavy-quark fragmentation function is done by convoluting the perturbative result with a phenomenological non-perturbative form [183–188], see also section 17.8 of [189]. The parameters entering the non-perturbative forms are fitted together with some model of hard radiation, which can be either a shower Monte Carlo, a leading-log or NLL calculation (which may or may not include Sudakov resummation), or a fixed order calculation [181,190].

A more conventional approach [191] involves the introduction of a unique set of heavy quark fragmentation functions of non-perturbative nature that obey the usual massless evolution equations in Eq. (19.4). Finite mass terms of the form $(m_Q/p_T)^n$ are kept in the corresponding short distance coefficient function for each scattering process. Within this approach, the initial condition for the perturbative fragmentation function provides the term needed to define the correct subtraction scheme to match the massless limit for the coefficient function (see e.g. [192]). Such implementation is in line with the variable flavor number scheme introduced for parton distributions functions, as described in Section 18 of this *Review*.

High statistics data for charmed mesons production near the Υ resonance (excluding decay products of B mesons) have been published [193,194]. They include results for D and D^* , D_s (see also [195,196]) and Λ_c . Shown in Fig. 19.10(a) are the CLEO and BELLE inclusive cross-sections times branching ratio \mathcal{B} , $s \cdot \mathcal{B} d\sigma/dx_p$, for the production of D^0 and D^{*+} . The variable x_p approximates the light-cone momentum fraction z , but is not identical to it. The two measurements are consistent with each other.

The branching ratio \mathcal{B} represents $D^0 \rightarrow K^-\pi^+$ for the D^0 results and for the D^{*+} the product branching fraction: $D^{*+} \rightarrow D^0\pi^+$, $D^0 \rightarrow K^-\pi^+$. Given the high precision of CLEO's and BELLE's data, a superposition of different parametric forms for the non-perturbative contribution is needed to obtain a good fit [22]. Older studies are reported in Refs. [197–199]. Charmed meson spectra on the Z peak have been published by OPAL and ALEPH [200,201].

Charm quark production has also been extensively studied at HERA by the H1 and ZEUS collaborations. Measurements have been made of $D^{*\pm}$, D^\pm , and D_s^\pm mesons; see, for example, Refs. [202,203]. The production of the Λ_c baryon has also been studied [204].

Experimental studies of the fragmentation function for b quarks, shown in Fig. 19.10(b), have been performed at LEP and SLD [205–207]. Commonly used methods identify the B meson

Figure 19.10: (a) Efficiency-corrected inclusive cross-section measurements for the production of D^0 and D^{*+} in e^+e^- measurements at $\sqrt{s} \approx 10.6$ GeV, excluding B decay products [193,194]. (b) Measured e^+e^- fragmentation function of b quarks into B hadrons at $\sqrt{s} \approx 91$ GeV [206].

through its semileptonic decay or based upon tracks emerging from the B secondary vertex. The studies in [206] fit the B spectrum using a Monte Carlo shower model supplemented with non-perturbative fragmentation functions yielding consistent results.

The experiments measure primarily the spectrum of B mesons. This defines a fragmentation function which includes the effect of the decay of higher mass excitations, like the B^* and B^{**} . In the literature, there is sometimes ambiguity in what is defined to be the bottom fragmentation function. Instead of using what is directly measured (*i.e.*, the B meson spectrum) corrections are applied to account for B^* or B^{**} production in some cases. For a more detailed discussion see section 17.8 of [189].

Heavy-flavor production in e^+e^- collisions is the primary source of information for the role of fragmentation effects in heavy-flavor production in hadron-hadron and lepton-hadron collisions. The QCD calculations tend to underestimate the data in certain regions of phase space. The discrepancy observed between theoretical calculations and the measured B meson spectrum at the hadron colliders [208] is substantially reduced when a more refined use of information on heavy flavor production from e^+e^- data is made [209] and when up-to-date parton distributions and strong coupling constant values are considered [210].

Both bottomed- and charmed-mesons spectra have been measured at the Tevatron with unprecedented accuracy [211]. The measured spectra are in good agreement with QCD calculations (including non-perturbative fragmentation effects inferred from e^+e^- data [212]),

no longer supporting the previously reported discrepancies [208].

The HERA collaborations have produced a number of measurements of beauty production; see, for example, Refs. [202,213–215]. As for the Tevatron data, the HERA results are described well by QCD-based calculations using fragmentation models optimised with e^+e^- data.

Besides degrading the fragmentation function by gluon radiation, QCD evolution can also generate soft heavy quarks, increasing in the small x region as \sqrt{s} increases. Several theoretical studies are available on the issue of how often $b\bar{b}$ or $c\bar{c}$ pairs are produced indirectly, via a gluon splitting mechanism [216–218]. Experimental results from studies on charm and bottom production via gluon splitting, given in [201,219–223], yield weighted averages of $\pi_{g \rightarrow c\bar{c}} = 3.05 \pm 0.45\%$ and $\pi_{g \rightarrow b\bar{b}} = 0.277 \pm 0.072\%$, respectively.

20. EXPERIMENTAL TESTS OF GRAVITATIONAL THEORY

Revised October 2011 by T. Damour (IHES, Bures-sur-Yvette, France).

Einstein's General Relativity, the current "standard" theory of gravitation, describes gravity as a universal deformation of the Minkowski metric:

$$g_{\mu\nu}(x^\lambda) = \eta_{\mu\nu} + h_{\mu\nu}(x^\lambda), \text{ where } \eta_{\mu\nu} = \text{diag}(-1, +1, +1, +1). \quad (20.1)$$

General Relativity is classically defined by two postulates. One postulate states that the Lagrangian density describing the propagation and self-interaction of the gravitational field is

$$\mathcal{L}_{\text{Ein}}[g_{\mu\nu}] = \frac{c^4}{16\pi G_N} \sqrt{g} g^{\mu\nu} R_{\mu\nu}(g), \quad (20.2)$$

$$R_{\mu\nu}(g) = \partial_\alpha \Gamma_{\mu\nu}^\alpha - \partial_\nu \Gamma_{\mu\alpha}^\alpha + \Gamma_{\alpha\beta}^\beta \Gamma_{\mu\nu}^\alpha - \Gamma_{\alpha\nu}^\beta \Gamma_{\mu\beta}^\alpha, \quad (20.3)$$

$$\Gamma_{\mu\nu}^\lambda = \frac{1}{2} g^{\lambda\sigma} (\partial_\mu g_{\nu\sigma} + \partial_\nu g_{\mu\sigma} - \partial_\sigma g_{\mu\nu}), \quad (20.4)$$

where G_N is Newton's constant, $g = -\det(g_{\mu\nu})$, and $g^{\mu\nu}$ is the matrix inverse of $g_{\mu\nu}$. A second postulate states that $g_{\mu\nu}$ couples universally, and minimally, to all the fields of the Standard Model by replacing everywhere the Minkowski metric $\eta_{\mu\nu}$. Schematically (suppressing matrix indices and labels for the various gauge fields and fermions and for the Higgs doublet),

$$\begin{aligned} \mathcal{L}_{\text{SM}}[\psi, A_\mu, H, g_{\mu\nu}] = & -\frac{1}{4} \sum \sqrt{g} g^{\mu\alpha} g^{\nu\beta} F_{\mu\nu}^a F_{\alpha\beta}^a \\ & - \sum \sqrt{g} \bar{\psi} \gamma^\mu D_\mu \psi \\ & - \frac{1}{2} \sqrt{g} g^{\mu\nu} D_\mu \bar{H} D_\nu H - \sqrt{g} V(H) \\ & - \sum \lambda \sqrt{g} \bar{\psi} H \psi, \end{aligned} \quad (20.5)$$

where $\gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu = 2g^{\mu\nu}$, and where the covariant derivative D_μ contains, besides the usual gauge field terms, a spin-dependent gravitational contribution. From the total action follow Einstein's field equations,

$$R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu} = \frac{8\pi G_N}{c^4} T_{\mu\nu}. \quad (20.6)$$

Here $R = g^{\mu\nu} R_{\mu\nu}$, $T_{\mu\nu} = g_{\mu\alpha} g_{\nu\beta} T^{\alpha\beta}$, and $T^{\mu\nu} = (2/\sqrt{g}) \delta \mathcal{L}_{\text{SM}} / \delta g_{\mu\nu}$ is the (symmetric) energy-momentum tensor of the Standard Model matter. The theory is invariant under arbitrary coordinate transformations: $x'^\mu = f^\mu(x^\nu)$. To solve the field equations Eq. (20.6), one needs to fix this coordinate gauge freedom. *E.g.*, the "harmonic gauge" (which is the analogue of the Lorenz gauge, $\partial_\mu A^\mu = 0$, in electromagnetism) corresponds to imposing the condition $\partial_\nu (\sqrt{g} g^{\mu\nu}) = 0$.

In this *Review*, we only consider the classical limit of gravitation (*i.e.* classical matter and classical gravity). Considering quantum matter in a classical gravitational background already poses interesting challenges, notably the possibility that the zero-point fluctuations of the matter fields generate a nonvanishing vacuum energy density ρ_{vac} , corresponding to a term $-\sqrt{g} \rho_{\text{vac}}$ in \mathcal{L}_{SM} [1]. This is equivalent to adding a "cosmological constant" term $+\Lambda g_{\mu\nu}$ on the left-hand side of Einstein's equations Eq. (20.6), with $\Lambda = 8\pi G_N \rho_{\text{vac}}/c^4$. Recent cosmological observations (see the following *Reviews*) suggest a positive value of Λ corresponding to $\rho_{\text{vac}} \approx (2.3 \times 10^{-3} \text{eV})^4$. Such a small value has a negligible effect on the tests discussed below.

20.1. Experimental tests of the coupling between matter and gravity

The universality of the coupling between $g_{\mu\nu}$ and the Standard Model matter postulated in Eq. (20.5) ("Equivalence Principle") has many observable consequences [2,3]. First, it predicts that the outcome of a local non-gravitational experiment, referred to local standards, does not depend on where, when, and in which locally inertial frame, the experiment is performed. This means, for instance, that local experiments should neither feel the cosmological evolution of the universe (constancy of the "constants"), nor exhibit preferred directions in spacetime (isotropy of space, local Lorentz

invariance). These predictions are consistent with many experiments and observations. Stringent limits on a possible time variation of the basic coupling constants have been obtained by analyzing a natural fission reactor phenomenon which took place at Oklo, Gabon, two billion years ago [4,5]. These limits are at the 1×10^{-7} level for the fractional variation of the fine-structure constant α_{em} [5], and at the 4×10^{-9} level for the fractional variation of the ratio between the light quark masses and Λ_{QCD} [6]. The determination of the lifetime of Rhenium 187 from isotopic measurements of some meteorites dating back to the formation of the solar system (about 4.6 Gyr ago) yields comparably strong limits [7]. Measurements of absorption lines in astronomical spectra also give stringent limits on the variability of both α_{em} (at the 10^{-5} level [8]), and $\mu = m_p/m_e$, *e.g.*

$$|\Delta\mu/\mu| < 1.8 \times 10^{-6} (95\% \text{ C.L.}), \quad (20.7)$$

at a redshift $z = 0.68466$ [9], and $\Delta\mu/\mu = (0.3 \pm 3.2_{\text{stat}} \pm 1.9_{\text{sys}}) \times 10^{-6}$ at the large redshift $z = 2.811$ [10]. Direct laboratory limits on the (present) time variation of α_{em} (based on monitoring the frequency ratio of several different atomic clocks) have recently reached the level [11]:

$$\dot{\alpha}_{\text{em}}/\alpha_{\text{em}} = (-1.6 \pm 2.3) \times 10^{-17} \text{yr}^{-1}.$$

There are also experimental limits on a possible dependence of coupling constants on the gravitational potential [12]. See [13] for a review of the issue of "variable constants."

The highest precision tests of the isotropy of space have been performed by looking for possible quadrupolar shifts of nuclear energy levels [14]. The (null) results can be interpreted as testing the fact that the various pieces in the matter Lagrangian Eq. (20.5) are indeed coupled to one and the same external metric $g_{\mu\nu}$ to the 10^{-29} level. For astrophysical constraints on possible Planck-scale violations of Lorentz invariance, see Ref. 15.

The universal coupling to $g_{\mu\nu}$ postulated in Eq. (20.5) implies that two (electrically neutral) test bodies dropped at the same location and with the same velocity in an external gravitational field fall in the same way, independently of their masses and compositions. The universality of the acceleration of free fall has been verified at the 10^{-13} level for laboratory bodies, notably Beryllium and Titanium test bodies [16],

$$(\Delta a/a)_{\text{BeTi}} = (0.3 \pm 1.8) \times 10^{-13}, \quad (20.8)$$

as well as for the gravitational accelerations of the Earth and the Moon toward the Sun [17],

$$(\Delta a/a)_{\text{EarthMoon}} = (-1.0 \pm 1.4) \times 10^{-13}. \quad (20.9)$$

The latter result constrains not only how $g_{\mu\nu}$ couples to matter, but also how it couples to itself [18] ("strong equivalence principle"; see Eq. (20.15) below, and the end of the section on binary pulsar tests). See also Ref. 19 for a review of torsion balance experiments.

Finally, Eq. (20.5) also implies that two identically constructed clocks located at two different positions in a static external Newtonian potential $U(\mathbf{x}) = \sum G_N m/r$ exhibit, when intercompared by means of electromagnetic signals, the (apparent) difference in clock rate, $\tau_1/\tau_2 = \nu_2/\nu_1 = 1 + [U(\mathbf{x}_1) - U(\mathbf{x}_2)]/c^2 + O(1/c^4)$, independently of their nature and constitution. This universal gravitational redshift of clock rates has been verified at the 10^{-4} level by comparing a hydrogen-maser clock flying on a rocket up to an altitude $\sim 10,000$ km to a similar clock on the ground [20]. The redshift due to a height change of only 33 cm has been recently detected by comparing two optical clocks based on $^{27}\text{Al}^+$ ions [21].

20.2. Tests of the dynamics of the gravitational field in the weak field regime

The effect on matter of one-graviton exchange, *i.e.*, the interaction Lagrangian obtained when solving Einstein's field equations Eq. (20.6) written in, say, the harmonic gauge at first order in $h_{\mu\nu}$,

$$\square h_{\mu\nu} = -\frac{16\pi G_N}{c^4}(T_{\mu\nu} - \frac{1}{2}T\eta_{\mu\nu}) + O(h^2) + O(hT), \quad (20.10)$$

reads $-(8\pi G_N/c^4)T^{\mu\nu}\square^{-1}(T_{\mu\nu} - \frac{1}{2}T\eta_{\mu\nu})$. For a system of N moving

point masses, with free Lagrangian $L^{(1)} = \sum_{A=1}^N -m_A c^2 \sqrt{1 - v_A^2/c^2}$, this interaction, expanded to order v^2/c^2 , reads (with $r_{AB} \equiv |\mathbf{x}_A - \mathbf{x}_B|$, $\mathbf{n}_{AB} \equiv (\mathbf{x}_A - \mathbf{x}_B)/r_{AB}$)

$$L^{(2)} = \frac{1}{2} \sum_{A \neq B} \frac{G_N m_A m_B}{r_{AB}} \left[1 + \frac{3}{2c^2}(v_A^2 + v_B^2) - \frac{7}{2c^2}(\mathbf{v}_A \cdot \mathbf{v}_B) - \frac{1}{2c^2}(\mathbf{n}_{AB} \cdot \mathbf{v}_A)(\mathbf{n}_{AB} \cdot \mathbf{v}_B) + O\left(\frac{1}{c^4}\right) \right]. \quad (20.11)$$

The two-body interactions, Eq. (20.11), exhibit v^2/c^2 corrections to Newton's $1/r$ potential induced by spin-2 exchange ("gravito-magnetism"). Consistency at the "post-Newtonian" level $v^2/c^2 \sim G_N m/r c^2$ requires that one also considers the three-body interactions induced by some of the three-graviton vertices and other nonlinearities (terms $O(h^2)$ and $O(hT)$ in Eq. (20.10)),

$$L^{(3)} = -\frac{1}{2} \sum_{B \neq A \neq C} \frac{G_N^2 m_A m_B m_C}{r_{AB} r_{AC} c^2} + O\left(\frac{1}{c^4}\right). \quad (20.12)$$

All currently performed gravitational experiments in the solar system, including perihelion advances of planetary orbits, the bending and delay of electromagnetic signals passing near the Sun, and very accurate ranging data to the Moon obtained by laser echoes, are compatible with the post-Newtonian results Eqs. (20.10)–(20.12). The "gravito-magnetic" interactions $\propto v_A v_B$ contained in Eq. (20.11) are involved in many of these experimental tests. They have been particularly tested in lunar laser ranging data [17], in the LAGEOS satellite observations [22], and in the dedicated Gravity Probe B mission [23].

Similar to what is done in discussions of precision electroweak experiments, it is useful to quantify the significance of precision gravitational experiments by parameterizing plausible deviations from General Relativity. The addition of a mass-term in Einstein's field equations leads to a score of theoretical difficulties which have not yet received any consensual solution. We shall, therefore, not consider here the ill-defined "mass of the graviton" as a possible deviation parameter from General Relativity (see, however, Ref. 24). Deviations from Einstein's pure spin-2 theory are then defined by adding new, bosonic light or massless, macroscopically coupled fields. The possibility of new gravitational-strength couplings leading (on small, and possibly large, scales) to deviations from Einsteinian (and Newtonian) gravity is suggested by String Theory [25], and by Brane World ideas [26]. For reviews of experimental constraints on Yukawa-type additional interactions, see Refs. [19,27]. Recent experiments have set limits on non-Newtonian forces below 0.056 mm [28].

Here, we shall focus on the parametrization of long-range deviations from relativistic gravity obtained by adding a strictly massless (*i.e.* without self-interaction $V(\varphi) = 0$) scalar field φ coupled to the trace of the energy-momentum tensor $T = g_{\mu\nu} T^{\mu\nu}$ [29]. The most general such theory contains an arbitrary function $a(\varphi)$ of the scalar field, and can be defined by the Lagrangian

$$\mathcal{L}_{\text{tot}}[g_{\mu\nu}, \varphi, \psi, A_\mu, H] = \frac{c^4}{16\pi G} \sqrt{g}(R(g_{\mu\nu}) - 2g^{\mu\nu} \partial_\mu \varphi \partial_\nu \varphi) + \mathcal{L}_{\text{SM}}[\psi, A_\mu, H, \tilde{g}_{\mu\nu}], \quad (20.13)$$

where G is a "bare" Newton constant, and where the Standard Model matter is coupled not to the "Einstein" (pure spin-2) metric $g_{\mu\nu}$, but to the conformally related ("Jordan-Fierz") metric $\tilde{g}_{\mu\nu} = \exp(2a(\varphi))g_{\mu\nu}$. The scalar field equation $\square_g \varphi = -(4\pi G/c^4)\alpha(\varphi)T$ displays $\alpha(\varphi) \equiv \partial a(\varphi)/\partial \varphi$ as the basic (field-dependent) coupling between φ and matter [30]. The one-parameter (ω) Jordan-Fierz-Brans-Dicke theory [29] is the special case $a(\varphi) = \alpha_0 \varphi$ leading to a field-independent coupling $\alpha(\varphi) = \alpha_0$ (with $\alpha_0^2 = 1/(2\omega + 3)$). The addition of a self-interaction term $V(\varphi)$ in Eq. (20.13) introduces new phenomenological possibilities; notably the "chameleon mechanism" [31].

In the weak-field slow-motion limit appropriate to describing gravitational experiments in the solar system, the addition of φ modifies Einstein's predictions only through the appearance of two "post-Einstein" dimensionless parameters: $\bar{\gamma} = -2\alpha_0^2/(1 + \alpha_0^2)$ and $\bar{\beta} = +\frac{1}{2}\beta_0\alpha_0^2/(1 + \alpha_0^2)^2$, where $\alpha_0 \equiv \alpha(\varphi_0)$, $\beta_0 \equiv \partial\alpha(\varphi_0)/\partial\varphi_0$, φ_0 denoting the vacuum expectation value of φ . These parameters show up also naturally (in the form $\gamma_{\text{PPN}} = 1 + \bar{\gamma}$, $\beta_{\text{PPN}} = 1 + \bar{\beta}$) in phenomenological discussions of possible deviations from General Relativity [2]. The parameter $\bar{\gamma}$ measures the admixture of spin 0 to Einstein's graviton, and contributes an extra term $+\bar{\gamma}(\mathbf{v}_A - \mathbf{v}_B)^2/c^2$ in the square brackets of the two-body Lagrangian Eq. (20.11). The parameter $\bar{\beta}$ modifies the three-body interaction Eq. (20.12) by an overall multiplicative factor $1 + 2\bar{\beta}$. Moreover, the combination $\eta \equiv 4\bar{\beta} - \bar{\gamma}$ parameterizes the lowest order effect of the self-gravity of orbiting masses by modifying the Newtonian interaction energy terms in Eq. (20.11) into $G_{AB} m_A m_B / r_{AB}$, with a body-dependent gravitational "constant" $G_{AB} = G_N [1 + \eta(E_A^{\text{grav}}/m_A c^2 + E_B^{\text{grav}}/m_B c^2) + O(1/c^4)]$, where $G_N = G \exp[2a(\varphi_0)](1 + \alpha_0^2)$ and where E_A^{grav} denotes the gravitational binding energy of body A .

The best current limits on the post-Einstein parameters $\bar{\gamma}$ and $\bar{\beta}$ are (at the 68% confidence level):

$$\bar{\gamma} = (2.1 \pm 2.3) \times 10^{-5}, \quad (20.14)$$

deduced from the additional Doppler shift experienced by radio-wave beams connecting the Earth to the Cassini spacecraft when they passed near the Sun [32], and

$$4\bar{\beta} - \bar{\gamma} = (4.4 \pm 4.5) \times 10^{-4}, \quad (20.15)$$

from Lunar Laser Ranging measurements [17] of a possible polarization of the Moon toward the Sun [18]. More stringent limits on $\bar{\gamma}$ are obtained in models (*e.g.*, string-inspired ones [25]) where scalar couplings violate the Equivalence Principle.

20.3. Tests of the dynamics of the gravitational field in the radiative and/or strong field regimes

The discovery of pulsars (*i.e.*, rotating neutron stars emitting a beam of radio noise) in gravitationally bound orbits [33,34] has opened up an entirely new testing ground for relativistic gravity, giving us an experimental handle on the regime of radiative and/or strong gravitational fields. In these systems, the finite velocity of propagation of the gravitational interaction between the pulsar and its companion generates damping-like terms at order $(v/c)^5$ in the equations of motion [35]. These damping forces are the local counterparts of the gravitational radiation emitted at infinity by the system ("gravitational radiation reaction"). They cause the binary orbit to shrink and its orbital period P_b to decrease. The remarkable stability of pulsar clocks has allowed one to measure the corresponding very small orbital period decay $\dot{P}_b \equiv dP_b/dt \sim -(v/c)^5 \sim -10^{-12}$ in several binary systems, thereby giving us a direct experimental confirmation of the propagation properties of the gravitational field, and, in particular, an experimental confirmation that the speed of propagation of gravity is equal to the velocity of light to better than a part in a thousand. In addition, the surface gravitational potential of a neutron star $h_{00}(R) \simeq 2Gm/c^2 R \simeq 0.4$ being a factor $\sim 10^8$ higher than the surface potential of the Earth, and a mere factor 2.5 below the black hole limit ($h_{00}(R) = 1$), pulsar data have allowed one to obtain several accurate tests of the strong-gravitational-field regime, as we discuss next.

Binary pulsar timing data record the times of arrival of successive electromagnetic pulses emitted by a pulsar orbiting around the center of mass of a binary system. After correcting for the Earth motion around the Sun and for the dispersion due to propagation in the interstellar plasma, the time of arrival of the N th pulse t_N can be described by a generic, parameterized “timing formula” [36] whose functional form is common to the whole class of tensor-scalar gravitation theories:

$$t_N - t_0 = F[T_N(\nu_p, \dot{\nu}_p, \ddot{\nu}_p); \{p^K\}; \{p^{PK}\}]. \quad (20.16)$$

Here, T_N is the pulsar proper time corresponding to the N th turn given by $N/2\pi = \nu_p T_N + \frac{1}{2}\dot{\nu}_p T_N^2 + \frac{1}{6}\ddot{\nu}_p T_N^3$ (with $\nu_p \equiv 1/P_p$ the spin frequency of the pulsar, *etc.*), $\{p^K\} = \{P_b, T_0, e, \omega_0, x\}$ is the set of “Keplerian” parameters (notably, orbital period P_b , eccentricity e , periastron longitude ω_0 and projected semi-major axis $x = a \sin i/c$), and $\{p^{PK}\} = \{k, \gamma_{\text{timing}}, \dot{P}_b, r, s, \delta\theta, \dot{e}, \dot{x}\}$ denotes the set of (separately measurable) “post-Keplerian” parameters. Most important among these are: the fractional periastron advance per orbit $k \equiv \dot{\omega} P_b / 2\pi$, a dimensionful time-dilation parameter γ_{timing} , the orbital period derivative \dot{P}_b , and the “range” and “shape” parameters of the gravitational time delay caused by the companion, r and s .

Without assuming any specific theory of gravity, one can phenomenologically analyze the data from any binary pulsar by least-squares fitting the observed sequence of pulse arrival times to the timing formula Eq. (20.16). This fit yields the “measured” values of the parameters $\{\nu_p, \dot{\nu}_p, \ddot{\nu}_p\}$, $\{p^K\}$, $\{p^{PK}\}$. Now, each specific relativistic theory of gravity predicts that, for instance, k , γ_{timing} , \dot{P}_b , r and s (to quote parameters that have been successfully measured from some binary pulsar data) are some theory-dependent functions of the Keplerian parameters and of the (unknown) masses m_1, m_2 of the pulsar and its companion. For instance, in General Relativity, one finds (with $M \equiv m_1 + m_2$, $n \equiv 2\pi/P_b$)

$$\begin{aligned} k^{\text{GR}}(m_1, m_2) &= 3(1 - e^2)^{-1} (G_N M n / c^3)^{2/3}, \\ \gamma_{\text{timing}}^{\text{GR}}(m_1, m_2) &= e n^{-1} (G_N M n / c^3)^{2/3} m_2 (m_1 + 2m_2) / M^2, \\ \dot{P}_b^{\text{GR}}(m_1, m_2) &= - (192\pi/5) (1 - e^2)^{-7/2} \left(1 + \frac{73}{24} e^2 + \frac{37}{96} e^4 \right) \\ &\quad \times (G_N M n / c^3)^{5/3} m_1 m_2 / M^2, \\ r(m_1, m_2) &= G_N m_2 / c^3, \\ s(m_1, m_2) &= n x (G_N M n / c^3)^{-1/3} M / m_2. \end{aligned} \quad (20.17)$$

In tensor-scalar theories, each of the functions $k^{\text{theory}}(m_1, m_2)$, $\gamma_{\text{timing}}^{\text{theory}}(m_1, m_2)$, $\dot{P}_b^{\text{theory}}(m_1, m_2)$, *etc.*, is modified by quasi-static strong field effects (associated with the self-gravities of the pulsar and its companion), while the particular function $\dot{P}_b^{\text{theory}}(m_1, m_2)$ is further modified by radiative effects (associated with the spin 0 propagator) [30,37,38].

Let us give some highlights of the current experimental situation (see Ref. 39 for a more extensive review). In the first discovered binary pulsar PSR1913 + 16 [33,34], it has been possible to measure with accuracy *three* post-Keplerian parameters: k , γ_{timing} and \dot{P}_b . The three equations $k^{\text{measured}} = k^{\text{theory}}(m_1, m_2)$, $\gamma_{\text{timing}}^{\text{measured}} = \gamma_{\text{timing}}^{\text{theory}}(m_1, m_2)$, $\dot{P}_b^{\text{measured}} = \dot{P}_b^{\text{theory}}(m_1, m_2)$ determine, for each given theory, three curves in the two-dimensional mass plane. This yields *one* (combined radiative/strong-field) test of the specified theory, according to whether the three curves meet at one point, as they should. After subtracting a small ($\sim 10^{-14}$ level in $\dot{P}_b^{\text{obs}} = (-2.423 \pm 0.001) \times 10^{-12}$), but significant, Newtonian perturbing effect caused by the Galaxy [40], one finds that General Relativity passes this $(k - \gamma_{\text{timing}} - \dot{P}_b)_{1913+16}$ test with complete success at the 10^{-3} level [34,41,42]

$$\left[\frac{\dot{P}_b^{\text{obs}} - \dot{P}_b^{\text{galactic}}}{\dot{P}_b^{\text{GR}}[k^{\text{obs}}, \gamma_{\text{timing}}^{\text{obs}}]} \right]_{1913+16} = 0.997 \pm 0.002. \quad (20.18)$$

Here $\dot{P}_b^{\text{GR}}[k^{\text{obs}}, \gamma_{\text{timing}}^{\text{obs}}]$ is the result of inserting in $\dot{P}_b^{\text{GR}}(m_1, m_2)$ the values of the masses predicted by the two equations $k^{\text{obs}} =$

$k^{\text{GR}}(m_1, m_2)$, $\gamma_{\text{timing}}^{\text{obs}} = \gamma_{\text{timing}}^{\text{GR}}(m_1, m_2)$. This yields experimental evidence for the reality of gravitational radiation damping forces at the $(-3 \pm 2) \times 10^{-3}$ level.

The discovery of the binary pulsar PSR1534 + 12 [43] has allowed one to measure *five* post-Keplerian parameters: k , γ_{timing} , r , s , and (with less accuracy) \dot{P}_b [44,45]. This allows one to obtain *three* (five observables minus two masses) tests of relativistic gravity. Two among these tests probe strong field gravity, without mixing of radiative effects [44]. General Relativity passes all these tests within the measurement accuracy. The most precise of the new, pure strong-field tests is the one obtained by combining the measurements of k , γ , and s . Using the most recent data [45], one finds agreement at the 1% level:

$$\left[\frac{s^{\text{obs}}}{s^{\text{GR}}[k^{\text{obs}}, \gamma_{\text{timing}}^{\text{obs}}]} \right]_{1534+12} = 1.000 \pm 0.007. \quad (20.19)$$

The discovery of the binary pulsar PSR J1141 – 6545 [46] (whose companion is probably a white dwarf) has allowed one to measure *four* observable parameters: k , γ_{timing} , \dot{P}_b [47,48], and the parameter s [49,48]. The latter parameter (which is equal to the sine of the inclination angle, $s = \sin i$) was consistently measured in two ways: from a scintillation analysis [49], and from timing measurements [48]. General Relativity passes all the corresponding tests within measurement accuracy. See Fig. 20.1 which uses the (more precise) scintillation measurement of $s = \sin i$.

The discovery of the remarkable *double* binary pulsar PSR J0737 – 3039 A and B [50,51] has led to the measurement of *seven* independent parameters [52,53]: five of them are the post-Keplerian parameters k , γ_{timing} , r , s and \dot{P}_b entering the relativistic timing formula of the fast-spinning pulsar PSR J0737 – 3039 A, a sixth is the ratio $R = x_B/x_A$ between the projected semi-major axis of the more slowly spinning companion pulsar PSR J0737 – 3039 B, and that of PSR J0737 – 3039 A. [The theoretical prediction for the ratio $R = x_B/x_A$, considered as a function of the (inertial) masses $m_1 = m_A$ and $m_2 = m_B$, is $R^{\text{theory}} = m_1/m_2 + O((v/c)^4)$ [36], independently of the gravitational theory considered.] Finally, the seventh parameter $\Omega_{\text{SO,B}}$ is the angular rate of (spin-orbit) precession of PSR J0737 – 3039 B around the total angular momentum [53]. These seven measurements give us *five* tests of relativistic gravity [52,54]. General Relativity passes all those tests with flying colors (see Fig. 20.1). Let us highlight here two of them.

One test is a new, precise confirmation of the reality of gravitational radiation

$$\left[\frac{\dot{P}_b^{\text{obs}}}{\dot{P}_b^{\text{GR}}[k^{\text{obs}}, R^{\text{obs}}]} \right]_{0737-3039} = 1.003 \pm 0.014. \quad (20.20)$$

Another one is an accurate (5×10^{-4} level) new strong-field confirmation of General Relativity:

$$\left[\frac{s^{\text{obs}}}{s^{\text{GR}}[k^{\text{obs}}, R^{\text{obs}}]} \right]_{0737-3039} = 0.99987 \pm 0.00050. \quad (20.21)$$

Fig. 20.1 illustrates all the tests of strong-field and radiative gravity derived from the above-mentioned binary pulsars: $(3 - 2 =)$ one test from PSR1913 + 16, $(5 - 2 =)$ 3 tests from PSR1534 + 12, $(4 - 2 =)$ 2 tests from PSR J1141 – 6545, and $(7 - 2 =)$ 5 tests from PSR J0737 – 3039.

Data from several nearly circular binary systems (made of a neutron star and a white dwarf) have also led to strong-field confirmations (at the 4.6×10^{-3} level) of the ‘strong equivalence principle,’ *i.e.*, the fact that neutron stars and white dwarfs fall with the same acceleration in the gravitational field of the Galaxy [55,56]. The measurements of \dot{P}_b in some pulsar-white dwarf systems lead to strong constraints on the variation of Newton’s G_N , and on the existence of gravitational dipole radiation [57,58]. In addition, arrays of millisecond pulsars are sensitive detectors of (very low frequency) gravitational waves [59].

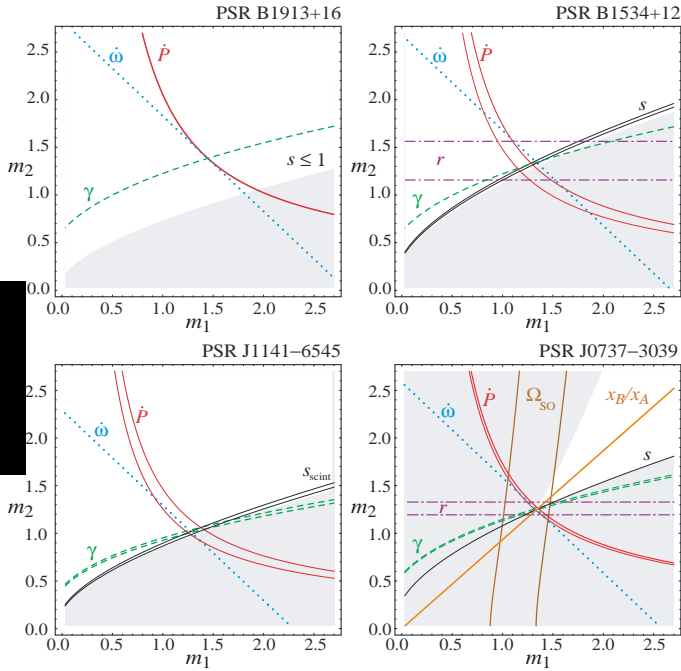

Figure 20.1: Illustration of the *eleven* tests of relativistic gravity obtained in the four different binary pulsar systems: PSR1913 + 16 (one test), PSR1534 + 12 (3 tests), PSR J1141 – 6545 (2 tests), and PSR J0737 – 3039 A,B (5 tests). Each curve (or strip) in the mass plane corresponds to the interpretation, within General Relativity, of some observable parameter among: \dot{P}_b , $k \equiv \dot{\omega}P_b/2\pi$, γ_{timing} , r , $s = \sin i$, $\Omega_{\text{SO,B}}$ and R . (Figure updated from [61]; courtesy of G. Esposito-Farèse.)

They constrain the contribution $\Omega_{gw}(f)$ to the critical cosmological density of a stochastic background of gravitational waves to the level $\Omega_{gw}(1/(\text{Syr})) < 2 \times 10^{-8} h^{-2}$ [60] (here, h denotes the normalized Hubble expansion rate).

The constraints on tensor-scalar theories provided by the various binary-pulsar “experiments” have been analyzed in [38,61,62] and shown to exclude a large portion of the parameter space allowed by solar-system tests. Finally, measurements over several years of the pulse profiles of various pulsars have detected secular profile changes compatible with the prediction [63] that the general relativistic spin-orbit coupling should cause a secular change in the orientation of the pulsar beam with respect to the line of sight (“geodetic precession”). Such confirmations of general-relativistic spin-orbit effects were obtained in PSR 1913+16 [64], PSR B1534+12 [65], PSR J1141–6545 [66], and PSR J0737 – 3039 [53].

The tests considered above have examined the gravitational interaction on scales between a fraction of a millimeter and a few astronomical units. On the other hand, the general relativistic action on light and matter of an external gravitational field have been verified on much larger scales in many gravitational lensing systems. For quantitative tests on kiloparsec scales see Ref. 67. Some tests on cosmological scales are also available [68].

20.4. Conclusions

All present experimental tests are compatible with the predictions of the current “standard” theory of gravitation: Einstein’s General Relativity. The universality of the coupling between matter and gravity (Equivalence Principle) has been verified around the 10^{-13} level. Solar system experiments have tested the weak-field predictions of Einstein’s theory at the 10^{-4} level (and down to the 2×10^{-5} level for the post-Einstein parameter $\bar{\gamma}$). The propagation properties of relativistic gravity, as well as several of its strong-field aspects, have been verified at the 10^{-3} level in binary pulsar experiments. Recent laboratory experiments have also set strong constraints on sub-millimeter modifications of Newtonian gravity.

21. BIG-BANG COSMOLOGY

Revised September 2011 by K.A. Olive (University of Minnesota) and J.A. Peacock (University of Edinburgh).

21.1. Introduction to Standard Big-Bang Model

The observed expansion of the Universe [1,2,3] is a natural (almost inevitable) result of any homogeneous and isotropic cosmological model based on general relativity. However, by itself, the Hubble expansion does not provide sufficient evidence for what we generally refer to as the Big-Bang model of cosmology. While general relativity is in principle capable of describing the cosmology of any given distribution of matter, it is extremely fortunate that our Universe appears to be homogeneous and isotropic on large scales. Together, homogeneity and isotropy allow us to extend the Copernican Principle to the Cosmological Principle, stating that all spatial positions in the Universe are essentially equivalent.

The formulation of the Big-Bang model began in the 1940s with the work of George Gamow and his collaborators, Alpher and Herman. In order to account for the possibility that the abundances of the elements had a cosmological origin, they proposed that the early Universe which was once very hot and dense (enough so as to allow for the nucleosynthetic processing of hydrogen), and has expanded and cooled to its present state [4,5]. In 1948, Alpher and Herman predicted that a direct consequence of this model is the presence of a relic background radiation with a temperature of order a few K [6,7]. Of course this radiation was observed 16 years later as the microwave background radiation [8]. Indeed, it was the observation of the 3 K background radiation that singled out the Big-Bang model as the prime candidate to describe our Universe. Subsequent work on Big-Bang nucleosynthesis further confirmed the necessity of our hot and dense past. (See the review on BBN—Sec. 22 of this *Review* for a detailed discussion of BBN.) These relativistic cosmological models face severe problems with their initial conditions, to which the best modern solution is inflationary cosmology, discussed in Sec. 21.3.5. If correct, these ideas would strictly render the term ‘Big Bang’ redundant, since it was first coined by Hoyle to represent a criticism of the lack of understanding of the initial conditions.

21.1.1. The Robertson-Walker Universe :

The observed homogeneity and isotropy enable us to describe the overall geometry and evolution of the Universe in terms of two cosmological parameters accounting for the spatial curvature and the overall expansion (or contraction) of the Universe. These two quantities appear in the most general expression for a space-time metric which has a (3D) maximally symmetric subspace of a 4D space-time, known as the Robertson-Walker metric:

$$ds^2 = dt^2 - R^2(t) \left[\frac{dr^2}{1 - kr^2} + r^2 (d\theta^2 + \sin^2 \theta d\phi^2) \right] \quad (21.1)$$

Note that we adopt $c = 1$ throughout. By rescaling the radial coordinate, we can choose the curvature constant k to take only the discrete values $+1$, -1 , or 0 corresponding to closed, open, or spatially flat geometries. In this case, it is often more convenient to re-express the metric as

$$ds^2 = dt^2 - R^2(t) \left[d\chi^2 + S_k^2(\chi) (d\theta^2 + \sin^2 \theta d\phi^2) \right], \quad (21.2)$$

where the function $S_k(\chi)$ is $(\sin \chi, \chi, \sinh \chi)$ for $k = (+1, 0, -1)$. The coordinate r (in Eq. (21.1)) and the ‘angle’ χ (in Eq. (21.2)) are both dimensionless; the dimensions are carried by $R(t)$, which is the cosmological scale factor which determines proper distances in terms of the comoving coordinates. A common alternative is to define a dimensionless scale factor, $a(t) = R(t)/R_0$, where $R_0 \equiv R(t_0)$ is R at the present epoch. It is also sometimes convenient to define a dimensionless or conformal time coordinate, η , by $d\eta = dt/R(t)$. Along constant spatial sections, the proper time is defined by the time coordinate, t . Similarly, for $dt = d\theta = d\phi = 0$, the proper distance is given by $R(t)\chi$. For standard texts on cosmological models see *e.g.*, Refs. [9–16].

21.1.2. The redshift :

The cosmological redshift is a direct consequence of the Hubble expansion, determined by $R(t)$. A local observer detecting light from a distant emitter sees a redshift in frequency. We can define the redshift as

$$z \equiv \frac{\nu_1 - \nu_2}{\nu_2} \simeq \frac{v_{12}}{c}, \quad (21.3)$$

where ν_1 is the frequency of the emitted light, ν_2 is the observed frequency and v_{12} is the relative velocity between the emitter and the observer. While the definition, $z = (\nu_1 - \nu_2)/\nu_2$ is valid on all distance scales, relating the redshift to the relative velocity in this simple way is only true on small scales (*i.e.*, less than cosmological scales) such that the expansion velocity is non-relativistic. For light signals, we can use the metric given by Eq. (21.1) and $ds^2 = 0$ to write

$$\frac{v_{12}}{c} = \dot{R} \delta r = \frac{\dot{R}}{R} \delta t = \frac{\delta R}{R} = \frac{R_2 - R_1}{R_1}, \quad (21.4)$$

where $\delta r(\delta t)$ is the radial coordinate (temporal) separation between the emitter and observer. Thus, we obtain the simple relation between the redshift and the scale factor

$$1 + z = \frac{\nu_1}{\nu_2} = \frac{R_2}{R_1}. \quad (21.5)$$

This result does not depend on the non-relativistic approximation.

21.1.3. The Friedmann-Lemaître equations of motion :

The cosmological equations of motion are derived from Einstein’s equations

$$\mathcal{R}_{\mu\nu} - \frac{1}{2}g_{\mu\nu}\mathcal{R} = 8\pi G_N T_{\mu\nu} + \Lambda g_{\mu\nu}. \quad (21.6)$$

Gliner [17] and Zeldovich [18] have pioneered the modern view, in which the Λ term is taken to the rhs and interpreted as an effective energy–momentum tensor $T_{\mu\nu}$ for the vacuum of $\Lambda g_{\mu\nu}/8\pi G_N$. It is common to assume that the matter content of the Universe is a perfect fluid, for which

$$T_{\mu\nu} = -pg_{\mu\nu} + (p + \rho)u_\mu u_\nu, \quad (21.7)$$

where $g_{\mu\nu}$ is the space-time metric described by Eq. (21.1), p is the isotropic pressure, ρ is the energy density and $u = (1, 0, 0, 0)$ is the velocity vector for the isotropic fluid in co-moving coordinates. With the perfect fluid source, Einstein’s equations lead to the Friedmann-Lemaître equations

$$H^2 \equiv \left(\frac{\dot{R}}{R} \right)^2 = \frac{8\pi G_N \rho}{3} - \frac{k}{R^2} + \frac{\Lambda}{3}, \quad (21.8)$$

and

$$\frac{\ddot{R}}{R} = \frac{\Lambda}{3} - \frac{4\pi G_N}{3}(\rho + 3p), \quad (21.9)$$

where $H(t)$ is the Hubble parameter and Λ is the cosmological constant. The first of these is sometimes called the Friedmann equation. Energy conservation via $T^{\mu\nu}_{;\mu} = 0$, leads to a third useful equation [which can also be derived from Eq. (21.8) and Eq. (21.9)]

$$\dot{\rho} = -3H(\rho + p). \quad (21.10)$$

Eq. (21.10) can also be simply derived as a consequence of the first law of thermodynamics.

Eq. (21.8) has a simple classical mechanical analog if we neglect (for the moment) the cosmological term Λ . By interpreting $-k/R^2$ Newtonianly as a ‘total energy’, then we see that the evolution of the Universe is governed by a competition between the potential energy, $8\pi G_N \rho/3$, and the kinetic term $(\dot{R}/R)^2$. For $\Lambda = 0$, it is clear that the Universe must be expanding or contracting (except at the turning point prior to collapse in a closed Universe). The ultimate fate of the Universe is determined by the curvature constant k . For $k = +1$, the Universe will recollapse in a finite time, whereas for $k = 0, -1$, the Universe will expand indefinitely. These simple conclusions can be altered when $\Lambda \neq 0$ or more generally with some component with $(\rho + 3p) < 0$.

21.1.4. Definition of cosmological parameters :

In addition to the Hubble parameter, it is useful to define several other measurable cosmological parameters. The Friedmann equation can be used to define a critical density such that $k = 0$ when $\Lambda = 0$,

$$\begin{aligned} \rho_c &\equiv \frac{3H^2}{8\pi G_N} = 1.88 \times 10^{-26} h^2 \text{ kg m}^{-3} \\ &= 1.05 \times 10^{-5} h^2 \text{ GeV cm}^{-3}, \end{aligned} \quad (21.11)$$

where the scaled Hubble parameter, h , is defined by

$$\begin{aligned} H &\equiv 100 h \text{ km s}^{-1} \text{ Mpc}^{-1} \\ \Rightarrow H^{-1} &= 9.78 h^{-1} \text{ Gyr} \\ &= 2998 h^{-1} \text{ Mpc}. \end{aligned} \quad (21.12)$$

The cosmological density parameter Ω_{tot} is defined as the energy density relative to the critical density,

$$\Omega_{\text{tot}} = \rho/\rho_c. \quad (21.13)$$

Note that one can now rewrite the Friedmann equation as

$$k/R^2 = H^2(\Omega_{\text{tot}} - 1). \quad (21.14)$$

From Eq. (21.14), one can see that when $\Omega_{\text{tot}} > 1$, $k = +1$ and the Universe is closed, when $\Omega_{\text{tot}} < 1$, $k = -1$ and the Universe is open, and when $\Omega_{\text{tot}} = 1$, $k = 0$, and the Universe is spatially flat.

It is often necessary to distinguish different contributions to the density. It is therefore convenient to define present-day density parameters for pressureless matter (Ω_m) and relativistic particles (Ω_r), plus the quantity $\Omega_\Lambda = \Lambda/3H^2$. In more general models, we may wish to drop the assumption that the vacuum energy density is constant, and we therefore denote the present-day density parameter of the vacuum by Ω_v . The Friedmann equation then becomes

$$k/R_0^2 = H_0^2(\Omega_m + \Omega_r + \Omega_v - 1), \quad (21.15)$$

where the subscript 0 indicates present-day values. Thus, it is the sum of the densities in matter, relativistic particles, and vacuum that determines the overall sign of the curvature. Note that the quantity $-k/R_0^2 H_0^2$ is sometimes referred to as Ω_k . This usage is unfortunate: it encourages one to think of curvature as a contribution to the energy density of the Universe, which is not correct.

21.1.5. Standard Model solutions :

Much of the history of the Universe in the standard Big-Bang model can be easily described by assuming that either matter or radiation dominates the total energy density. During inflation and again today the expansion rate for the Universe is accelerating, and domination by a cosmological constant or some other form of dark energy should be considered. In the following, we shall delineate the solutions to the Friedmann equation when a single component dominates the energy density. Each component is distinguished by an equation of state parameter $w = p/\rho$.

21.1.5.1. Solutions for a general equation of state:

Let us first assume a general equation of state parameter for a single component, w which is constant. In this case, Eq. (21.10) can be written as $\dot{\rho} = -3(1+w)\rho\dot{R}/R$ and is easily integrated to yield

$$\rho \propto R^{-3(1+w)}. \quad (21.16)$$

Note that at early times when R is small, the less singular curvature term k/R^2 in the Friedmann equation can be neglected so long as $w > -1/3$. Curvature domination occurs at rather late times (if a cosmological constant term does not dominate sooner). For $w \neq -1$, one can insert this result into the Friedmann equation Eq. (21.8), and if one neglects the curvature and cosmological constant terms, it is easy to integrate the equation to obtain,

$$R(t) \propto t^{2/[3(1+w)]}. \quad (21.17)$$

21.1.5.2. A Radiation-dominated Universe:

In the early hot and dense Universe, it is appropriate to assume an equation of state corresponding to a gas of radiation (or relativistic particles) for which $w = 1/3$. In this case, Eq. (21.16) becomes $\rho \propto R^{-4}$. The ‘extra’ factor of $1/R$ is due to the cosmological redshift; not only is the number density of particles in the radiation background decreasing as R^{-3} since volume scales as R^3 , but in addition, each particle’s energy is decreasing as $E \propto \nu \propto R^{-1}$. Similarly, one can substitute $w = 1/3$ into Eq. (21.17) to obtain

$$R(t) \propto t^{1/2}; \quad H = 1/2t. \quad (21.18)$$

21.1.5.3. A Matter-dominated Universe:

At relatively late times, non-relativistic matter eventually dominates the energy density over radiation (see Sec. 21.3.8). A pressureless gas ($w = 0$) leads to the expected dependence $\rho \propto R^{-3}$ from Eq. (21.16) and, if $k = 0$, we get

$$R(t) \propto t^{2/3}; \quad H = 2/3t. \quad (21.19)$$

21.1.5.4. A Universe dominated by vacuum energy:

If there is a dominant source of vacuum energy, V_0 , it would act as a cosmological constant with $\Lambda = 8\pi G_N V_0$ and equation of state $w = -1$. In this case, the solution to the Friedmann equation is particularly simple and leads to an exponential expansion of the Universe

$$R(t) \propto e^{\sqrt{\Lambda/3}t}. \quad (21.20)$$

A key parameter is the equation of state of the vacuum, $w \equiv p/\rho$: this need not be the $w = -1$ of Λ , and may not even be constant [19,20,21]. There is now much interest in the more general possibility of a dynamically evolving vacuum energy, for which the name ‘dark energy’ has become commonly used. A variety of techniques exist whereby the vacuum density as a function of time may be measured, usually expressed as the value of w as a function of epoch [22,23]. The best current measurement for the equation of state (assumed constant, but without assuming zero curvature) is $w = -1.00 \pm 0.06$ [24]. Unless stated otherwise, we will assume that the vacuum energy is a cosmological constant with $w = -1$ exactly.

The presence of vacuum energy can dramatically alter the fate of the Universe. For example, if $\Lambda < 0$, the Universe will eventually recollapse independent of the sign of k . For large values of $\Lambda > 0$ (larger than the Einstein static value needed to halt any cosmological expansion or contraction), even a closed Universe will expand forever. One way to quantify this is the deceleration parameter, q_0 , defined as

$$q_0 = -\left. \frac{R\ddot{R}}{\dot{R}^2} \right|_0 = \frac{1}{2}\Omega_m + \Omega_r + \frac{(1+3w)}{2}\Omega_v. \quad (21.21)$$

This equation shows us that $w < -1/3$ for the vacuum may lead to an accelerating expansion. To the continuing astonishment of cosmologists, such an effect has been observed; one piece of direct evidence is the Supernova Hubble diagram [26–32] (see Fig. 21.1 below); current data indicate that vacuum energy is indeed the largest contributor to the cosmological density budget, with $\Omega_v = 0.73 \pm 0.03$ and $\Omega_m = 0.27 \pm 0.03$ if $k = 0$ is assumed (7-year mean WMAP) [24].

The existence of this constituent is without doubt the greatest puzzle raised by the current cosmological model; the final section of this review discusses some of the ways in which the vacuum-energy problem is being addressed.

21.2. Introduction to Observational Cosmology

21.2.1. Fluxes, luminosities, and distances :

The key quantities for observational cosmology can be deduced quite directly from the metric.

(1) The *proper* transverse size of an object seen by us to subtend an angle $d\psi$ is its comoving size $d\psi S_k(\chi)$ times the scale factor at the time of emission:

$$d\ell = d\psi R_0 S_k(\chi)/(1+z) . \quad (21.22)$$

(2) The apparent flux density of an object is deduced by allowing its photons to flow through a sphere of current radius $R_0 S_k(\chi)$; but photon energies and arrival rates are redshifted, and the bandwidth $d\nu$ is reduced. The observed photons at frequency ν_0 were emitted at frequency $\nu_0(1+z)$, so the flux density is the luminosity at this frequency, divided by the total area, divided by $1+z$:

$$S_\nu(\nu_0) = \frac{L_\nu([1+z]\nu_0)}{4\pi R_0^2 S_k^2(\chi)(1+z)} . \quad (21.23)$$

These relations lead to the following common definitions:

$$\begin{aligned} \text{angular-diameter distance: } D_A &= (1+z)^{-1} R_0 S_k(\chi) \\ \text{luminosity distance: } D_L &= (1+z) R_0 S_k(\chi) . \end{aligned} \quad (21.24)$$

These distance-redshift relations are expressed in terms of observables by using the equation of a null radial geodesic ($R(t)d\chi = dt$) plus the Friedmann equation:

$$\begin{aligned} R_0 d\chi &= \frac{1}{H(z)} dz = \frac{1}{H_0} \left[(1 - \Omega_m - \Omega_v - \Omega_r)(1+z)^2 \right. \\ &\quad \left. + \Omega_v(1+z)^{3+3w} + \Omega_m(1+z)^3 + \Omega_r(1+z)^4 \right]^{-1/2} dz . \end{aligned} \quad (21.25)$$

The main scale for the distance here is the Hubble length, $1/H_0$.

The flux density is the product of the specific intensity I_ν and the solid angle $d\Omega$ subtended by the source: $S_\nu = I_\nu d\Omega$. Combining the angular size and flux-density relations thus gives the relativistic version of surface-brightness conservation:

$$I_\nu(\nu_0) = \frac{B_\nu([1+z]\nu_0)}{(1+z)^3} , \quad (21.26)$$

where B_ν is surface brightness (luminosity emitted into unit solid angle per unit area of source). We can integrate over ν_0 to obtain the corresponding total or bolometric formula:

$$I_{\text{tot}} = \frac{B_{\text{tot}}}{(1+z)^4} . \quad (21.27)$$

This cosmology-independent form expresses Liouville's Theorem: photon phase-space density is conserved along rays.

21.2.2. Distance data and geometrical tests of cosmology :

In order to confront these theoretical predictions with data, we have to bridge the divide between two extremes. Nearby objects may have their distances measured quite easily, but their radial velocities are dominated by deviations from the ideal Hubble flow, which typically have a magnitude of several hundred km s^{-1} . On the other hand, objects at redshifts $z \gtrsim 0.01$ will have observed recessional velocities that differ from their ideal values by $\lesssim 10\%$, but absolute distances are much harder to supply in this case. The traditional solution to this problem is the construction of the distance ladder: an interlocking set of methods for obtaining relative distances between various classes of object, which begins with absolute distances at the 10 to 100 pc level, and terminates with galaxies at significant redshifts. This is reviewed in the review on Cosmological Parameters—Sec. 23 of this *Review*.

By far the most exciting development in this area has been the use of type Ia Supernovae (SNe), which now allow measurement of relative distances with 5% precision. In combination with Cepheid data from the HST and a direct geometrical distance to the maser

Figure 21.1: The type Ia supernova Hubble diagram [26–30]. The first panel shows that for $z \ll 1$ the large-scale Hubble flow is indeed linear and uniform; the second panel shows an expanded scale, with the linear trend divided out, and with the redshift range extended to show how the Hubble law becomes nonlinear. ($\Omega_r = 0$ is assumed.) Larger points with errors show median values in redshift bins. Comparison with the prediction of Friedmann-Lemaître models appears to favor a vacuum-dominated Universe.

galaxy NGC4258, SNe results extend the distance ladder to the point where deviations from uniform expansion are negligible, leading to the best existing direct value for H_0 : $73.8 \pm 2.4 \text{ km s}^{-1} \text{ Mpc}^{-1}$ [25]. Better still, the analysis of high- z SNe has allowed the first meaningful test of cosmological geometry to be carried out: as shown in Fig. 21.1 and Fig. 21.2, a combination of supernova data and measurements of microwave-background anisotropies strongly favors a $k = 0$ model dominated by vacuum energy. (See the review on Cosmological Parameters—Sec. 23 of this *Review* for a more comprehensive review of Hubble parameter determinations.)

21.2.3. Age of the Universe :

The most striking conclusion of relativistic cosmology is that the Universe has not existed forever. The dynamical result for the age of the Universe may be written as

$$\begin{aligned} H_0 t_0 &= \int_0^\infty \frac{dz}{(1+z)H(z)} \\ &= \int_0^\infty \frac{dz}{(1+z) [(1+z)^2(1+\Omega_m z) - z(2+z)\Omega_v]^{1/2}} , \end{aligned} \quad (21.28)$$

where we have neglected Ω_r and chosen $w = -1$. Over the range of interest ($0.1 \lesssim \Omega_m \lesssim 1$, $|\Omega_v| \lesssim 1$), this exact answer may be approximated to a few % accuracy by

$$H_0 t_0 \simeq \frac{2}{3} (0.7\Omega_m + 0.3 - 0.3\Omega_v)^{-0.3} . \quad (21.29)$$

For the special case that $\Omega_m + \Omega_v = 1$, the integral in Eq. (21.28) can be expressed analytically as

$$H_0 t_0 = \frac{2}{3\sqrt{\Omega_v}} \ln \frac{1 + \sqrt{\Omega_v}}{\sqrt{1 - \Omega_v}} \quad (\Omega_m < 1). \quad (21.30)$$

The most accurate means of obtaining ages for astronomical objects is based on the natural clocks provided by radioactive decay. The use of these clocks is complicated by a lack of knowledge of the initial conditions of the decay. In the Solar System, chemical fractionation of different elements helps pin down a precise age for the pre-Solar nebula of 4.6 Gyr, but for stars it is necessary to attempt an a priori calculation of the relative abundances of nuclei that result from supernova explosions. In this way, a lower limit for the age of stars in the local part of the Milky Way of about 11 Gyr is obtained [36,37].

The other major means of obtaining cosmological age estimates is based on the theory of stellar evolution. In principle, the main-sequence turnoff point in the color-magnitude diagram of a globular cluster should yield a reliable age. However, these have been controversial owing to theoretical uncertainties in the evolution model, as well as observational uncertainties in the distance, dust extinction, and metallicity of clusters. The present consensus favors ages for the oldest clusters of about 12 Gyr [38,39].

These methods are all consistent with the age deduced from studies of structure formation, using the microwave background and large-scale structure: $t_0 = 13.77 \pm 0.13$ Gyr [24], where the extra accuracy comes at the price of assuming the Cold Dark Matter model to be true.

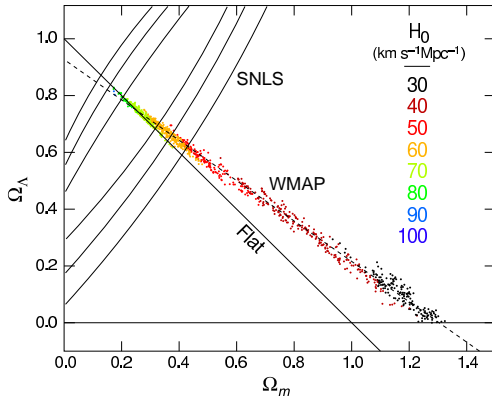

Figure 21.2: Likelihood-based probability densities on the plane Ω_Λ (i.e., Ω_v assuming $w = -1$) vs Ω_m . The colored Monte-Carlo points derive from WMAP [34] and show that the CMB alone requires a flat universe $\Omega_v + \Omega_m \simeq 1$ if the Hubble constant is not too high. The SNe Ia results [35] very nearly constrain the orthogonal combination $\Omega_v - \Omega_m$. The intersection of these constraints is the most direct (but far from the only) piece of evidence favoring a flat model with $\Omega_m \simeq 0.25$.

21.2.4. Horizon, isotropy, flatness problems :

For photons, the radial equation of motion is just $c dt = R d\chi$. How far can a photon get in a given time? The answer is clearly

$$\Delta\chi = \int_{t_1}^{t_2} \frac{dt}{R(t)} \equiv \Delta\eta, \quad (21.31)$$

i.e., just the interval of conformal time. We can replace dt by dR/\dot{R} , which the Friedmann equation says is $\propto dR/\sqrt{\rho R^2}$ at early times. Thus, this integral converges if $\rho R^2 \rightarrow \infty$ as $t_1 \rightarrow 0$, otherwise it diverges. Provided the equation of state is such that ρ changes faster than R^{-2} , light signals can only propagate a finite distance between the Big Bang and the present; there is then said to be a particle horizon. Such a horizon therefore exists in conventional Big-Bang models, which are dominated by radiation ($\rho \propto R^{-4}$) at early times.

At late times, the integral for the horizon is largely determined by the matter-dominated phase, for which

$$D_H = R_0 \chi_H \equiv R_0 \int_0^{t(z)} \frac{dt}{R(t)} \simeq \frac{6000}{\sqrt{\Omega_z}} h^{-1} \text{Mpc} \quad (z \gg 1). \quad (21.32)$$

The horizon at the time of formation of the microwave background ('last scattering': $z \simeq 1100$) was thus of order 100 Mpc in size, subtending an angle of about 1° . Why then are the large number of causally disconnected regions we see on the microwave sky all at the same temperature? The Universe is very nearly isotropic and homogeneous, even though the initial conditions appear not to permit such a state to be constructed.

A related problem is that the $\Omega = 1$ Universe is unstable:

$$\Omega(a) - 1 = \frac{\Omega - 1}{1 - \Omega + \Omega_v a^2 + \Omega_m a^{-1} + \Omega_r a^{-2}}, \quad (21.33)$$

where Ω with no subscript is the total density parameter, and $a(t) = R(t)/R_0$. This requires $\Omega(t)$ to be unity to arbitrary precision as the initial time tends to zero; a universe of non-zero curvature today requires very finely tuned initial conditions.

21.3. The Hot Thermal Universe

21.3.1. Thermodynamics of the early Universe :

As alluded to above, we expect that much of the early Universe can be described by a radiation-dominated equation of state. In addition, through much of the radiation-dominated period, thermal equilibrium is established by the rapid rate of particle interactions relative to the expansion rate of the Universe (see Sec. 21.3.3 below). In equilibrium, it is straightforward to compute the thermodynamic quantities, ρ , p , and the entropy density, s . In general, the energy density for a given particle type i can be written as

$$\rho_i = \int E_i dn_{q_i}, \quad (21.34)$$

with the density of states given by

$$dn_{q_i} = \frac{g_i}{2\pi^2} (\exp[(E_{q_i} - \mu_i)/T_i] \pm 1)^{-1} q_i^2 dq_i, \quad (21.35)$$

where g_i counts the number of degrees of freedom for particle type i , $E_{q_i}^2 = m_i^2 + q_i^2$, μ_i is the chemical potential, and the \pm corresponds to either Fermi or Bose statistics. Similarly, we can define the pressure of a perfect gas as

$$p_i = \frac{1}{3} \int \frac{q_i^2}{E_i} dn_{q_i}. \quad (21.36)$$

The number density of species i is simply

$$n_i = \int dn_{q_i}, \quad (21.37)$$

and the entropy density is

$$s_i = \frac{\rho_i + p_i - \mu_i n_i}{T_i}. \quad (21.38)$$

In the Standard Model, a chemical potential is often associated with baryon number, and since the net baryon density relative to the photon density is known to be very small (of order 10^{-10}), we can neglect any such chemical potential when computing total thermodynamic quantities.

For photons, we can compute all of the thermodynamic quantities rather easily. Taking $g_i = 2$ for the 2 photon polarization states, we have (in units where $\hbar = k_B = 1$)

$$\rho_\gamma = \frac{\pi^2}{15} T^4; \quad p_\gamma = \frac{1}{3} \rho_\gamma; \quad s_\gamma = \frac{4\rho_\gamma}{3T}; \quad n_\gamma = \frac{2\zeta(3)}{\pi^2} T^3, \quad (21.39)$$

with $2\zeta(3)/\pi^2 \simeq 0.2436$. Note that Eq. (21.10) can be converted into an equation for entropy conservation. Recognizing that $\dot{p} = s\dot{T}$, Eq. (21.10) becomes

$$d(sR^3)/dt = 0. \quad (21.40)$$

For radiation, this corresponds to the relationship between expansion and cooling, $T \propto R^{-1}$ in an adiabatically expanding universe. Note also that both s and n_γ scale as T^3 .

Figure 21.3: The effective numbers of relativistic degrees of freedom as a function of temperature. The sharp drop corresponds to the quark-hadron transition. The solid curve assume a QCD scale of 150 MeV, while the dashed curve assumes 450 MeV.

21.3.2. Radiation content of the Early Universe :

At the very high temperatures associated with the early Universe, massive particles are pair produced, and are part of the thermal bath. If for a given particle species i we have $T \gg m_i$, then we can neglect the mass in Eq. (21.34) to Eq. (21.38), and the thermodynamic quantities are easily computed as in Eq. (21.39). In general, we can approximate the energy density (at high temperatures) by including only those particles with $m_i \ll T$. In this case, we have

$$\rho = \left(\sum_B g_B + \frac{7}{8} \sum_F g_F \right) \frac{\pi^2}{30} T^4 \equiv \frac{\pi^2}{30} N(T) T^4, \quad (21.41)$$

where $g_{B(F)}$ is the number of degrees of freedom of each boson (fermion) and the sum runs over all boson and fermion states with $m \ll T$. The factor of $7/8$ is due to the difference between the Fermi and Bose integrals. Eq. (21.41) defines the effective number of degrees of freedom, $N(T)$, by taking into account new particle degrees of freedom as the temperature is raised. This quantity is plotted in Fig. 21.3 [40].

The value of $N(T)$ at any given temperature depends on the particle physics model. In the standard $SU(3) \times SU(2) \times U(1)$ model, we can specify $N(T)$ up to temperatures of $O(100)$ GeV. The change in N (ignoring mass effects) can be seen in the table below.

Temperature	New Particles	$4N(T)$
$T < m_e$	γ 's + ν 's	29
$m_e < T < m_\mu$	e^\pm	43
$m_\mu < T < m_\pi$	μ^\pm	57
$m_\pi < T < T_c^\dagger$	π 's	69
$T_c < T < m_{\text{strange}}$	π 's + u, \bar{u}, d, \bar{d} + gluons	205
$m_s < T < m_{\text{charm}}$	s, \bar{s}	247
$m_c < T < m_\tau$	c, \bar{c}	289
$m_\tau < T < m_{\text{bottom}}$	τ^\pm	303
$m_b < T < m_{W,Z}$	b, \bar{b}	345
$m_{W,Z} < T < m_{\text{Higgs}}$	W^\pm, Z	381
$m_H < T < m_{\text{top}}$	H^0	385
$m_t < T$	t, \bar{t}	427

$^\dagger T_c$ corresponds to the confinement-deconfinement transition between quarks and hadrons.

At higher temperatures, $N(T)$ will be model-dependent. For example, in the minimal $SU(5)$ model, one needs to add 24 states to $N(T)$ for the X and Y gauge bosons, another 24 from the adjoint Higgs, and another 6 (in addition to the 4 already counted in W^\pm, Z , and H) from the $\bar{\mathbf{5}}$ of Higgs. Hence for $T > m_X$ in minimal $SU(5)$, $N(T) = 160.75$. In a supersymmetric model this would at least double, with some changes possibly necessary in the table if the lightest supersymmetric particle has a mass below m_t .

In the radiation-dominated epoch, Eq. (21.10) can be integrated (neglecting the T -dependence of N) giving us a relationship between the age of the Universe and its temperature

$$t = \left(\frac{90}{32\pi^3 G_N N(T)} \right)^{1/2} T^{-2}. \quad (21.42)$$

Put into a more convenient form

$$t T_{\text{MeV}}^2 = 2.4 [N(T)]^{-1/2}, \quad (21.43)$$

where t is measured in seconds and T_{MeV} in units of MeV.

21.3.3. Neutrinos and equilibrium : Due to the expansion of the Universe, certain rates may be too slow to either establish or maintain equilibrium. Quantitatively, for each particle i , as a minimal condition for equilibrium, we will require that some rate Γ_i involving that type be larger than the expansion rate of the Universe or

$$\Gamma_i > H. \quad (21.44)$$

Recalling that the age of the Universe is determined by H^{-1} , this condition is equivalent to requiring that on average, at least one interaction has occurred over the lifetime of the Universe.

A good example for a process which goes in and out of equilibrium is the weak interactions of neutrinos. On dimensional grounds, one can estimate the thermally averaged scattering cross section

$$\langle \sigma v \rangle \sim O(10^{-2}) T^2 / m_W^4 \quad (21.45)$$

for $T \lesssim m_W$. Recalling that the number density of leptons is $n \propto T^3$, we can compare the weak interaction rate, $\Gamma_{\text{wk}} \sim n \langle \sigma v \rangle$, with the expansion rate,

$$H = \left(\frac{8\pi G_N \rho}{3} \right)^{1/2} = \left(\frac{8\pi^3}{90} N(T) \right)^{1/2} T^2 / M_{\text{P}} \sim 1.66 N(T)^{1/2} T^2 / M_{\text{P}}, \quad (21.46)$$

where the Planck mass $M_{\text{P}} = G_N^{-1/2} = 1.22 \times 10^{19}$ GeV.

Neutrinos will be in equilibrium when $\Gamma_{\text{wk}} > H$ or

$$T > (500 m_W^4 / M_{\text{P}})^{1/3} \sim 1 \text{ MeV}. \quad (21.47)$$

However, this condition assumes $T \ll m_W$; for higher temperatures, we should write $\langle \sigma v \rangle \sim O(10^{-2}) / T^2$, so that $\Gamma \sim 10^{-2} T$. Thus, in the very early stages of expansion, at temperatures $T \gtrsim 10^{-2} M_{\text{P}} / \sqrt{N}$, equilibrium will not have been established.

Having attained a quasi-equilibrium stage, the Universe then cools further to the point where the interaction and expansion timescales match once again. The temperature at which these rates are equal is commonly referred to as the neutrino decoupling or freeze-out temperature and is defined by $\Gamma_{\text{wk}}(T_d) = H(T_d)$. For $T < T_d$, neutrinos drop out of equilibrium. The Universe becomes transparent to neutrinos and their momenta simply redshift with the cosmic expansion. The effective neutrino temperature will simply fall with $T \sim 1/R$.

Soon after decoupling, e^\pm pairs in the thermal background begin to annihilate (when $T \lesssim m_e$). Because the neutrinos are decoupled, the energy released due to annihilation heats up the photon background relative to the neutrinos. The change in the photon temperature can be easily computed from entropy conservation. The neutrino entropy must be conserved separately from the entropy of interacting particles. A straightforward computation yields

$$T_\nu = (4/11)^{1/3} T_\gamma \simeq 1.9 \text{ K}. \quad (21.48)$$

Today, the total entropy density is therefore given by

$$s = \frac{4}{3} \frac{\pi^2}{30} \left(2 + \frac{21}{4} (T_\nu / T_\gamma)^3 \right) T_\gamma^3 = \frac{4}{3} \frac{\pi^2}{30} \left(2 + \frac{21}{11} \right) T_\gamma^3 = 7.04 n_\gamma. \quad (21.49)$$

Similarly, the total relativistic energy density today is given by

$$\rho_r = \frac{\pi^2}{30} \left[2 + \frac{21}{4} (T_\nu/T_\gamma)^4 \right] T_\gamma^4 \simeq 1.68 \rho_\gamma. \quad (21.50)$$

In practice, a small correction is needed to this, since neutrinos are not totally decoupled at e^\pm annihilation: the effective number of massless neutrino species is 3.04, rather than 3 [41].

This expression ignores neutrino rest masses, but current oscillation data require at least one neutrino eigenstate to have a mass exceeding 0.05 eV. In this minimal case, $\Omega_\nu h^2 = 5 \times 10^{-4}$, so the neutrino contribution to the matter budget would be negligibly small (which is our normal assumption). However, a nearly degenerate pattern of mass eigenstates could allow larger densities, since oscillation experiments only measure differences in m^2 values. Note that a 0.05-eV neutrino has $kT_\nu = m_\nu$ at $z \simeq 297$, so the above expression for the total present relativistic density is really only an extrapolation. However, neutrinos are almost certainly relativistic at all epochs where the radiation content of the Universe is dynamically significant.

21.3.4. Field Theory and Phase transitions :

It is very likely that the Universe has undergone one or more phase transitions during the course of its evolution [42–45]. Our current vacuum state is described by $SU(3)_c \times U(1)_{em}$, which in the Standard Model is a remnant of an unbroken $SU(3)_c \times SU(2)_L \times U(1)_Y$ gauge symmetry. Symmetry breaking occurs when a non-singlet gauge field (the Higgs field in the Standard Model) picks up a non-vanishing vacuum expectation value, determined by a scalar potential. For example, a simple (non-gauged) potential describing symmetry breaking is $V(\phi) = \frac{1}{4}\lambda\phi^4 - \frac{1}{2}\mu^2\phi^2 + V(0)$. The resulting expectation value is simply $\langle\phi\rangle = \mu/\sqrt{\lambda}$.

In the early Universe, finite temperature radiative corrections typically add terms to the potential of the form $\phi^2 T^2$. Thus, at very high temperatures, the symmetry is restored and $\langle\phi\rangle = 0$. As the Universe cools, depending on the details of the potential, symmetry breaking will occur via a first order phase transition in which the field tunnels through a potential barrier, or via a second order transition in which the field evolves smoothly from one state to another (as would be the case for the above example potential).

The evolution of scalar fields can have a profound impact on the early Universe. The equation of motion for a scalar field ϕ can be derived from the energy-momentum tensor

$$T_{\mu\nu} = \partial_\mu\phi\partial_\nu\phi - \frac{1}{2}g_{\mu\nu}\partial_\rho\phi\partial^\rho\phi - g_{\mu\nu}V(\phi). \quad (21.51)$$

By associating $\rho = T_{00}$ and $p = R^{-2}(t)T_{ii}$ we have

$$\begin{aligned} \rho &= \frac{1}{2}\dot{\phi}^2 + \frac{1}{2}R^{-2}(t)(\nabla\phi)^2 + V(\phi) \\ p &= \frac{1}{2}\dot{\phi}^2 - \frac{1}{6}R^{-2}(t)(\nabla\phi)^2 - V(\phi), \end{aligned} \quad (21.52)$$

and from Eq. (21.10) we can write the equation of motion (by considering a homogeneous region, we can ignore the gradient terms)

$$\ddot{\phi} + 3H\dot{\phi} = -\partial V/\partial\phi. \quad (21.53)$$

21.3.5. Inflation :

In Sec. 21.2.4, we discussed some of the problems associated with the standard Big-Bang model. However, during a phase transition, our assumptions of an adiabatically expanding universe are generally not valid. If, for example, a phase transition occurred in the early Universe such that the field evolved slowly from the symmetric state to the global minimum, the Universe may have been dominated by the vacuum energy density associated with the potential near $\phi \simeq 0$. During this period of slow evolution, the energy density due to radiation will fall below the vacuum energy density, $\rho \ll V(0)$. When this happens, the expansion rate will be dominated by the constant $V(0)$, and we obtain the exponentially expanding solution given in Eq. (21.20). When the field evolves towards the global minimum it will

begin to oscillate about the minimum, energy will be released during its decay, and a hot thermal universe will be restored. If released fast enough, it will produce radiation at a temperature $NT_R^4 \lesssim V(0)$. In this reheating process, entropy has been created and the final value of RT is greater than the initial value of RT . Thus, we see that, during a phase transition, the relation $RT \sim$ constant need not hold true. This is the basis of the inflationary Universe scenario [46–48].

If, during the phase transition, the value of RT changed by a factor of $O(10^{29})$, the cosmological problems discussed above would be solved. The observed isotropy would be generated by the immense expansion; one small causal region could get blown up, and thus our entire visible Universe would have been in thermal contact some time in the past. In addition, the density parameter Ω would have been driven to 1 (with exponential precision). Density perturbations will be stretched by the expansion, $\lambda \sim R(t)$. Thus it will appear that $\lambda \gg H^{-1}$ or that the perturbations have left the horizon, where in fact the size of the causally connected region is now no longer simply H^{-1} . However, not only does inflation offer an explanation for large scale perturbations, it also offers a source for the perturbations themselves through quantum fluctuations.

Early models of inflation were based on a first order phase transition of a Grand Unified Theory [49]. Although these models led to sufficient exponential expansion, completion of the transition through bubble percolation did not occur, and lack of bubble collisions meant that the interior of the bubbles was not reheated. Subsequent models of inflation [50,51] considered second-order transitions within Grand Unified theories, thus successfully ending inflation with reheating from oscillations of the scalar field. But these models predicted too high an amplitude of relic density fluctuations. As a result, current models of inflation postulate second-order transitions in a completely new scalar field: the inflaton, ϕ . The potential of this field, $V(\phi)$, needs to have a very low gradient and curvature in order to match observed metric fluctuations.

In viable inflation models of this type, reheated bubbles again typically do not percolate, so inflation is ‘eternal’ and continues with exponential expansion in the region outside bubbles. These causally disconnected bubble universes constitute a ‘multiverse’, where low-energy physics can vary between different bubbles. This has led to a controversial ‘anthropic’ approach to cosmology [82–84], where observer selection within the multiverse can be introduced as a means of understanding e.g. why the observed level of vacuum energy is so low (because larger values suppress growth of structure).

21.3.6. Baryogenesis :

The Universe appears to be populated exclusively with matter rather than antimatter. Indeed antimatter is only detected in accelerators or in cosmic rays. However, the presence of antimatter in the latter is understood to be the result of collisions of primary particles in the interstellar medium. There is in fact strong evidence against primary forms of antimatter in the Universe. Furthermore, the density of baryons compared to the density of photons is extremely small, $\eta \sim 10^{-10}$.

The production of a net baryon asymmetry requires baryon number violating interactions, C and CP violation and a departure from thermal equilibrium [52]. The first two of these ingredients are expected to be contained in grand unified theories as well as in the non-perturbative sector of the Standard Model, the third can be realized in an expanding universe where as we have seen interactions come in and out of equilibrium.

There are several interesting and viable mechanisms for the production of the baryon asymmetry. While, we can not review any of them here in any detail, we mention some of the important scenarios. In all cases, all three ingredients listed above are incorporated. One of the first mechanisms was based on the out of equilibrium decay of a massive particle such as a superheavy GUT gauge of Higgs boson [53,54]. A novel mechanism involving the decay of flat directions in supersymmetric models is known as the Affleck-Dine scenario [55]. There is also the possibility of generating the baryon asymmetry at the electro-weak scale using the non-perturbative interactions of sphalerons [56]. Because these interactions conserve the sum of baryon and lepton number, $B + L$, it is possible to first

generate a lepton asymmetry (*e.g.*, by the out-of-equilibrium decay of a superheavy right-handed neutrino), which is converted to a baryon asymmetry at the electro-weak scale [57]. This mechanism is known as lepto-baryogenesis.

21.3.7. Nucleosynthesis :

An essential element of the standard cosmological model is Big-Bang nucleosynthesis (BBN), the theory which predicts the abundances of the light element isotopes D, ^3He , ^4He , and ^7Li . Nucleosynthesis takes place at a temperature scale of order 1 MeV. The nuclear processes lead primarily to ^4He , with a primordial mass fraction of about 25%. Lesser amounts of the other light elements are produced: about 10^{-5} of D and ^3He and about 10^{-10} of ^7Li by number relative to H. The abundances of the light elements depend almost solely on one key parameter, the baryon-to-photon ratio, η . The nucleosynthesis predictions can be compared with observational determinations of the abundances of the light elements. Consistency between theory and observations leads to a conservative range of

$$5.1 \times 10^{-10} < \eta < 6.5 \times 10^{-10} . \quad (21.54)$$

η is related to the fraction of Ω contained in baryons, Ω_b ,

$$\Omega_b = 3.66 \times 10^7 \eta h^{-2} , \quad (21.55)$$

or $10^{10} \eta = 274 \Omega_b h^2$. The WMAP result [24] for $\Omega_b h^2$ of 0.0225 ± 0.0006 translates into a value of $\eta = 6.16 \pm 0.15$. This result can be used to ‘predict’ the light element abundance which can in turn be compared with observation [58]. The resulting D/H abundance is in excellent agreement with that found in quasar absorption systems. It is in reasonable agreement with the helium abundance observed in extra-galactic HII regions (once systematic uncertainties are accounted for), but is in poor agreement with the Li abundance observed in the atmospheres of halo dwarf stars [59]. (See the review on BBN—Sec. 22 of this *Review* for a detailed discussion of BBN or references [60,61].)

21.3.8. The transition to a matter-dominated Universe :

In the Standard Model, the temperature (or redshift) at which the Universe undergoes a transition from a radiation dominated to a matter dominated Universe is determined by the amount of dark matter. Assuming three nearly massless neutrinos, the energy density in radiation at temperatures $T \ll 1$ MeV, is given by

$$\rho_r = \frac{\pi^2}{30} \left[2 + \frac{21}{4} \left(\frac{4}{11} \right)^{4/3} \right] T^4 . \quad (21.56)$$

In the absence of non-baryonic dark matter, the matter density can be written as

$$\rho_m = m_N \eta n_\gamma , \quad (21.57)$$

where m_N is the nucleon mass. Recalling that $n_\gamma \propto T^3$ [cf. Eq. (21.39)], we can solve for the temperature or redshift at the matter-radiation equality when $\rho_r = \rho_m$,

$$T_{eq} = 0.22 m_N \eta \quad \text{or} \quad (1 + z_{eq}) = 0.22 \eta \frac{m_N}{T_0} , \quad (21.58)$$

where T_0 is the present temperature of the microwave background. For $\eta = 6.2 \times 10^{-10}$, this corresponds to a temperature $T_{eq} \simeq 0.13$ eV or $(1 + z_{eq}) \simeq 550$. A transition this late is very problematic for structure formation (see Sec. 21.4.5).

The redshift of matter domination can be pushed back significantly if non-baryonic dark matter is present. If instead of Eq. (21.57), we write

$$\rho_m = \Omega_m \rho_c \left(\frac{T}{T_0} \right)^3 , \quad (21.59)$$

we find that

$$T_{eq} = 0.9 \frac{\Omega_m \rho_c}{T_0^3} \quad \text{or} \quad (1 + z_{eq}) = 2.4 \times 10^4 \Omega_m h^2 . \quad (21.60)$$

21.4. The Universe at late times

21.4.1. The CMB :

One form of the infamous Olbers’ paradox says that, in Euclidean space, surface brightness is independent of distance. Every line of sight will terminate on matter that is hot enough to be ionized and so scatter photons: $T \gtrsim 10^3$ K; the sky should therefore shine as brightly as the surface of the Sun. The reason the night sky is dark is entirely due to the expansion, which cools the radiation temperature to 2.73 K. This gives a Planck function peaking at around 1 mm to produce the microwave background (CMB).

The CMB spectrum is a very accurate match to a Planck function [62]. (See the review on CBR—Sec. 25 of this *Review*.) The COBE estimate of the temperature is [63]

$$T = 2.7255 \pm 0.0006 \text{ K} . \quad (21.61)$$

The lack of any distortion of the Planck spectrum is a strong physical constraint. It is very difficult to account for in any expanding universe other than one that passes through a hot stage. Alternative schemes for generating the radiation, such as thermalization of starlight by dust grains, inevitably generate a superposition of temperatures. What is required in addition to thermal equilibrium is that $T \propto 1/R$, so that radiation from different parts of space appears identical.

Although it is common to speak of the CMB as originating at ‘recombination,’ a more accurate terminology is the era of ‘last scattering.’ In practice, this takes place at $z \simeq 1100$, almost independently of the main cosmological parameters, at which time the fractional ionization is very small. This occurred when the age of the Universe was a few hundred thousand years. (See the review on CBR—Sec. 25 of this *Review* for a full discussion of the CMB.)

21.4.2. Matter in the Universe :

One of the main tasks of cosmology is to measure the density of the Universe, and how this is divided between dark matter and baryons. The baryons consist partly of stars, with $0.002 \lesssim \Omega_* \lesssim 0.003$ [64] but mainly inhabit the intergalactic medium (IGM). One powerful way in which this can be studied is via the absorption of light from distant luminous objects such as quasars. Even very small amounts of neutral hydrogen can absorb rest-frame UV photons (the Gunn-Peterson effect), and should suppress the continuum by a factor $\exp(-\tau)$, where

$$\tau \simeq 10^{4.62} h^{-1} \left[\frac{n_{\text{HI}}(z)/m^{-3}}{(1+z)\sqrt{1+\Omega_m z}} \right] , \quad (21.62)$$

and this expression applies while the Universe is matter dominated ($z \gtrsim 1$ in the $\Omega_m = 0.3$ $\Omega_v = 0.7$ model). It is possible that this general absorption has now been seen at $z = 6.2 - 6.4$ [65]. In any case, the dominant effect on the spectrum is a ‘forest’ of narrow absorption lines, which produce a mean $\tau = 1$ in the Ly α forest at about $z = 3$, and so we have $\Omega_{\text{HI}} \simeq 10^{-6.7} h^{-1}$. This is such a small number that clearly the IGM is very highly ionized at these redshifts.

The Ly α forest is of great importance in pinning down the abundance of deuterium. Because electrons in deuterium differ in reduced mass by about 1 part in 4000 compared to hydrogen, each absorption system in the Ly α forest is accompanied by an offset deuterium line. By careful selection of systems with an optimal HI column density, a measurement of the D/H ratio can be made. This has now been done in 7 quasars, with relatively consistent results [66]. Combining these determinations with the theory of primordial nucleosynthesis yields a baryon density of $\Omega_b h^2 = 0.019 - 0.024$ (95% confidence). (See also the review on BBN—Sec. 22 of this *Review*.)

Ionized IGM can also be detected in emission when it is densely clumped, via bremsstrahlung radiation. This generates the spectacular X-ray emission from rich clusters of galaxies. Studies of this phenomenon allow us to achieve an accounting of the total baryonic material in clusters. Within the central $\simeq 1$ Mpc, the masses in stars, X-ray emitting gas and total dark matter can be determined with reasonable accuracy (perhaps 20% rms), and this allows a minimum baryon fraction to be determined [67,68]:

$$\frac{M_{\text{baryons}}}{M_{\text{total}}} \gtrsim 0.009 + (0.066 \pm 0.003) h^{-3/2} . \quad (21.63)$$

Because clusters are the largest collapsed structures, it is reasonable to take this as applying to the Universe as a whole. This equation implies a minimum baryon fraction of perhaps 12% (for reasonable h), which is too high for $\Omega_m = 1$ if we take $\Omega_b h^2 \simeq 0.02$ from nucleosynthesis. This is therefore one of the more robust arguments in favor of $\Omega_m \simeq 0.3$. (See the review on Cosmological Parameters—Sec. 23 of this *Review*.) This argument is also consistent with the inference on Ω_m that can be made from Fig. 21.2.

This method is much more robust than the older classical technique for weighing the Universe: ‘ $L \times M/L$.’ The overall light density of the Universe is reasonably well determined from redshift surveys of galaxies, so that a good determination of mass M and luminosity L for a single object suffices to determine Ω_m if the mass-to-light ratio is universal.

21.4.3. Gravitational lensing :

A robust method for determining masses in cosmology is to use gravitational light deflection. Most systems can be treated as a geometrically thin gravitational lens, where the light bending is assumed to take place only at a single distance. Simple geometry then determines a mapping between the coordinates in the intrinsic source plane and the observed image plane:

$$\alpha(D_L \theta_I) = \frac{D_S}{D_{LS}} (\theta_I - \theta_S), \quad (21.64)$$

where the angles θ_I, θ_S and α are in general two-dimensional vectors on the sky. The distances D_{LS} etc. are given by an extension of the usual distance-redshift formula:

$$D_{LS} = \frac{R_0 S_k (\chi_S - \chi_L)}{1 + z_S}. \quad (21.65)$$

This is the angular-diameter distance for objects on the source plane as perceived by an observer on the lens.

Solutions of this equation divide into weak lensing, where the mapping between source plane and image plane is one-to-one, and strong lensing, in which multiple imaging is possible. For circularly-symmetric lenses, an on-axis source is multiply imaged into a ‘caustic’ ring, whose radius is the Einstein radius:

$$\begin{aligned} \theta_E &= \left(4GM \frac{D_{LS}}{D_L D_S} \right)^{1/2} \\ &= \left(\frac{M}{10^{11.09} M_\odot} \right)^{1/2} \left(\frac{D_L D_S / D_{LS}}{\text{Gpc}} \right)^{-1/2} \text{ arcsec}. \end{aligned} \quad (21.66)$$

The observation of ‘arcs’ (segments of near-perfect Einstein rings) in rich clusters of galaxies has thus given very accurate masses for the central parts of clusters—generally in good agreement with other indicators, such as analysis of X-ray emission from the cluster IGM [69].

Gravitational lensing has also developed into a particularly promising probe of cosmological structure on 10 to 100 Mpc scales. Weak image distortions manifest themselves as an additional ellipticity of galaxy images (‘shear’), which can be observed by averaging many images together (the corresponding flux amplification is less readily detected). The result is a ‘cosmic shear’ field of order 1% ellipticity, coherent over scales of around 30 arcmin, which is directly related to the cosmic mass field, without any astrophysical uncertainties. For this reason, weak lensing is seen as potentially the cleanest probe of matter fluctuations, next to the CMB. Already, impressive results have been obtained in measuring cosmological parameters, based on survey data from only $\sim 50 \text{ deg}^2$ [85]. The particular current strength of this technique is the ability to measure the amplitude of mass fluctuations; this can be deduced from the CMB only subject to uncertainty over the optical depth due to Thomson scattering after reionization.

21.4.4. Density Fluctuations :

The overall properties of the Universe are very close to being homogeneous; and yet telescopes reveal a wealth of detail on scales varying from single galaxies to large-scale structures of size exceeding 100 Mpc. The existence of these structures must be telling us something important about the initial conditions of the Big Bang, and about the physical processes that have operated subsequently. This motivates the study of the density perturbation field, defined as

$$\delta(\mathbf{x}) \equiv \frac{\rho(\mathbf{x}) - \langle \rho \rangle}{\langle \rho \rangle}. \quad (21.67)$$

A critical feature of the δ field is that it inhabits a universe that is isotropic and homogeneous in its large-scale properties. This suggests that the statistical properties of δ should also be statistically homogeneous—*i.e.*, it is a stationary random process.

It is often convenient to describe δ as a Fourier superposition:

$$\delta(\mathbf{x}) = \sum \delta_{\mathbf{k}} e^{-i\mathbf{k} \cdot \mathbf{x}}. \quad (21.68)$$

We avoid difficulties with an infinite universe by applying periodic boundary conditions in a cube of some large volume V . The cross-terms vanish when we compute the variance in the field, which is just a sum over modes of the power spectrum

$$\langle \delta^2 \rangle = \sum |\delta_{\mathbf{k}}|^2 \equiv \sum P(k). \quad (21.69)$$

Note that the statistical nature of the fluctuations must be isotropic, so we write $P(k)$ rather than $P(\mathbf{k})$. The $\langle \dots \rangle$ average here is a volume average. Cosmological density fields are an example of an ergodic process, in which the average over a large volume tends to the same answer as the average over a statistical ensemble.

The statistical properties of discrete objects sampled from the density field are often described in terms of N -point correlation functions, which represent the excess probability over random for finding one particle in each of N boxes in a given configuration. For the 2-point case, the correlation function is readily shown to be identical to the autocorrelation function of the δ field: $\xi(r) = \langle \delta(x)\delta(x+r) \rangle$.

The power spectrum and correlation function are Fourier conjugates, and thus are equivalent descriptions of the density field (similarly, k -space equivalents exist for the higher-order correlations). It is convenient to take the limit $V \rightarrow \infty$ and use k -space integrals, defining a dimensionless power spectrum, which measures the contribution to the fractional variance in density per unit logarithmic range of scale, as $\Delta^2(k) = d\langle \delta^2 \rangle / d \ln k = V k^3 P(k) / 2\pi^2$:

$$\xi(r) = \int \Delta^2(k) \frac{\sin kr}{kr} d \ln k; \quad \Delta^2(k) = \frac{2}{\pi} k^3 \int_0^\infty \xi(r) \frac{\sin kr}{kr} r^2 dr. \quad (21.70)$$

For many years, an adequate approximation to observational data on galaxies was $\xi = (r/r_0)^{-\gamma}$, with $\gamma \simeq 1.8$ and $r_0 \simeq 5 h^{-1} \text{ Mpc}$. Modern surveys are now able to probe into the large-scale linear regime where unaltered traces of the curved post-recombination spectrum can be detected [70,71,72].

21.4.5. Formation of cosmological structure :

The simplest model for the generation of cosmological structure is gravitational instability acting on some small initial fluctuations (for the origin of which a theory such as inflation is required). If the perturbations are adiabatic (*i.e.*, fractionally perturb number densities of photons and matter equally), the linear growth law for matter perturbations is simple:

$$\delta \propto \begin{cases} a^2(t) & (\text{radiation domination; } \Omega_r = 1) \\ a(t) & (\text{matter domination; } \Omega_m = 1). \end{cases} \quad (21.71)$$

For low density universes, the present-day amplitude is suppressed by a factor $g(\Omega)$, where

$$g(\Omega) \simeq \frac{5}{2} \Omega_m \left[\Omega_m^{4/7} - \Omega_v + (1 + \Omega_m/2)(1 + \frac{1}{70} \Omega_v) \right]^{-1} \quad (21.72)$$

is an accurate fit for models with matter plus cosmological constant. The alternative perturbation mode is isocurvature: only the equation of state changes, and the total density is initially unperturbed. These modes perturb the total entropy density, and thus induce additional large-scale CMB anisotropies [73]. Although the character of perturbations in the simplest inflationary theories are purely adiabatic, correlated adiabatic and isocurvature modes are predicted in many models; the simplest example is the curvaton, which is a scalar field that decays to yield a perturbed radiation density. If the matter content already exists at this time, the overall perturbation field will have a significant isocurvature component. Such a prediction is inconsistent with current CMB data [74], and most analyses of CMB and LSS data assume the adiabatic case to hold exactly.

Linear evolution preserves the shape of the power spectrum. However, a variety of processes mean that growth actually depends on the matter content:

- (1) Pressure opposes gravity effectively for wavelengths below the horizon length while the Universe is radiation dominated. The *comoving* horizon size at z_{eq} is therefore an important scale:

$$D_{\text{H}}(z_{\text{eq}}) = \frac{2(\sqrt{2}-1)}{(\Omega_{\text{m}} z_{\text{eq}})^{1/2} H_0} = \frac{16.0}{\Omega_{\text{m}} h^2} \text{Mpc} . \quad (21.73)$$
- (2) At early times, dark matter particles will undergo free streaming at the speed of light, and so erase all scales up to the horizon—a process that only ceases when the particles go nonrelativistic. For light massive neutrinos, this happens at z_{eq} ; all structure up to the horizon-scale power-spectrum break is in fact erased. Hot(cold) dark matter models are thus sometimes dubbed large(small)-scale damping models.
- (3) A further important scale arises where photon diffusion can erase perturbations in the matter–radiation fluid; this process is named Silk damping.

Figure 21.4: A plot of transfer functions for various models. For adiabatic models, $T_k \rightarrow 1$ at small k , whereas the opposite is true for isocurvature models. For dark-matter models, the characteristic wavenumber scales proportional to $\Omega_{\text{m}} h^2$. The scaling for baryonic models does not obey this exactly; the plotted cases correspond to $\Omega_{\text{m}} = 1$, $h = 0.5$.

The overall effect is encapsulated in the transfer function, which gives the ratio of the late-time amplitude of a mode to its initial value (see Fig. 21.4). The overall power spectrum is thus the primordial power-law, times the square of the transfer function:

$$P(k) \propto k^n T_k^2 . \quad (21.74)$$

The most generic power-law index is $n = 1$: the ‘Zeldovich’ or ‘scale-invariant’ spectrum. Inflationary models tend to predict a small ‘tilt’: $|n - 1| \lesssim 0.03$ [12,13]. On the assumption that the dark matter is cold, the power spectrum then depends on 5 parameters: n , h , Ω_{b} , Ω_{cdm} ($\equiv \Omega_{\text{m}} - \Omega_{\text{b}}$) and an overall amplitude. The latter is often specified as σ_8 , the linear-theory fractional rms in density when a spherical filter of radius $8 h^{-1} \text{Mpc}$ is applied in linear theory. This

scale can be probed directly via weak gravitational lensing, and also via its effect on the abundance of rich galaxy clusters. The favored value is approximately [34,75]

$$\sigma_8 \simeq (0.803 \pm 0.011) (\Omega_{\text{m}}/0.25)^{-0.47} . \quad (21.75)$$

A direct measure of mass inhomogeneity is valuable, since the galaxies inevitably are biased with respect to the mass. This means that the fractional fluctuations in galaxy number, $\delta n/n$, may differ from the mass fluctuations, $\delta\rho/\rho$. It is commonly assumed that the two fields obey some proportionality on large scales where the fluctuations are small, $\delta n/n = b\delta\rho/\rho$, but even this is not guaranteed [76].

Figure 21.5: The galaxy power spectrum from the 2dFGRS [71], shown in dimensionless form, $\Delta^2(k) \propto k^3 P(k)$. The solid points with error bars show the power estimate. The window function correlates the results at different k values, and also distorts the large-scale shape of the power spectrum. An approximate correction for the latter effect has been applied. The solid and dashed lines show various CDM models, all assuming $n = 1$. For the case with non-negligible baryon content, a big-bang nucleosynthesis value of $\Omega_{\text{b}} h^2 = 0.02$ is assumed, together with $h = 0.7$. A good fit is clearly obtained for $\Omega_{\text{m}} h \simeq 0.2$.

The main shape of the transfer function is a break around the horizon scale at z_{eq} , which depends just on $\Omega_{\text{m}} h$ when wavenumbers are measured in observable units ($h \text{Mpc}^{-1}$). For reasonable baryon content, weak oscillations in the transfer function are also expected, and these BAOs (Baryon Acoustic Oscillations) have been clearly detected [77,78]. As well as directly measuring the baryon fraction, the scale of the oscillations directly measures the acoustic horizon at decoupling; this can be used as an additional standard ruler for cosmological tests, and the BAO method is likely to be important in future large galaxy surveys. Overall, current power-spectrum data [70,71,72] favor $\Omega_{\text{m}} h \simeq 0.20$ and a baryon fraction of about 0.15 for $n = 1$ (see Fig. 21.5).

In principle, accurate data over a wide range of k could determine both Ωh and n , but in practice there is a strong degeneracy between these. In order to constrain n itself, it is necessary to examine data on anisotropies in the CMB.

21.4.6. CMB anisotropies :

The CMB has a clear dipole anisotropy, of magnitude 1.23×10^{-3} . This is interpreted as being due to the Earth’s motion, which is equivalent to a peculiar velocity for the Milky Way of

$$v_{\text{MW}} \simeq 600 \text{ km s}^{-1} \quad \text{towards } (\ell, b) \simeq (270^\circ, 30^\circ) . \quad (21.76)$$

All higher-order multipole moments of the CMB are however much smaller (of order 10^{-5}), and interpreted as signatures of density fluctuations at last scattering ($\simeq 1100$). To analyze these, the sky is expanded in spherical harmonics as explained in the review on CBR–Sec. 25 of this *Review*. The dimensionless power per $\ln k$ or ‘bandpower’ for the CMB is defined as

$$\mathcal{T}^2(\ell) = \frac{\ell(\ell+1)}{2\pi} C_\ell . \quad (21.77)$$

This function encodes information from the three distinct mechanisms that cause CMB anisotropies:

- (1) Gravitational (Sachs–Wolfe) perturbations. Photons from high-density regions at last scattering have to climb out of potential wells, and are thus redshifted.
- (2) Intrinsic (adiabatic) perturbations. In high-density regions, the coupling of matter and radiation can compress the radiation also, giving a higher temperature.
- (3) Velocity (Doppler) perturbations. The plasma has a non-zero velocity at recombination, which leads to Doppler shifts in frequency and hence shifts in brightness temperature.

Because the potential fluctuations obey Poisson’s equation, $\nabla^2\Phi = 4\pi G\rho\delta$, and the velocity field satisfies the continuity equation $\nabla \cdot \mathbf{u} = -\dot{\delta}$, the resulting different powers of k ensure that the Sachs-Wolfe effect dominates on large scales and adiabatic effects on small scales.

The relation between angle and comoving distance on the last-scattering sphere requires the comoving angular-diameter distance to the last-scattering sphere; because of its high redshift, this is effectively identical to the horizon size at the present epoch, D_H :

$$\begin{aligned} D_H &= \frac{2}{\Omega_m H_0} \quad (\Omega_v = 0) \\ D_H &\simeq \frac{2}{\Omega_m^{0.4} H_0} \quad (\text{flat} : \Omega_m + \Omega_v = 1). \end{aligned} \quad (21.78)$$

These relations show how the CMB is strongly sensitive to curvature: the horizon length at last scattering is $\propto 1/\sqrt{\Omega_m}$, so that this subtends an angle that is virtually independent of Ω_m for a flat model. Observations of a peak in the CMB power spectrum at relatively large scales ($\ell \simeq 225$) are thus strongly inconsistent with zero- Λ models with low density: current CMB + BAO +SN data require $\Omega_m + \Omega_v = 1.006 \pm 0.007$ [24]. (See *e.g.*, Fig. 21.2).

In addition to curvature, the CMB encodes information about several other key cosmological parameters. Within the compass of simple adiabatic CDM models, there are 9 of these:

$$\omega_c, \omega_b, \Omega_t, h, \tau, n_s, n_t, r, Q. \quad (21.79)$$

The symbol ω denotes the physical density, Ωh^2 : the transfer function depends only on the densities of CDM (ω_c) and baryons (ω_b). Transcribing the power spectrum at last scattering into an angular power spectrum brings in the total density parameter ($\Omega_t \equiv \Omega_m + \Omega_v = \Omega_c + \Omega_b + \Omega_v$) and h : there is an exact geometrical degeneracy [79] between these that keeps the angular-diameter distance to last scattering invariant, so that models with substantial spatial curvature and large vacuum energy cannot be ruled out without prior knowledge of the Hubble parameter. Alternatively, the CMB alone cannot measure the Hubble parameter.

The other main parameter degeneracy involves the tensor contribution to the CMB anisotropies. These are important at large scales (up to the horizon scales); for smaller scales, only scalar fluctuations (density perturbations) are important. Each of these components is characterized by a spectral index, n , and a ratio between the power spectra of tensors and scalars (r). See the review on Cosmological Parameters—Sec. 23 of this *Review* for a technical definition of the r parameter. Finally, the overall amplitude of the spectrum must be specified (Q), together with the optical depth to Compton scattering owing to recent reionization (τ). The tensor degeneracy operates as follows: the main effect of adding a large tensor contribution is to reduce the contrast between low ℓ and the peak at $\ell \simeq 225$ (because the tensor spectrum has no acoustic component). The required height of the peak can be recovered by increasing n_s to increase the small-scale power in the scalar component; this in turn over-predicts the power at $\ell \sim 1000$, but this effect can be counteracted by raising the baryon density [80]. In order to break this degeneracy, additional data are required. For example, an excellent fit to the CMB data is obtained with a scalar-only model with zero curvature and $\omega_b = 0.0225$, $\omega_c = 0.1120$, $h = 0.704$, $n_s = 0.967$ [24]. However, this is indistinguishable from a model where tensors dominate at $\ell \lesssim 100$,

if we raise ω_b to 0.03 and n_s to 1.2. This baryon density is too high for nucleosynthesis, which disfavors the high-tensor solution [81].

The reason the tensor component is introduced, and why it is so important, is that it is the only non-generic prediction of inflation. Slow-roll models of inflation involve two dimensionless parameters:

$$\epsilon \equiv \frac{M_{\text{P}}^2}{16\pi} \left(\frac{V'}{V} \right)^2, \quad \eta \equiv \frac{M_{\text{P}}^2}{8\pi} \left(\frac{V''}{V} \right), \quad (21.80)$$

where V is the inflaton potential, and dashes denote derivatives with respect to the inflation field. In terms of these, the tensor-to-scalar ratio is $r \simeq 16\epsilon$, and the spectral indices are $n_s = 1 - 6\epsilon + 2\eta$ and $n_t = -2\epsilon$. The natural expectation of inflation is that the quasi-exponential phase ends once the slow-roll parameters become significantly non-zero, so that both $n_s \neq 1$ and a significant tensor component are expected. These prediction can be avoided in some models, but it is undeniable that observation of such features would be a great triumph for inflation. Cosmology therefore stands at a fascinating point given that the most recent CMB data appear to reject the zero-tensor $n_s = 1$ model at around 2.4σ : $n_s = 0.967 \pm 0.014$ [24]. If we insist on $n_s = 1$, then a very substantial tensor fraction would be required ($r \simeq 0.2$), although the fit is better with $r = 0$. Assuming that no systematic error in this result can be identified, cosmology has passed a critical hurdle; the years ahead will be devoted to the task of breaking the tensor degeneracy — for which the main tool will be the polarization of the CMB [14].

21.4.7. Probing dark energy and the nature of gravity :

The most radical element of our current cosmological model is the dark energy that accelerates the expansion. The energy density of this component is approximately $(2.4 \text{ meV})^4$ (for $w = -1$, $\Omega_v = 0.75$, $h = 0.73$), or roughly $10^{-123} M_{\text{P}}^4$, and such an un-naturally small number is hard to understand. Various quantum effects (most simply zero-point energy) should make contributions to the vacuum energy density: these may be truncated by new physics at high energy, but this presumably occurs at $> 1 \text{ TeV}$ scales, not meV; thus the apparent energy scale of the vacuum is at least 10^{15} times smaller than its natural value. This situation is well analysed in [82], which lists extreme escape routes — especially the multiverse viewpoint, according to which low values of Λ are rare, but high values suppress the formation of structure and observers. It is certainly impressive that Weinberg used such reasoning to predict the value of Λ before any data strongly indicated a non-zero value.

But it may be that the phenomenon of dark energy is entirely illusory. The necessity for this constituent arises from using the Friedmann equation to describe the evolution of the cosmic expansion; if this equation is incorrect, it would require the replacement of Einstein’s relativistic theory of gravity with some new alternative. A frontier of current cosmological research is to distinguish these possibilities [87,88]. We also note that it has been suggested that dark energy might be an illusion even within general relativity, owing to an incorrect treatment of averaging in an inhomogeneous Universe [89,90]. Many would argue that a standard Newtonian treatment of such issues should be adequate inside the cosmological horizon, but debate on this issue continues.

Dark Energy can differ from a classical cosmological constant in being a dynamical phenomenon [33,91], *e.g.*, a rolling scalar field (sometimes dubbed ‘quintessence’). Empirically, this means that it is endowed with two thermodynamic properties that astronomers can try to measure: the bulk equation of state and the sound speed. If the sound speed is close to the speed of light, the effect of this property is confined to very large scales, and mainly manifests itself in the large-angle multipoles of the CMB anisotropies [92]. The equation of state parameter governs the rate of change of the vacuum density: $d \ln \rho_v / d \ln a = -3(1+w)$, so it can be accessed via the evolving expansion rate, $H(a)$. This can be measured most cleanly by using the inbuilt natural ruler of large-scale structure: the Baryon Acoustic Oscillation horizon scale [93]:

$$D_{\text{BAO}} \simeq 147 (\Omega_m h^2 / 0.13)^{-0.25} (\Omega_b h^2 / 0.023)^{-0.08} \text{ Mpc}. \quad (21.81)$$

$H(a)$ is measured by radial clustering, since $dr/dz = c/H$; clustering in the plane of the sky measures the integral of this. The expansion

rate is also measured by the growth of density fluctuations, where the pressure-free growth equation for the density perturbation is $\ddot{\delta} + 2H(a)\dot{\delta} = 4\pi G\rho_0\delta$. Thus, both the scale and amplitude of density fluctuations are sensitive to $w(a)$ – but only weakly. These observables change by only typically 0.2% for a 1% change in w . Current constraints [24] are $-1.11 < w < -0.89$ (95% confidence), so a substantial improvement will require us to limit systematics in data to a few parts in 1000.

Testing whether theories of gravity require revision can also be done using data on cosmological inhomogeneities. Two separate issues arise, concerning the metric perturbation potentials Ψ and Φ , which affect respectively the time and space parts of the metric. In Einstein gravity, these potentials are both equal to the Newtonian gravitational potential, which satisfies Poisson's equation: $\nabla^2\Phi/a^2 = 4\pi G\bar{\rho}\delta$. Empirically, modifications of gravity require us to explore a change with scale and with time of the 'slip' (Ψ/Φ) and the effective G on the rhs of the Poisson equation. The former aspect can only be probed via gravitational lensing, whereas the latter can be addressed on 10-100 Mpc scales via the growth of clustering. Various schemes for parameterising modified gravity exist, but a practical approach is to assume that the growth rate can be tied to the density parameter: $d\ln\delta/d\ln a = \Omega_m(a)$ [94]. The parameter γ is close to 0.55 for standard relativistic gravity, but can differ by around 0.1 from this value in many non-standard models. Clearly this parameterization is incomplete, since it explicitly rejects the possibility of early dark energy ($\Omega_m(a) \rightarrow 1$ as $a \rightarrow 0$), but it is a convenient way of capturing the power of various experiments. Current data are consistent with standard Λ CDM [86], and exclude variations in slip or effective G of larger than a few times 10%.

Current planning envisages a set of satellite probes that, a decade hence, will pursue these fundamental tests via gravitational lensing measurements over thousands of square degrees, $> 10^8$ redshifts, and photometry of > 1000 supernovae (WFIRST in the USA, Euclid in Europe) [22,23]. These experiments will measure both w and the perturbation growth rate to an accuracy of around 1%. The outcome will be either a validation of the standard relativistic vacuum-dominated big bang cosmology at a level of precision far beyond anything attempted to date, or the opening of entirely new directions in cosmological models.

22. BIG-BANG NUCLEOSYNTHESIS

Revised August 2011 by B.D. Fields (Univ. of Illinois) and S. Sarkar (Univ. of Oxford).

Big-Bang nucleosynthesis (BBN) offers the deepest reliable probe of the early Universe, being based on well-understood Standard Model physics [1–8]. Predictions of the abundances of the light elements, D, ^3He , ^4He , and ^7Li , synthesized at the end of the ‘first three minutes’, are in good overall agreement with the primordial abundances inferred from observational data, thus validating the standard hot Big-Bang cosmology (see [9] for a review). This is particularly impressive given that these abundances span nine orders of magnitude – from $^4\text{He}/\text{H} \sim 0.08$ down to $^7\text{Li}/\text{H} \sim 10^{-10}$ (ratios by number). Thus BBN provides powerful constraints on possible deviations from the standard cosmology, and on new physics beyond the Standard Model [4–7].

22.1. Theory

The synthesis of the light elements is sensitive to physical conditions in the early radiation-dominated era at a temperature $T \sim 1$ MeV, corresponding to an age $t \sim 1$ s. At higher temperatures, weak interactions were in thermal equilibrium, thus fixing the ratio of the neutron and proton number densities to be $n/p = e^{-Q/T}$, where $Q = 1.293$ MeV is the neutron-proton mass difference. As the temperature dropped, the neutron-proton inter-conversion rate, $\Gamma_{n \leftrightarrow p} \sim G_F^2 T^5$, fell faster than the Hubble expansion rate, $H \sim \sqrt{g_* G_N} T^2$, where g_* counts the number of relativistic particle species determining the energy density in radiation (see ‘Big Bang Cosmology’ review). This resulted in departure from chemical equilibrium (‘freeze-out’) at $T_{\text{fr}} \sim (g_* G_N / G_F^4)^{1/6} \simeq 1$ MeV. The neutron fraction at this time, $n/p = e^{-Q/T_{\text{fr}}} \simeq 1/6$, is thus sensitive to every known physical interaction, since Q is determined by both strong and electromagnetic interactions while T_{fr} depends on the weak as well as gravitational interactions. Moreover, the sensitivity to the Hubble expansion rate affords a probe of *e.g.*, the number of relativistic neutrino species [10]. After freeze-out, the neutrons were free to β -decay, so the neutron fraction dropped to $n/p \simeq 1/7$ by the time nuclear reactions began. A simplified analytic model of freeze-out yields the n/p ratio to an accuracy of $\sim 1\%$ [11,12].

The rates of these reactions depend on the density of baryons (strictly speaking, nucleons), which is usually expressed normalized to the relic blackbody photon density as $\eta \equiv n_b/n_\gamma$. As we shall see, all the light-element abundances can be explained with $\eta_{10} \equiv \eta \times 10^{10}$ in the range 5.1–6.5 (95% CL). With n_γ fixed by the present CMB temperature 2.725 K (see ‘Cosmic Microwave Background’ review), this can be stated as the allowed range for the baryon mass density today, $\rho_b = (3.5\text{--}4.5) \times 10^{-31}$ g cm $^{-3}$, or as the baryonic fraction of the critical density, $\Omega_b = \rho_b/\rho_{\text{crit}} \simeq \eta_{10} h^{-2}/274 = (0.019\text{--}0.024)h^{-2}$, where $h \equiv H_0/100$ km s $^{-1}$ Mpc $^{-1} = 0.72 \pm 0.08$ is the present Hubble parameter (see Cosmological Parameters review).

The nucleosynthesis chain begins with the formation of deuterium in the process $p(n,\gamma)\text{D}$. However, photo-dissociation by the high number density of photons delays production of deuterium (and other complex nuclei) well after T drops below the binding energy of deuterium, $\Delta_{\text{D}} = 2.23$ MeV. The quantity $\eta^{-1}e^{-\Delta_{\text{D}}/T}$, *i.e.*, the number of photons per baryon above the deuterium photo-dissociation threshold, falls below unity at $T \simeq 0.1$ MeV; nuclei can then begin to form without being immediately photo-dissociated again. Only 2-body reactions, such as $\text{D}(p,\gamma)^3\text{He}$, $^3\text{He}(\text{D},p)^4\text{He}$, are important because the density by this time has become rather low – comparable to that of air!

Nearly all neutrons end up bound in the most stable light element ^4He . Heavier nuclei do not form in any significant quantity both because of the absence of stable nuclei with mass number 5 or 8 (which impedes nucleosynthesis via $n^4\text{He}$, $p^4\text{He}$ or $^4\text{He}^4\text{He}$ reactions), and the large Coulomb barriers for reactions such as $^3\text{He}(^4\text{He},\gamma)^7\text{Li}$ and $^3\text{He}(^4\text{He},\gamma)^7\text{Be}$. Hence the primordial mass fraction of ^4He , conventionally referred to as Y_p , can be estimated by the simple counting argument

$$Y_p = \frac{2(n/p)}{1+n/p} \simeq 0.25. \quad (22.1)$$

There is little sensitivity here to the actual nuclear reaction rates, which are, however, important in determining the other ‘left-over’

abundances: D and ^3He at the level of a few times 10^{-5} by number relative to H, and $^7\text{Li}/\text{H}$ at the level of about 10^{-10} (when η_{10} is in the range 1–10). These values can be understood in terms of approximate analytic arguments [12,13]. The experimental parameter most important in determining Y_p is the neutron lifetime, τ_n , which normalizes (the inverse of) $\Gamma_{n \leftrightarrow p}$. The experimental uncertainty in τ_n has been thought small, at $\tau_n = 885.7 \pm 0.8$ s but recent measurements and re-analyses suggest possible systematic errors ~ 6 times larger (see *N Baryons Listing*).

The elemental abundances shown in Fig. 22.1 as a function of η_{10} were calculated [14] using an updated version [15] of the Wagoner code [1]; other modern versions [16,17] are publicly available. The ^4He curve includes small corrections due to radiative processes at zero and finite temperatures [18], non-equilibrium neutrino heating during e^\pm annihilation [19], and finite nucleon mass effects [20]; the range reflects primarily the 2σ uncertainty in the neutron lifetime. The spread in the curves for D, ^3He , and ^7Li corresponds to the 2σ uncertainties in nuclear cross sections, as estimated by Monte Carlo methods [21–22]. The input nuclear data have been carefully reassessed [14, 23–27], leading to improved precision in the abundance predictions. In particular, the uncertainty in $^7\text{Li}/\text{H}$ at interesting values of η has been reduced recently by a factor ~ 2 , a consequence of a similar reduction in the error budget [28] for the dominant mass-7 production channel $^3\text{He}(^4\text{He},\gamma)^7\text{Be}$. Polynomial fits to the predicted abundances and the error correlation matrix have been given [22,29]. The boxes in Fig. 22.1 show the observationally inferred primordial abundances with their associated statistical and systematic uncertainties, as discussed below.

Figure 22.1: The abundances of ^4He , D, ^3He , and ^7Li as predicted by the standard model of Big-Bang nucleosynthesis [14] – the bands show the 95% CL range. Boxes indicate the observed light element abundances (smaller boxes: $\pm 2\sigma$ statistical errors; larger boxes: $\pm 2\sigma$ statistical and systematic errors). The narrow vertical band indicates the CMB measure of the cosmic baryon density, while the wider band indicates the BBN concordance range (both at 95% CL).

22.2. Light Element Abundances

BBN theory predicts the universal abundances of D, ^3He , ^4He , and ^7Li , which are essentially fixed by $t \sim 180$ s. Abundances are, however, usually observed at much later epochs, after stellar nucleosynthesis has commenced. The ejected remains of this stellar processing can alter the light element abundances from their primordial values, and also produce heavy elements such as C, N, O, and Fe ('metals'). Thus, one seeks astrophysical sites with low metal abundances, in order to measure light element abundances which are closer to primordial. For all of the light elements, systematic errors are an important (and often dominant) limitation to the precision with which primordial abundances can be inferred.

High-resolution spectra reveal the presence of D in high-redshift, low-metallicity quasar absorption systems via its isotope-shifted Lyman- α absorption [30–33]. It is believed that there are no astrophysical sources of deuterium [34], so any detection provides a lower limit to primordial D/H, and thus an upper limit on η ; for example, the local interstellar value of $\text{D}/\text{H}|_{\text{p}} = (1.56 \pm 0.04) \times 10^{-5}$ [35] requires $\eta_{10} \leq 9$. Recent observations find an unexpected scatter of a factor of ~ 2 [36], as well as correlations with heavy element abundances which suggest that interstellar D may suffer stellar processing (astration), but also partly reside in dust particles which evade gas-phase observations. This is supported by a measurement in the lower halo [37], which indicates that the Galactic D abundance has been reduced by a factor of only 1.12 ± 0.13 since its formation. For the high-redshift systems, conventional models of galactic nucleosynthesis (chemical evolution) do not predict either of these effects for D/H [38].

The observed extragalactic D values are bracketed by the non-detection of D in a high-redshift system, $\text{D}/\text{H}|_{\text{p}} < 6.7 \times 10^{-5}$ at 1σ [39], and low values in some (damped Lyman- α) systems [30,31]. Averaging the seven most precise observations of deuterium in quasar absorption systems gives $\text{D}/\text{H} = (2.82 \pm 0.12) \times 10^{-5}$, where the error is statistical only [32,33]. However, there remains concern over systematic errors, the dispersion between the values being much larger than is expected from the individual measurement errors ($\chi^2 = 17.7$ for $\nu = 6$ d.o.f.). Increasing the error by a factor $\sqrt{\chi^2/\nu}$ gives, as shown in Fig. 22.1:

$$\text{D}/\text{H}|_{\text{p}} = (2.82 \pm 0.21) \times 10^{-5}. \quad (22.2)$$

^4He can be observed in clouds of ionized hydrogen (H II regions), the most metal-poor of which are in dwarf galaxies. There is now a large body of data on ^4He and CNO in such systems [40]. These data confirm that the small stellar contribution to helium is positively correlated with metal production. Extrapolating to zero metallicity gives the primordial ^4He abundance [41]

$$Y_{\text{p}} = 0.249 \pm 0.009. \quad (22.3)$$

Here the latter error is a careful (and significantly enlarged) estimate of the systematic uncertainties which dominate, and is based on the scatter in different analyses of the physical properties of the H II regions [40,41]. Other recent extrapolations to zero metallicity give $Y_{\text{p}} = 0.247 \pm 0.001$ or 0.252 ± 0.001 depending on which set of He I emissivities are used [42], and $Y_{\text{p}} = 0.248 \pm 0.003$ [43]. These are consistent (given the systematic errors) with the above estimate [41], which appears in Fig. 22.1. The CMB damping tail (see Cosmic Microwave Background review) is sensitive to the primordial ^4He abundance [44]. Recent measurements find $Y_{\text{p}} = 0.296 \pm 0.030$ [45], consistent with the above; future *Planck* measurements should tighten this result.

As we will see in more detail below, the primordial abundance of lithium now plays a central role in BBN, and possibly points to new physics. The systems best suited for Li observations are metal-poor stars in the spheroid (Pop II) of our Galaxy, which have metallicities going down to at least 10^{-4} , and perhaps 10^{-5} of the Solar value [46]. Observations have long shown [47–51] that Li does not vary significantly in Pop II stars with metallicities $\lesssim 1/30$ of Solar — the 'Spite plateau' [47]. Precision data suggest a small but significant correlation between Li and Fe [48], which

can be understood as the result of Li production from Galactic cosmic rays [49]. Extrapolating to zero metallicity, one arrives at a primordial value $\text{Li}/\text{H}|_{\text{p}} = (1.23 \pm 0.06^{+0.68}_{-0.32}) \times 10^{-10}$ [50], where the first error given is statistical and is very small due to the relatively large sample of 22 stars used. One source of systematic error stems from the differences in techniques used to determine the physical parameters (*e.g.*, the temperature) of the stellar atmosphere in which the Li absorption line is formed. Alternative analyses, using methods that give systematically higher temperatures, and in some cases different stars and stellar systems (globular clusters), yield $\text{Li}/\text{H}|_{\text{p}} = (2.19 \pm 0.28) \times 10^{-10}$ [51], $\text{Li}/\text{H}|_{\text{p}} = (2.34 \pm 0.32) \times 10^{-10}$ [52], and $\text{Li}/\text{H}|_{\text{p}} = (1.26 \pm 0.26) \times 10^{-10}$ [53]; the differences with [50] indicate a systematic uncertainty of a factor of ~ 2 . Moreover, it is possible that the Li in Pop II stars has been partially destroyed, due to mixing of the outer layers with the hotter interior [54]. Such processes can be constrained by the absence of significant scatter in Li versus Fe [48], and by observations of the fragile isotope ^6Li [49]. Nevertheless, some depletion is likely to exist: a factor as large as ~ 1.8 has been suggested [55] (and recent observations find a puzzling drop in Li/H in ultra-metal-poor stars [56]). Including these systematics, we estimate a primordial Li range which spans the ranges above, as shown in Fig. 22.1:

$$\text{Li}/\text{H}|_{\text{p}} = (1.7 \pm 0.06 \pm 0.44) \times 10^{-10}. \quad (22.4)$$

Stellar determination of Li abundances typically sum over both stable isotopes ^6Li and ^7Li . Recent high-precision measurements are sensitive to the tiny isotopic shift in Li absorption (which manifests itself in the shape of the blended, thermally broadened line) and indicate $^6\text{Li}/^7\text{Li} \leq 0.15$ [57]. This confirms that ^7Li is dominant, but surprisingly there is indication of a ^6Li plateau (analogous to the ^7Li plateau) which suggests a significant primordial ^6Li abundance. However, caution must be exercised since convective motions in the star can generate similar asymmetries in the line shape, hence the deduced ^6Li abundance is presently best interpreted as an upper limit [58].

Turning to ^3He , the only data available are from the Solar system and (high-metallicity) H II regions in our Galaxy [59]. This makes inferring the primordial abundance difficult, a problem compounded by the fact that stellar nucleosynthesis models for ^3He are in conflict with observations [60]. Consequently, it is no longer appropriate to use ^3He as a cosmological probe; instead, one might hope to turn the problem around and constrain stellar astrophysics using the predicted primordial ^3He abundance [61].

22.3. Concordance, Dark Matter, and the CMB

We now use the observed light element abundances to test the theory. We first consider standard BBN, which is based on Standard Model physics alone, so $N_{\nu} = 3$ and the only free parameter is the baryon-to-photon ratio η . (The implications of BBN for physics beyond the Standard Model will be considered below, §4). Thus, any abundance measurement determines η , while additional measurements overconstrain the theory and thereby provide a consistency check.

First we note that the overlap in the η ranges spanned by the larger boxes in Fig. 22.1 indicates overall concordance. More quantitatively, when we account for theoretical uncertainties, as well as the statistical and systematic errors in observations, there is acceptable agreement among the abundances when

$$5.1 \leq \eta_{10} \leq 6.5 \quad (95\% \text{ CL}). \quad (22.5)$$

However, the agreement is much less satisfactory if we use only the quoted statistical errors in the observations. In particular, as seen in Fig. 22.1, D and ^4He are consistent with each other, but favor a value of η which is higher by a factor of at least 2.4, and by at least $\sim 4.2\sigma$ from that indicated by the ^7Li abundance determined in stars. Furthermore, if the ^6Li plateau [57] reflects a primordial component, it is ~ 1000 times that expected in standard BBN; both these "lithium problems" may indicate new physics (see below).

Even so, the overall concordance is remarkable: using well-established microphysics we have extrapolated back to an age of ~ 1 s

to correctly predict light element abundances spanning 9 orders of magnitude. This is a major success for the standard cosmology, and inspires confidence in extrapolation back to still earlier times.

This concordance provides a measure of the baryon content

$$0.019 \leq \Omega_b h^2 \leq 0.024 \text{ (95\% CL)}, \quad (22.6)$$

a result that plays a key role in our understanding of the matter budget of the Universe. First we note that $\Omega_b \ll 1$, *i.e.*, baryons cannot close the Universe [62]. Furthermore, the cosmic density of (optically) luminous matter is $\Omega_{\text{lum}} \simeq 0.0024 h^{-1}$ [63], so that $\Omega_b \gg \Omega_{\text{lum}}$: most baryons are optically dark, probably in the form of a diffuse intergalactic medium [64]. Finally, given that $\Omega_m \sim 0.3$ (see Dark Matter and Cosmological Parameters reviews), we infer that most matter in the Universe is not only dark, but also takes some non-baryonic (more precisely, non-nucleonic) form.

The BBN prediction for the cosmic baryon density can be tested through precision observations of CMB temperature fluctuations (see Cosmic Microwave Background review). One can determine η from the amplitudes of the acoustic peaks in the CMB angular power spectrum [65], making it possible to compare two measures of η using very different physics, at two widely separated epochs. In the standard cosmology, there is no change in η between BBN and CMB decoupling, thus, a comparison of η_{BBN} and η_{CMB} is a key test. Agreement would endorse the standard picture while disagreement could point to new physics during/between the BBN and CMB epochs.

The release of the WMAP results was a landmark event in this test of BBN. As with other cosmological parameter determinations from CMB data, the derived η_{CMB} depends on the adopted priors [66], in particular the form assumed for the power spectrum of primordial density fluctuations. If this is taken to be a scale-free power-law, the five-year WMAP data imply $\Omega_b h^2 = 0.02273 \pm 0.00062$ or $\eta_{10} = 6.23 \pm 0.17$ [67] as shown in Fig. 22.1. Other assumptions for the shape of the power spectrum can lead to baryon densities as low as $\Omega_b h^2 = 0.0175 \pm 0.0007$ [68]. Thus, outstanding uncertainties regarding priors are a source of systematic error which presently exceeds the statistical error in the prediction for η .

It is remarkable that the CMB estimate of the baryon density is consistent with the BBN range quoted in Eq. (22.6), and in very good agreement with the value inferred from recent high-redshift D/H measurements [33] and ${}^4\text{He}$ determinations; together these observations span diverse environments from redshifts $z = 1000$ to the present.

Bearing in mind the importance of priors, the promise of precision determinations of the baryon density using the CMB motivates the use of this value as an input to BBN calculations. Within the context of the Standard Model, BBN then becomes a zero-parameter theory, and the light element abundances are completely determined to within the uncertainties in η_{CMB} and the BBN theoretical errors. Comparison with the observed abundances then can be used to test the astrophysics of post-BBN light element evolution [71]. Alternatively, one can consider possible physics beyond the Standard Model (*e.g.*, which might change the expansion rate during BBN) and then use all of the abundances to test such models; this is the subject of our final section.

22.4. The Lithium Problem

As Fig. 22.1 shows, stellar Li/H measurements are inconsistent with the CMB (and D/H), given the error budgets we have quoted. Recent updates in nuclear cross sections, stellar abundance systematics, and the WMAP results all *increase* the discrepancy to as much as 5.3σ , depending on the stellar abundance analysis adopted. [14].

The question then becomes more pressing as to whether this mismatch comes from systematic errors in the observed abundances, and/or uncertainties in stellar astrophysics or nuclear inputs, or whether there might be new physics at work [7]. Nucleosynthesis models in which the baryon-to-photon ratio is inhomogeneous can alter abundances for a given η_{BBN} , but will overproduce ${}^7\text{Li}$ [69]. Entropy generation by some non-standard process could have decreased η between the BBN era and CMB decoupling, however the lack of

spectral distortions in the CMB rules out any significant energy injection upto a redshift $z \sim 10^7$ [70]. The most intriguing resolution of the lithium problem thus involves new physics during BBN [5–6].

For now this is a central unresolved issue in BBN. Nevertheless, the remarkable concordance between the CMB and D/H, as well as ${}^4\text{He}$, remain as non-trivial successes, and open windows onto the early Universe and particle physics, as we now discuss.

22.5. Beyond the Standard Model

Given the simple physics underlying BBN, it is remarkable that it still provides the most effective test for the cosmological viability of ideas concerning physics beyond the Standard Model. Although baryogenesis and inflation must have occurred at higher temperatures in the early Universe, we do not as yet have ‘standard models’ for these, so BBN still marks the boundary between the established and the speculative in Big Bang cosmology. It might appear possible to push the boundary back to the quark-hadron transition at $T \sim \Lambda_{\text{QCD}}$, or electroweak symmetry breaking at $T \sim 1/\sqrt{G_{\text{F}}}$; however, so far no observable relics of these epochs have been identified, either theoretically or observationally. Thus, although the Standard Model provides a precise description of physics up to the Fermi scale, cosmology cannot be traced in detail before the BBN era.

Limits on particle physics beyond the Standard Model come mainly from the observational bounds on the ${}^4\text{He}$ abundance. This is proportional to the n/p ratio which is determined when the weak-interaction rates fall behind the Hubble expansion rate at $T_{\text{fr}} \sim 1 \text{ MeV}$. The presence of additional neutrino flavors (or of any other relativistic species) at this time increases g_* , hence the expansion rate, leading to a larger value of T_{fr} , n/p , and therefore Y_{p} [10,72]. In the Standard Model, the number of relativistic particle species at 1 MeV is $g_* = 5.5 + \frac{7}{4}N_\nu$, where the factor 5.5 accounts for photons and e^\pm , and N_ν is the *effective* number of (nearly massless) neutrino flavors (see Big Bang Cosmology review). The helium curves in Fig. 22.1 were computed taking $N_\nu = 3$; small corrections for non-equilibrium neutrino heating [19] are included in the thermal evolution and lead to an effective $N_\nu = 3.04$ compared to assuming instantaneous neutrino freezeout (see, *e.g.*, Big Bang Cosmology review). The computed ${}^4\text{He}$ abundance scales as $\Delta Y_{\text{p}} \simeq 0.013 \Delta N_\nu$ [11]. Clearly the central value for N_ν from BBN will depend on η , which is independently determined (with weaker sensitivity to N_ν) by the adopted D or ${}^7\text{Li}$ abundance. For example, if the best value for the observed primordial ${}^4\text{He}$ abundance is 0.249, then, for $\eta_{10} \sim 6$, the central value for N_ν is very close to 3. This limit depends sensitively on the adopted light element abundances, particularly Y_{p} . A maximum likelihood analysis on η and N_ν based on the above ${}^4\text{He}$ and D abundances finds the (correlated) 95% CL ranges to be $4.9 < \eta_{10} < 7.1$ and $1.8 < N_\nu < 4.5$ [73]. Similar results were obtained in another study [74] which presented a simpler method to extract such bounds based on χ^2 statistics, given a set of input abundances. Using the CMB determination of η improves the constraints: including the most recent WMAP data yields $N_\nu < 4.2$ (95% CL) [75]. It is also worth noting that CMB damping tail measurements alone now find $N_\nu = 3.85 \pm 0.62$ [45].

Just as one can use the measured helium abundance to place limits on g_* [72], any changes in the strong, weak, electromagnetic, or gravitational coupling constants, arising *e.g.*, from the dynamics of new dimensions, can be similarly constrained [76], as can be any speed-up of the expansion rate in *e.g.* scalar-tensor theories of gravity [77].

The limits on N_ν can be translated into limits on other types of particles or particle masses that would affect the expansion rate of the Universe during nucleosynthesis. For example, consider ‘sterile’ neutrinos with only right-handed interactions of strength $G_{\text{R}} < G_{\text{F}}$. Such particles would decouple at higher temperature than (left-handed) neutrinos, so their number density ($\propto T^3$) relative to neutrinos would be reduced by any subsequent entropy release, *e.g.*, due to annihilations of massive particles that become non-relativistic between the two decoupling temperatures. Thus (relativistic) particles with less than full strength weak interactions contribute less to the energy density than particles that remain in equilibrium up to the time of nucleosynthesis [78]. If we impose $N_\nu < 4$ as an

illustrative constraint, then the three right-handed neutrinos must have a temperature $3(T_{\nu_R}/T_{\nu_L})^4 < 1$. Since the temperature of the decoupled ν_R 's is determined by entropy conservation (see Big Bang Cosmology review), $T_{\nu_R}/T_{\nu_L} = [(43/4)/g_*(T_d)]^{1/3} < 0.76$, where T_d is the decoupling temperature of the ν_R 's. This requires $g_*(T_d) > 24$, so decoupling must have occurred at $T_d > 140$ MeV. The decoupling temperature is related to G_R through $(G_R/G_F)^2 \sim (T_d/3 \text{ MeV})^{-3}$, where 3 MeV is the decoupling temperature for ν_L 's. This yields a limit $G_R \lesssim 10^{-2} G_F$. The above argument sets lower limits on the masses of new Z' gauge bosons to which right-handed neutrinos would be coupled in models of superstrings [79], or extended technicolor [80]. Similarly a Dirac magnetic moment for neutrinos, which would allow the right-handed states to be produced through scattering and thus increase g_* , can be significantly constrained [81], as can any new interactions for neutrinos which have a similar effect [82]. Right-handed states can be populated directly by helicity-flip scattering if the neutrino mass is large enough, and this property has been used to infer a bound of $m_{\nu\tau} \lesssim 1$ MeV taking $N_\nu < 4$ [83]. If there is mixing between active and sterile neutrinos then the effect on BBN is more complicated [84].

The limit on the expansion rate during BBN can also be translated into bounds on the mass/lifetime of non-relativistic particles which decay during BBN. This results in an even faster speed-up rate, and typically also change the entropy [85]. If the decays include Standard Model particles, the resulting electromagnetic [86–87] and/or hadronic [88] cascades can strongly perturb the light elements, which leads to even stronger constraints. Such arguments have been applied to rule out a MeV mass ν_τ , which decays during nucleosynthesis [89].

Such arguments have proved very effective in constraining supersymmetry. For example, if the gravitino is very light and contributes to g_* , the illustrative BBN limit $N_\nu < 4$ requires its mass to exceed ~ 1 eV [90]. Alternatively, much recent interest has focussed on the case in which the next-to-lightest supersymmetric particle is metastable and decays during or after BBN. The constraints on unstable particles discussed above imply stringent bounds on the allowed abundance of such particles [88]; if the metastable particle is charged (*e.g.*, the stau), then it is possible for it to form atom-like electromagnetic bound states with nuclei, and the resulting impact on light elements can be quite complex [91]. Such decays can destroy ${}^7\text{Li}$ and/or produce ${}^6\text{Li}$, leading to a possible supersymmetric solution to the lithium problems noted above [92] (see [5] for a review). In addition, these arguments impose powerful constraints on supersymmetric inflationary cosmology [87–88], in particular thermal leptogenesis [93]. These can be evaded only if the gravitino is massive enough to decay before BBN, *i.e.*, $m_{3/2} \gtrsim 50$ TeV [94] (which would be unnatural), or if it is in fact the lightest supersymmetric particle and thus stable [87,95]. Similar constraints apply to moduli – very weakly coupled fields in string theory which obtain an electroweak-scale mass from supersymmetry breaking [96].

Finally, we mention that BBN places powerful constraints on the possibility that there are new large dimensions in nature, perhaps enabling the scale of quantum gravity to be as low as the electroweak scale [97]. Thus, Standard Model fields may be localized on a ‘brane,’ while gravity alone propagates in the ‘bulk.’ It has been further noted that the new dimensions may be non-compact, even infinite [98], and the cosmology of such models has attracted considerable attention. The expansion rate in the early Universe can be significantly modified, so BBN is able to set interesting constraints on such possibilities [99].

23. THE COSMOLOGICAL PARAMETERS

Updated September 2011, by O. Lahav (University College London) and A.R. Liddle (University of Sussex).

23.1. Parametrizing the Universe

Rapid advances in observational cosmology have led to the establishment of a precision cosmological model, with many of the key cosmological parameters determined to one or two significant figure accuracy. Particularly prominent are measurements of cosmic microwave background (CMB) anisotropies, led by the seven-year results from the Wilkinson Microwave Anisotropy Probe (WMAP) [1–3]. However the most accurate model of the Universe requires consideration of a wide range of different types of observation, with complementary probes providing consistency checks, lifting parameter degeneracies, and enabling the strongest constraints to be placed.

The term ‘cosmological parameters’ is forever increasing in its scope, and nowadays includes the parametrization of some functions, as well as simple numbers describing properties of the Universe. The original usage referred to the parameters describing the global dynamics of the Universe, such as its expansion rate and curvature. Also now of great interest is how the matter budget of the Universe is built up from its constituents: baryons, photons, neutrinos, dark matter, and dark energy. We need to describe the nature of perturbations in the Universe, through global statistical descriptors such as the matter and radiation power spectra. There may also be parameters describing the physical state of the Universe, such as the ionization fraction as a function of time during the era since recombination. Typical comparisons of cosmological models with observational data now feature between five and ten parameters.

23.1.1. The global description of the Universe :

Ordinarily, the Universe is taken to be a perturbed Robertson–Walker space-time with dynamics governed by Einstein’s equations. This is described in detail by Olive and Peacock in this volume. Using the density parameters Ω_i for the various matter species and Ω_Λ for the cosmological constant, the Friedmann equation can be written

$$\sum_i \Omega_i + \Omega_\Lambda - 1 = \frac{k}{R^2 H^2}, \quad (23.1)$$

where the sum is over all the different species of material in the Universe. This equation applies at any epoch, but later in this article we will use the symbols Ω_i and Ω_Λ to refer to the present values. A typical collection would be baryons, photons, neutrinos, and dark matter (given charge neutrality, the electron density is guaranteed to be too small to be worth considering separately and is included with the baryons).

The complete present state of the homogeneous Universe can be described by giving the current values of all the density parameters and of the Hubble parameter h . These also allow us to track the history of the Universe back in time, at least until an epoch where interactions allow interchanges between the densities of the different species, which is believed to have last happened at neutrino decoupling, shortly before Big Bang Nucleosynthesis (BBN). To probe further back into the Universe’s history requires assumptions about particle interactions, and perhaps about the nature of physical laws themselves.

23.1.2. Neutrinos :

The standard neutrino sector has three flavors. For neutrinos of mass in the range 5×10^{-4} eV to 1 MeV, the density parameter in neutrinos is predicted to be

$$\Omega_\nu h^2 = \frac{\sum m_\nu}{93 \text{ eV}}, \quad (23.2)$$

where the sum is over all families with mass in that range (higher masses need a more sophisticated calculation). We use units with $c = 1$ throughout. Results on atmospheric and Solar neutrino oscillations [4] imply non-zero mass-squared differences between the three neutrino flavors. These oscillation experiments cannot tell us the absolute neutrino masses, but within the simple assumption of a mass hierarchy suggest a lower limit of approximately 0.05 eV on the sum of the neutrino masses.

For a total mass as small as 0.1 eV, this could have a potentially observable effect on the formation of structure, as neutrino free-streaming damps the growth of perturbations. Present cosmological observations have shown no convincing evidence of any effects from either neutrino masses or an otherwise non-standard neutrino sector, and impose quite stringent limits, which we summarize in Section 23.3.4. Accordingly, the usual assumption is that the masses are too small to have a significant cosmological impact at present data accuracy. However, we note that the inclusion of neutrino mass as a free parameter can affect the derived values of other cosmological parameters.

The cosmological effect of neutrinos can also be modified if the neutrinos have decay channels, or if there is a large asymmetry in the lepton sector manifested as a different number density of neutrinos versus anti-neutrinos. This latter effect would need to be of order unity to be significant (rather than the 10^{-9} seen in the baryon sector), which may be in conflict with nucleosynthesis [5].

23.1.3. Inflation and perturbations :

A complete model of the Universe should include a description of deviations from homogeneity, at least in a statistical way. Indeed, some of the most powerful probes of the parameters described above come from the evolution of perturbations, so their study is naturally intertwined in the determination of cosmological parameters.

There are many different notations used to describe the perturbations, both in terms of the quantity used to describe the perturbations and the definition of the statistical measure. We use the dimensionless power spectrum Δ^2 as defined in Olive and Peacock (also denoted \mathcal{P} in some of the literature). If the perturbations obey Gaussian statistics, the power spectrum provides a complete description of their properties.

From a theoretical perspective, a useful quantity to describe the perturbations is the curvature perturbation \mathcal{R} , which measures the spatial curvature of a comoving slicing of the space-time. A case of particular interest is the Harrison–Zel’dovich spectrum, which corresponds to a constant $\Delta_{\mathcal{R}}^2$. More generally, one can approximate the spectrum by a power-law, writing

$$\Delta_{\mathcal{R}}^2(k) = \Delta_{\mathcal{R}}^2(k_*) \left[\frac{k}{k_*} \right]^{n-1}, \quad (23.3)$$

where n is known as the spectral index, always defined so that $n = 1$ for the Harrison–Zel’dovich spectrum, and k_* is an arbitrarily chosen scale. The initial spectrum, defined at some early epoch of the Universe’s history, is usually taken to have a simple form such as this power-law, and we will see that observations require n close to one, which corresponds to the perturbations in the curvature being independent of scale. Subsequent evolution will modify the spectrum from its initial form.

The simplest viable mechanism for generating the observed perturbations is the inflationary cosmology, which posits a period of accelerated expansion in the Universe’s early stages [6,7]. It is a useful working hypothesis that this is the sole mechanism for generating perturbations, and it may further be assumed to be the simplest class of inflationary model, where the dynamics are equivalent to that of a single scalar field ϕ slowly rolling on a potential $V(\phi)$. One may seek to verify that this simple picture can match observations and to determine the properties of $V(\phi)$ from the observational data. Alternatively, more complicated models, perhaps motivated by contemporary fundamental physics ideas, may be tested on a model-by-model basis.

Inflation generates perturbations through the amplification of quantum fluctuations, which are stretched to astrophysical scales by the rapid expansion. The simplest models generate two types, density perturbations which come from fluctuations in the scalar field and its corresponding scalar metric perturbation, and gravitational waves which are tensor metric fluctuations. The former experience gravitational instability and lead to structure formation, while the latter can influence the CMB anisotropies. Defining slow-roll parameters, with primes indicating derivatives with respect to the scalar field, as

$$\epsilon = \frac{m_{\text{Pl}}^2}{16\pi} \left(\frac{V'}{V} \right)^2 \quad ; \quad \eta = \frac{m_{\text{Pl}}^2}{8\pi} \frac{V''}{V}, \quad (23.4)$$

which should satisfy $\epsilon, |\eta| \ll 1$, the spectra can be computed using the slow-roll approximation as

$$\Delta_{\mathcal{R}}^2(k) \simeq \frac{8}{3m_{\text{Pl}}^4} \frac{V}{\epsilon} \Big|_{k=aH} ; \quad \Delta_{\text{grav}}^2(k) \simeq \frac{128}{3m_{\text{Pl}}^4} V \Big|_{k=aH}. \quad (23.5)$$

In each case, the expressions on the right-hand side are to be evaluated when the scale k is equal to the Hubble radius during inflation. The symbol ‘ \simeq ’ here indicates use of the slow-roll approximation, which is expected to be accurate to a few percent or better.

From these expressions, we can compute the spectral indices

$$n \simeq 1 - 6\epsilon + 2\eta \quad ; \quad n_{\text{grav}} \simeq -2\epsilon. \quad (23.6)$$

Another useful quantity is the ratio of the two spectra, defined by

$$r \equiv \frac{\Delta_{\text{grav}}^2(k_*)}{\Delta_{\mathcal{R}}^2(k_*)}. \quad (23.7)$$

This convention matches that used by WMAP [2] (there are some alternative historical definitions which lead to a slightly different prefactor in the following equation). We have

$$r \simeq 16\epsilon \simeq -8n_{\text{grav}}, \quad (23.8)$$

which is known as the consistency equation.

In general, one could consider corrections to the power-law approximation, which we discuss later. However, for now we make the working assumption that the spectra can be approximated by power laws. The consistency equation shows that r and n_{grav} are not independent parameters, and so the simplest inflation models give initial conditions described by three parameters, usually taken as $\Delta_{\mathcal{R}}^2$, n , and r , all to be evaluated at some scale k_* , usually the ‘statistical center’ of the range explored by the data. Alternatively, one could use the parametrization V , ϵ , and η , all evaluated at a point on the putative inflationary potential.

After the perturbations are created in the early Universe, they undergo a complex evolution up until the time they are observed in the present Universe. While the perturbations are small, this can be accurately followed using a linear theory numerical code such as CMBFAST or CAMB [8]. This works right up to the present for the CMB, but for density perturbations on small scales non-linear evolution is important and can be addressed by a variety of semi-analytical and numerical techniques. However the analysis is made, the outcome of the evolution is in principle determined by the cosmological model, and by the parameters describing the initial perturbations, and hence can be used to determine them.

Of particular interest are CMB anisotropies. Both the total intensity and two independent polarization modes are predicted to have anisotropies. These can be described by the radiation angular power spectra C_ℓ as defined in the article of Scott and Smoot in this volume, and again provide a complete description if the density perturbations are Gaussian.

23.1.4. The standard cosmological model :

We now have most of the ingredients in place to describe the cosmological model. Beyond those of the previous subsections, there are two parameters which are essential: a measure of the ionization state of the Universe and the galaxy bias parameter. The Universe is known to be highly ionized at low redshifts (otherwise radiation from distant quasars would be heavily absorbed in the ultra-violet), and the ionized electrons can scatter microwave photons altering the pattern of observed anisotropies. The most convenient parameter to describe this is the optical depth to scattering τ (*i.e.*, the probability that a given photon scatters once); in the approximation of instantaneous and complete reionization, this could equivalently be described by the redshift of reionization z_{ion} . The bias parameter, described fully later, is needed to relate the observed galaxy power spectrum to the predicted dark matter power spectrum. The basic set of cosmological parameters is therefore as shown in Table 23.1. The spatial curvature does not appear in the list, because it can be determined from the other parameters using Eq. (23.1) (and is assumed zero for the observed

values shown). The total present matter density $\Omega_{\text{m}} = \Omega_{\text{cdm}} + \Omega_{\text{b}}$ is sometimes used in place of the dark matter density.

Most attention to date has been on parameter estimation, where a set of parameters is chosen by hand and the aim is to constrain them. Interest has been growing towards the higher-level inference problem of model selection, which compares different choices of parameter sets. Bayesian inference offers an attractive framework for cosmological model selection, setting a tension between model predictiveness and ability to fit the data.

Table 23.1: The basic set of cosmological parameters. We give values (with some additional rounding) as obtained using a fit of a spatially-flat Λ CDM cosmology with a power-law initial spectrum to WMAP7 data alone: Table 10, left column of Ref. 2. Tensors are assumed zero except in quoting a limit on them. The exact values and uncertainties depend on both the precise data-sets used and the choice of parameters allowed to vary. Limits on Ω_{Λ} and h weaken if the Universe is not assumed flat. The density perturbation amplitude is specified by the derived parameter σ_8 . Uncertainties are one-sigma/68% confidence unless otherwise stated.

Parameter	Symbol	Value
Hubble parameter	h	0.704 ± 0.025
Cold dark matter density	Ω_{cdm}	$\Omega_{\text{cdm}} h^2 = 0.112 \pm 0.006$
Baryon density	Ω_{b}	$\Omega_{\text{b}} h^2 = 0.0225 \pm 0.0006$
Cosmological constant	Ω_{Λ}	0.73 ± 0.03
Radiation density	Ω_{r}	$\Omega_{\text{r}} h^2 = 2.47 \times 10^{-5}$
Neutrino density	Ω_{ν}	See Sec. 23.1.2
Density perturb. amplitude at $k = 0.002 \text{Mpc}^{-1}$	$\Delta_{\mathcal{R}}^2$	$(2.43 \pm 0.11) \times 10^{-9}$
Density perturb. spectral index	n	0.967 ± 0.014
Tensor to scalar ratio	r	$r < 0.36$ (95% conf.)
Ionization optical depth	τ	0.088 ± 0.015
Bias parameter	b	See Sec. 23.3.4

As described in Sec. 23.4, models based on these eleven parameters are able to give a good fit to the complete set of high-quality data available at present, and indeed some simplification is possible. Observations are consistent with spatial flatness, and indeed the inflation models so far described automatically generate negligible spatial curvature, so we can set $k = 0$; the density parameters then must sum to unity, and so one can be eliminated. The neutrino energy density is often not taken as an independent parameter. Provided the neutrino sector has the standard interactions, the neutrino energy density, while relativistic, can be related to the photon density using thermal physics arguments, and it is currently difficult to see the effect of the neutrino mass, although observations of large-scale structure have already placed interesting upper limits. This reduces the standard parameter set to nine. In addition, there is no observational evidence for the existence of tensor perturbations (though the upper limits are fairly weak), and so r could be set to zero. Presently n is in a somewhat uncertain position regarding whether it needs to be varied in a fit, or can be set to the Harrison–Zel’dovich value $n = 1$. Parameter estimation [3] indicates $n = 1$ is disfavoured at over $2\text{-}\sigma$, but Bayesian model selection techniques [9] suggest the data is not conclusive. With n set to one, this leaves seven parameters, which is the smallest set that can usefully be compared to the present cosmological data set. This model (usually with n kept as a parameter) is referred to by various names, including Λ CDM, the concordance cosmology, and the standard cosmological model.

Of these parameters, only Ω_{r} is accurately measured directly. The radiation density is dominated by the energy in the CMB, and the COBE satellite FIRAS experiment determined its temperature to be $T = 2.7255 \pm 0.0006 \text{K}$ [10], corresponding to $\Omega_{\text{r}} = 2.47 \times 10^{-5} h^{-2}$. It typically need not be varied in fitting other data. If galaxy clustering

data are not included in a fit, then the bias parameter is also unnecessary.

In addition to this minimal set, there is a range of other parameters which might prove important in future as the data-sets further improve, but for which there is so far no direct evidence, allowing them to be set to a specific value for now. We discuss various speculative options in the next section. For completeness at this point, we mention one other interesting parameter, the helium fraction, which is a non-zero parameter that can affect the CMB anisotropies at a subtle level. Presently, BBN provides the best measurement of this parameter (see the Fields and Sarkar article in this volume), and it is usually fixed in microwave anisotropy studies, but the data are just reaching a level where allowing its variation may become mandatory.

23.1.5. Derived parameters :

The parameter list of the previous subsection is sufficient to give a complete description of cosmological models which agree with observational data. However, it is not a unique parametrization, and one could instead use parameters derived from that basic set. Parameters which can be obtained from the set given above include the age of the Universe, the present horizon distance, the present neutrino background temperature, the epoch of matter–radiation equality, the epochs of recombination and decoupling, the epoch of transition to an accelerating Universe, the baryon-to-photon ratio, and the baryon to dark matter density ratio. In addition, the physical densities of the matter components, $\Omega_i h^2$, are often more useful than the density parameters. The density perturbation amplitude can be specified in many different ways other than the large-scale primordial amplitude, for instance, in terms of its effect on the CMB, or by specifying a short-scale quantity, a common choice being the present linear-theory mass dispersion on a scale of $8h^{-1}\text{Mpc}$, known as σ_8 , whose WMAP7 value is 0.81 ± 0.03 [2].

Different types of observation are sensitive to different subsets of the full cosmological parameter set, and some are more naturally interpreted in terms of some of the derived parameters of this subsection than on the original base parameter set. In particular, most types of observation feature degeneracies whereby they are unable to separate the effects of simultaneously varying several of the base parameters.

23.2. Extensions to the standard model

This section discusses some ways in which the standard model could be extended. At present, there is no positive evidence in favor of any of these possibilities, which are becoming increasingly constrained by the data, though there always remains the possibility of trace effects at a level below present observational capability.

23.2.1. More general perturbations :

The standard cosmology assumes adiabatic, Gaussian perturbations. Adiabaticity means that all types of material in the Universe share a common perturbation, so that if the space-time is foliated by constant-density hypersurfaces, then all fluids and fields are homogeneous on those slices, with the perturbations completely described by the variation of the spatial curvature of the slices. Gaussianity means that the initial perturbations obey Gaussian statistics, with the amplitudes of waves of different wavenumbers being randomly drawn from a Gaussian distribution of width given by the power spectrum. Note that gravitational instability generates non-Gaussianity; in this context, Gaussianity refers to a property of the initial perturbations, before they evolve significantly.

The simplest inflation models, based on one dynamical field, predict adiabatic perturbations and a level of non-Gaussianity which is too small to be detected by any experiment so far conceived. For present data, the primordial spectra are usually assumed to be power laws.

23.2.1.1. Non-power-law spectra:

For typical inflation models, it is an approximation to take the spectra as power laws, albeit usually a good one. As data quality improves, one might expect this approximation to come under pressure, requiring a more accurate description of the initial spectra, particularly for the density perturbations. In general, one can expand $\ln \Delta_{\mathcal{R}}^2$ as

$$\ln \Delta_{\mathcal{R}}^2(k) = \ln \Delta_{\mathcal{R}}^2(k_*) + (n_* - 1) \ln \frac{k}{k_*} + \frac{1}{2} \left. \frac{dn}{d \ln k} \right|_* \ln^2 \frac{k}{k_*} + \dots, \quad (23.9)$$

where the coefficients are all evaluated at some scale k_* . The term $dn/d \ln k|_*$ is often called the running of the spectral index [11]. Once non-power-law spectra are allowed, it is necessary to specify the scale k_* at which the spectral index is defined.

23.2.1.2. Isocurvature perturbations:

An isocurvature perturbation is one which leaves the total density unperturbed, while perturbing the relative amounts of different materials. If the Universe contains N fluids, there is one growing adiabatic mode and $N - 1$ growing isocurvature modes (for reviews see Ref. 12 and Ref. 7). These can be excited, for example, in inflationary models where there are two or more fields which acquire dynamically-important perturbations. If one field decays to form normal matter, while the second survives to become the dark matter, this will generate a cold dark matter isocurvature perturbation.

In general, there are also correlations between the different modes, and so the full set of perturbations is described by a matrix giving the spectra and their correlations. Constraining such a general construct is challenging, though constraints on individual modes are beginning to become meaningful, with no evidence that any other than the adiabatic mode must be non-zero.

23.2.1.3. Seeded perturbations:

An alternative to laying down perturbations at very early epochs is that they are seeded throughout cosmic history, for instance by topological defects such as cosmic strings. It has long been excluded that these are the sole original of structure, but they could contribute part of the perturbation signal, current limits being approximately ten percent [13]. In particular, cosmic defects formed in a phase transition ending inflation is a plausible scenario for such a contribution.

23.2.1.4. Non-Gaussianity:

Multi-field inflation models can also generate primordial non-Gaussianity (reviewed, *e.g.*, in Ref. 7). The extra fields can either be in the same sector of the underlying theory as the inflaton, or completely separate, an interesting example of the latter being the curvaton model [14]. Current upper limits on non-Gaussianity are becoming stringent, but there remains much scope to push down those limits and perhaps reveal trace non-Gaussianity in the data. If non-Gaussianity is observed, its nature may favor an inflationary origin, or a different one such as topological defects.

23.2.2. Dark matter properties :

Dark matter properties are discussed in the article by Drees and Gerbier in this volume. The simplest assumption concerning the dark matter is that it has no significant interactions with other matter, and that its particles have a negligible velocity as far as structure formation is concerned. Such dark matter is described as ‘cold,’ and candidates include the lightest supersymmetric particle, the axion, and primordial black holes. As far as astrophysicists are concerned, a complete specification of the relevant cold dark matter properties is given by the density parameter Ω_{cdm} , though those seeking to directly detect it are as interested in its interaction properties.

Cold dark matter is the standard assumption and gives an excellent fit to observations, except possibly on the shortest scales where there remains some controversy concerning the structure of dwarf galaxies and possible substructure in galaxy halos. It has long been excluded for all the dark matter to have a large velocity dispersion, so-called ‘hot’ dark matter, as it does not permit galaxies to form; for thermal relics the mass must be below about 1 keV to satisfy this

constraint, though relics produced non-thermally, such as the axion, need not obey this limit. However, in future further parameters might need to be introduced to describe dark matter properties relevant to astrophysical observations. Suggestions which have been made include a modest velocity dispersion (warm dark matter) and dark matter self-interactions. There remains the possibility that the dark matter comprises two separate components, *e.g.*, a cold one and a hot one, an example being if massive neutrinos have a non-negligible effect.

23.2.3. Dark energy :

While the standard cosmological model given above features a cosmological constant, in order to explain observations indicating that the Universe is presently accelerating, further possibilities exist under the general heading ‘dark energy’.[†] One possibility, usually called quintessence, is that a scalar field is responsible, with the mechanism mimicking that of early Universe inflation [15]. As described by Olive and Peacock, a fairly model-independent description of dark energy can be given using the equation of state parameter w , with $w = -1$ corresponding to a cosmological constant and w potentially varying with redshift. For high-precision predictions of CMB anisotropies, the scalar-field description has the advantage of a self-consistent evolution of the ‘sound speed’ associated with the dark energy perturbations.

A competing possibility is that the observed acceleration is due to a modification of gravity, *i.e.*, the left-hand side of Einstein’s equation rather than the right (for a review see Ref. 16). Observations of expansion kinematics alone cannot distinguish these two possibilities, but probes of the growth rate of structure formation may be able to. It is possible that certain modified theories of gravity could explain the late-time acceleration of the Universe without recourse to any dark energy or cosmological constant. In a ‘Newtonian’ gauge the perturbed metric can be written with two potentials. Non-relativistic particles only respond to the temporal one, essentially the Newtonian potential, while relativistic particles, *e.g.*, photons, respond to the full metric in the form of the sum of the two potentials. In standard general relativity the two potentials are the same (in absence of anisotropic stress). Measurements of redshift distortions from spectroscopic surveys and weak lensing from imaging surveys can in principle distinguish between the Dark Energy and Modified Gravity alternatives (*e.g.*, Ref. 17).

While present observations are consistent with a cosmological constant, to test dark energy models w must be varied. The most popular option is $w(a) = w_0 + (1 - a)w_a$ with w_0 and w_a constants to be determined [18]. Additionally the weak energy condition $w \geq -1$ may be imposed. Future data may require a more sophisticated parametrization of the dark energy, including its sound speed which influences structure formation.

23.2.4. Complex ionization history :

The full ionization history of the Universe is given by the ionization fraction as a function of redshift z . The simplest scenario takes the ionization to have the small residual value left after recombination up to some redshift z_{ion} , at which point the Universe instantaneously reionizes completely. Then there is a one-to-one correspondence between τ and z_{ion} (that relation, however, also depending on other cosmological parameters). An accurate treatment of this process will track separate histories for hydrogen and helium. While currently rapid ionization appears to be a good approximation, as data improve a more complex ionization history may need to be considered.

23.2.5. Varying ‘constants’ :

Variation of the fundamental constants of Nature over cosmological times is another possible enhancement of the standard cosmology. There is a long history of study of variation of the gravitational constant G , and more recently attention has been drawn to the possibility of small fractional variations in the fine-structure constant. There is presently no observational evidence for the former, which is tightly constrained by a variety of measurements. Evidence for

the latter has been claimed from studies of spectral line shifts in quasar spectra at redshifts of order two [19], but this is presently controversial and in need of further observational study.

23.2.6. Cosmic topology :

The usual hypothesis is that the Universe has the simplest topology consistent with its geometry, for example that a flat Universe extends forever. Observations cannot tell us whether that is true, but they can test the possibility of a non-trivial topology on scales up to roughly the present Hubble scale. Extra parameters would be needed to specify both the type and scale of the topology, for example, a cuboidal topology would need specification of the three principal axis lengths. At present, there is no direct evidence for cosmic topology, though the low values of the observed cosmic microwave quadrupole and octupole have been cited as a possible signature [20].

23.3. Probes

The goal of the observational cosmologist is to utilize astronomical information to derive cosmological parameters. The transformation from the observables to the key parameters usually involves many assumptions about the nature of the objects, as well as about the nature of the dark matter. Below we outline the physical processes involved in each probe, and the main recent results. The first two subsections concern probes of the homogeneous Universe, while the remainder consider constraints from perturbations.

In addition to statistical uncertainties we note three sources of systematic uncertainties that will apply to the cosmological parameters of interest: (i) due to the assumptions on the cosmological model and its priors (*i.e.*, the number of assumed cosmological parameters and their allowed range); (ii) due to the uncertainty in the astrophysics of the objects (*e.g.*, light curve fitting for supernovae or the mass–temperature relation of galaxy clusters); and (iii) due to instrumental and observational limitations (*e.g.*, the effect of ‘seeing’ on weak gravitational lensing measurements, or beam shape on CMB anisotropy measurements).

23.3.1. Direct measures of the Hubble constant :

In 1929, Edwin Hubble discovered the law of expansion of the Universe by measuring distances to nearby galaxies. The slope of the relation between the distance and recession velocity is defined to be the Hubble constant H_0 . Astronomers argued for decades on the systematic uncertainties in various methods and derived values over the wide range, $40 \text{ km s}^{-1} \text{ Mpc}^{-1} \lesssim H_0 \lesssim 100 \text{ km s}^{-1} \text{ Mpc}^{-1}$.

One of the most reliable results on the Hubble constant comes from the Hubble Space Telescope Key Project [21]. This study used the empirical period–luminosity relations for Cepheid variable stars to obtain distances to 31 galaxies, and calibrated a number of secondary distance indicators—Type Ia Supernovae (SNe Ia), the Tully–Fisher relation, surface-brightness fluctuations, and Type II Supernovae—measured over distances of 400 to 600 Mpc. They estimated $H_0 = 72 \pm 3$ (statistical) ± 7 (systematic) $\text{km s}^{-1} \text{ Mpc}^{-1}$.[‡]

A recent study [22] of over 600 Cepheids in the host galaxies of eight recent SNe Ia, observed with an improved camera on board the Hubble Space Telescope, was used to calibrate the magnitude–redshift relation for 240 SNe Ia. This yielded an even more accurate figure, $H_0 = 73.8 \pm 2.4 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (including both statistical and systematic errors). The major sources of uncertainty in this result are due to the heavy element abundance of the Cepheids and the distance to the fiducial nearby galaxy, the Large Magellanic Cloud, relative to which all Cepheid distances are measured. It is impressive that this result is in such good agreement with the result derived from the WMAP CMB measurements combined with other probes (see Table 23.2).

[†] It is actually the negative pressure of this material, not its energy, that is responsible for giving the acceleration. Furthermore, while generally in physics matter and energy are interchangeable terms, dark matter and dark energy are quite distinct concepts.

[‡] Unless stated otherwise, all quoted uncertainties in this article are one-sigma/68% confidence. Cosmological parameters often have significantly non-Gaussian uncertainties. Throughout we have rounded central values, and especially uncertainties, from original sources in cases where they appear to be given to excessive precision.

23.3.2. Supernovae as cosmological probes :

The relation between observed flux and the intrinsic luminosity of an object depends on the luminosity distance D_L , which in turn depends on cosmological parameters:

$$D_L = (1+z)r_e(z), \quad (23.10)$$

where $r_e(z)$ is the coordinate distance. For example, in a flat Universe

$$r_e(z) = \int_0^z \frac{dz'}{H(z')}. \quad (23.11)$$

For a general dark energy equation of state $w(z) = p_{de}(z)/\rho_{de}(z)$, the Hubble parameter is, still considering only the flat case,

$$\frac{H^2(z)}{H_0^2} = (1+z)^3 \Omega_m + \Omega_{de} \exp[3X(z)], \quad (23.12)$$

where

$$X(z) = \int_0^z [1+w(z')](1+z')^{-1} dz', \quad (23.13)$$

and Ω_{de} is the present density parameter of the dark energy component. If a general equation of state is allowed, then one has to solve for $w(z)$ (parametrized, for example, as $w(z) = w = \text{const.}$, or $w(z) = w_0 + w_1 z$) as well as for Ω_{de} .

Empirically, the peak luminosity of SNe Ia can be used as an efficient distance indicator (*e.g.*, Ref. 23). The favorite theoretical explanation for SNe Ia is the thermonuclear disruption of carbon–oxygen white dwarfs. Although not perfect ‘standard candles,’ it has been demonstrated that by correcting for a relation between the light curve shape, color, and the luminosity at maximum brightness, the dispersion of the measured luminosities can be greatly reduced. There are several possible systematic effects which may affect the accuracy of the use of SNe Ia as distance indicators, *e.g.*, evolution with redshift and interstellar extinction in the host galaxy and in the Milky Way.

Two major studies, the Supernova Cosmology Project and the High- z Supernova Search Team, found evidence for an accelerating Universe [24], interpreted as due to a cosmological constant or a dark energy component. Representative results from the ‘Union sample’ [25] of over 300 SNe Ia are shown in Fig. 23.1 (see also further results in Ref. 26). When combined with the CMB data (which indicates flatness, *i.e.*, $\Omega_m + \Omega_\Lambda \approx 1$), the best-fit values are $\Omega_m \approx 0.3$ and $\Omega_\Lambda \approx 0.7$. Most results in the literature are consistent with the $w = -1$ cosmological constant case. As an example of recent results, the SNLS3 team found, for a constant equation of state parameter, $w = -0.91^{+0.16}_{-0.20}$ (stat.) $^{+0.07}_{-0.14}$ (sys.) [27]. This includes a correction for the recently-discovered relationship between host galaxy mass and supernova absolute brightness. This agrees with earlier results [25,28]. Future experiments will aim to set constraints on the cosmic equation of state $w(z)$, though given the integral relation between the luminosity distance and $w(z)$ it is not straightforward to recover $w(z)$ (*e.g.*, Ref. 29).

23.3.3. Cosmic microwave background :

The physics of the CMB is described in detail by Scott and Smoot in this volume. Before recombination, the baryons and photons are tightly coupled, and the perturbations oscillate in the potential wells generated primarily by the dark matter perturbations. After decoupling, the baryons are free to collapse into those potential wells. The CMB carries a record of conditions at the time of last scattering, often called primary anisotropies. In addition, it is affected by various processes as it propagates towards us, including the effect of a time-varying gravitational potential (the integrated Sachs–Wolfe effect), gravitational lensing, and scattering from ionized gas at low redshift.

The primary anisotropies, the integrated Sachs–Wolfe effect, and scattering from a homogeneous distribution of ionized gas, can all be calculated using linear perturbation theory. Available codes include CMBFAST and CAMB [8], the latter widely used embedded within the analysis package CosmoMC [30]. Gravitational lensing is also calculated in these codes. Secondary effects such as inhomogeneities in the reionization process, and scattering from gravitationally-collapsed gas (the Sunyaev–Zel’dovich effect), require more complicated, and more uncertain, calculations.

Figure 23.1: Confidence level contours of 68.3%, 95.4% and 99.7% in the Ω_Λ – Ω_m plane from the CMB, BAOs and the Union SNe Ia set, as well as their combination (assuming $w = -1$). [Courtesy of Kowalski *et al.* [25]]

Figure 23.2: The angular power spectrum of the CMB temperature anisotropies from WMAP7, from Ref. 2. The grey band indicates the cosmic variance uncertainty. The solid line shows the prediction from the best-fitting Λ CDM model. [Figure courtesy NASA/WMAP Science Team.]

The upshot is that the detailed pattern of anisotropies depends on all of the cosmological parameters. In a typical cosmology, the anisotropy power spectrum [usually plotted as $\ell(\ell+1)C_\ell^T$] features a flat plateau at large angular scales (small ℓ), followed by a series of oscillatory features at higher angular scales, the first and most prominent being at around one degree ($\ell \simeq 200$). These features, known as acoustic peaks, represent the oscillations of the photon–baryon fluid around the time of decoupling. Some features can be

closely related to specific parameters—for instance, the location of the first peak probes the spatial geometry, while the relative heights of the peaks probes the baryon density—but many other parameters combine to determine the overall shape.

The seven-year data release from the WMAP satellite [1], henceforth WMAP7, has provided the most powerful results to date on the spectrum of CMB anisotropies, with a precision determination of the temperature power spectrum up to $\ell \simeq 900$, shown in Fig. 23.2, as well as measurements of the spectrum of E -polarization anisotropies and the correlation spectrum between temperature and polarization (those spectra having first been detected by DASI [31]). These are consistent with models based on the parameters we have described, and provide accurate determinations of many of those parameters [2].

WMAP7 provides an exquisite measurement of the location of the first acoustic peak, determining the angular-diameter distance of the last-scattering surface. In combination with other data this strongly constrains the spatial geometry, in a manner consistent with spatial flatness and excluding significantly-curved Universes. WMAP7 also gives a precision measurement of the age of the Universe. It gives a baryon density consistent with, and at higher precision than, that coming from BBN. It affirms the need for both dark matter and dark energy. It shows no evidence for dynamics of the dark energy, being consistent with a pure cosmological constant ($w = -1$). The density perturbations are consistent with a power-law primordial spectrum, with indications that the spectral slope may be less than the Harrison–Zel’dovich value $n = 1$ [2]. There is no indication of tensor perturbations, but the upper limit is quite weak. WMAP7’s current best-fit for the reionization optical depth, $\tau = 0.088$, is in reasonable agreement with models of how early structure formation induces reionization.

WMAP7 is consistent with other experiments and its dynamic range can be enhanced by including information from small-angle CMB experiments such as ACBAR, QUaD, the South Pole Telescope (SPT), and the Atacama Cosmology Telescope (ACT), which gives extra constraining power on some parameters. ACT has also announced the first detection of gravitational lensing of the CMB from the four-point correlation of temperature variations [32], agreeing with the expected effect in the standard cosmology.

23.3.4. Galaxy clustering :

The power spectrum of density perturbations depends on the nature of the dark matter. Within the Λ CDM model, the power spectrum shape depends primarily on the primordial power spectrum and on the combination $\Omega_m h$ which determines the horizon scale at matter–radiation equality, with a subdominant dependence on the baryon density.

The matter distribution is most easily probed by observing the galaxy distribution, but this must be done with care as the galaxies do not perfectly trace the dark matter distribution. Rather, they are a ‘biased’ tracer of the dark matter. The need to allow for such bias is emphasized by the observation that different types of galaxies show bias with respect to each other. In particular scale-dependent and stochastic biasing may introduce a systematic effect on the determination of cosmological parameters from redshift surveys. Prior knowledge from simulations of galaxy formation or from gravitational lensing data could help to quantify biasing. Furthermore, the observed 3D galaxy distribution is in redshift space, *i.e.*, the observed redshift is the sum of the Hubble expansion and the line-of-sight peculiar velocity, leading to linear and non-linear dynamical effects which also depend on the cosmological parameters. On the largest length scales, the galaxies are expected to trace the location of the dark matter, except for a constant multiplier b to the power spectrum, known as the linear bias parameter. On scales smaller than $20 h^{-1}$ Mpc or so, the clustering pattern is ‘squashed’ in the radial direction due to coherent infall, which depends approximately on the parameter $\beta \equiv \Omega_m^{0.6}/b$ (on these shorter scales, more complicated forms of biasing are not excluded by the data). On scales of a few h^{-1} Mpc, there is an effect of elongation along the line of sight (colloquially known as the ‘finger of God’ effect) which depends on the galaxy velocity dispersion.

Figure 23.3: The galaxy power spectrum from the SDSS LRGs. The best-fit LRG+WMAP Λ CDM model is shown for two sets of nuisance parameters (solid and dashed lines). The BAO inset shows the same data and model divided by a spline fit to the smooth component. [Figure courtesy B. Reid/W. Percival; see Ref. 35.]

23.3.4.1. Baryonic Acoustic Oscillations (BAOs):

The Fourier power spectra of the 2-degree Field (2dF) Galaxy Redshift Survey and the Sloan Digital Sky Survey (SDSS) are well fitted by a Λ CDM model and both surveys show evidence for BAOs [33,34]. Further analyses used the Luminous Red Galaxies (LRGs) in the SDSS 7th Data Release [35], shown in Fig. 23.3. Combining the so-called ‘halo’ power spectrum measurement with the then-current WMAP5 results, for the flat Λ CDM model they find $\Omega_m = 0.289 \pm 0.019$ and $H_0 = 69.4 \pm 1.6 \text{ km s}^{-1} \text{ Mpc}^{-1}$. A new survey, WiggleZ, combined with the 6dF and SDSS-LRG surveys, CMB and SNIa data, yields a constant equation of state $w = -1.03 \pm 0.08$ for a flat universe, consistent with a cosmological constant. However, allowing for epoch-dependent $w(a) = w_0 + (1-a)w_a$ they find that the uncertainties are much larger, $w_0 = -1.09 \pm 0.17$ and $w_a = 0.19 \pm 0.69$ [36]. Further BAO results are expected from the BOSS survey.

23.3.4.2. Integrated Sachs–Wolfe effect:

The integrated Sachs–Wolfe (ISW) effect, described in the article by Scott and Smoot, is the change in CMB photon energy when propagating through the changing gravitational potential wells of developing cosmic structures. In linear theory, the ISW signal is expected in universes where there is dark energy, curvature or modified gravity. Correlating the large-angle CMB anisotropies with very large scale structures, first proposed in Ref. 37, has provided results which vary from no detection of this effect to 4σ detection [38,39].

23.3.4.3. Limits on neutrino mass from galaxy surveys and other probes:

Large-scale structure data can put an upper limit on Ω_ν due to the neutrino ‘free streaming’ effect [40–43]. Upper limits on neutrino mass are commonly estimated by comparing the observed galaxy power spectrum with a four-component model of baryons, cold dark matter, a cosmological constant, and massive neutrinos. Such analyses also assume that the primordial power spectrum is adiabatic, scale-invariant, and Gaussian. Potential systematic effects include biasing of the galaxy distribution and non-linearities of the

power spectrum. An upper limit can also be derived from CMB anisotropies alone, but it is typically not below 2 eV [44]. Additional cosmological data sets can improve the results. Recent results using a photometric redshift sample of LRGs combined with WMAP, BAO, Hubble constant and SNe Ia data brought the upper limit on the total neutrino mass down to 0.28 eV [45], with a similar result for a combination of other data sets [46]. As the lower limit on neutrino mass from terrestrial experiments is 0.05 eV, it looks promising that cosmological surveys will detect the neutrino mass. Another probe of neutrino mass is the intergalactic medium, which manifests itself in quasar absorption lines (the Lyman- α forest), yielding from the SDSS flux power spectrum an upper limit of 0.9 eV (95% confidence) [47].

23.3.5. Clusters of galaxies :

A cluster of galaxies is a large collection of galaxies held together by their mutual gravitational attraction. The largest ones are around 10^{15} Solar masses, and are the largest gravitationally-collapsed structures in the Universe. Even at the present epoch they are relatively rare, with only a few percent of galaxies being in clusters. They provide various ways to study the cosmological parameters.

The first objects of a given kind form at the rare high peaks of the density distribution, and if the primordial density perturbations are Gaussian distributed, their number density is exponentially sensitive to the size of the perturbations, and hence can strongly constrain it. Clusters are an ideal application in the present Universe. They are usually used to constrain the amplitude σ_8 , as a box of side $8 h^{-1}$ Mpc contains about the right amount of material to form a cluster. The most useful observations at present are of X-ray emission from hot gas lying within the cluster, whose temperature is typically a few keV, and which can be used to estimate the mass of the cluster. A theoretical prediction for the mass function of clusters can come either from semi-analytic arguments or from numerical simulations. The same approach can be adopted at high redshift (which for clusters means redshifts of order one) to attempt to measure σ_8 at an earlier epoch. The evolution of σ_8 is primarily driven by the value of the matter density Ω_m , with a sub-dominant dependence on the dark energy properties.

At present, the main uncertainty is the relation between the observed gas temperature and the cluster mass, despite extensive study using simulations. Mantz *et al.* [48] used a large sample of X-ray selected clusters to find $\sigma_8 = 0.82 \pm 0.05$, $\Omega_m = 0.23 \pm 0.04$, and $w = -1.01 \pm 0.20$ for a constant dark energy equation of state w . This agrees well with the values predicted in cosmologies compatible with WMAP7.

A further use of clusters is to measure the ratio of baryon to dark matter mass, through modelling of the way the hot cluster gas is confined by the total gravitational potential. Allen *et al.* [49] give examples of constraints that can be obtained this way on both dark matter and dark energy using Chandra data across a range of redshifts.

23.3.6. Clustering in the inter-galactic medium :

It is commonly assumed, based on hydrodynamic simulations, that the neutral hydrogen in the inter-galactic medium (IGM) can be related to the underlying mass distribution. It is then possible to estimate the matter power spectrum on scales of a few megaparsecs from the absorption observed in quasar spectra, the so-called Lyman- α forest. The usual procedure is to measure the power spectrum of the transmitted flux, and then to infer the mass power spectrum. Photo-ionization heating by the ultraviolet background radiation and adiabatic cooling by the expansion of the Universe combine to give a simple power-law relation between the gas temperature and the baryon density. It also follows that there is a power-law relation between the optical depth τ and ρ_b . Therefore, the observed flux $F = \exp(-\tau)$ is strongly correlated with ρ_b , which itself traces the mass density. The matter and flux power spectra can be related by

$$P_m(k) = b^2(k) P_F(k), \quad (23.14)$$

where $b(k)$ is a bias function which is calibrated from simulations. Croft *et al.* [50] derived cosmological parameters from Keck Telescope observations of the Lyman- α forest at redshifts $z = 2$ to 4. Their

derived power spectrum corresponds to that of a CDM model, which is in good agreement with the 2dF galaxy power spectrum. A recent study using VLT spectra [51] agrees with the flux power spectrum of Ref. 50. This method depends on various assumptions. Seljak *et al.* [52] pointed out that uncertainties are sensitive to the range of cosmological parameters explored in the simulations, and the treatment of the mean transmitted flux. Nevertheless, this method has the potential of measuring accurately the power spectrum of mass perturbations in a different way to other methods.

23.3.7. Gravitational lensing :

Images of background galaxies are distorted by the gravitational effect of mass variations along the line of sight. Deep gravitational potential wells such as galaxy clusters generate ‘strong lensing’, leading to arcs, arclets and multiple images, while more moderate perturbations give rise to ‘weak lensing’. Weak lensing is now widely used to measure the mass power spectrum in selected regions of the sky (see Ref. 53 for recent reviews). As the signal is weak, the image of deformed galaxy shapes (the ‘shear map’) must be analyzed statistically to measure the power spectrum, higher moments, and cosmological parameters.

The shear measurements are mainly sensitive to the combination of Ω_m and the amplitude σ_8 . For example, the weak lensing signal detected by the CFHT Legacy Survey has been analyzed to yield $\sigma_8(\Omega_m/0.25)^{0.64} = 0.78 \pm 0.04$ [54] and $\sigma_8(\Omega_m/0.24)^{0.59} = 0.84 \pm 0.05$ [55] assuming a Λ CDM model. Earlier results are summarized in Ref. 53. There are various systematic effects in the interpretation of weak lensing, *e.g.*, due to atmospheric distortions during observations, the redshift distribution of the background galaxies, the intrinsic correlation of galaxy shapes, and non-linear modeling uncertainties.

23.3.8. Peculiar velocities :

Deviations from the Hubble flow directly probe the mass perturbations in the Universe, and hence provide a powerful probe of the dark matter [56]. Peculiar velocities are deduced from the difference between the redshift and the distance of a galaxy. The observational difficulty is in accurately measuring distances to galaxies. Even the best distance indicators (*e.g.*, the Tully–Fisher relation) give an uncertainty of 15% per galaxy, hence limiting the application of the method at large distances. Peculiar velocities are mainly sensitive to Ω_m , not to Ω_Λ or dark energy. While at present cosmological parameters derived from peculiar velocities are strongly affected by random and systematic errors, a new generation of surveys may improve their accuracy. Three promising approaches are the 6dF near-infrared survey of 15,000 peculiar velocities, peculiar velocities of SNe Ia, and the kinematic Sunyaev–Zel’dovich effect.

There is also a renewed interest in ‘redshift distortion’. As the measured redshift of a galaxy is the sum of its redshift due to the Hubble expansion and its peculiar velocity, this distortion depends on cosmological parameters [57] via the perturbation growth rate $f(z) = d \ln \delta / d \ln a \approx \Omega^\gamma(z)$, where $\gamma = 0.55$ for a concordance Λ CDM model, and is different for a modified gravity model. Recent observational results [58,59] show that by measuring $f(z)$ with redshift it is feasible to constrain γ and rule out certain modified gravity models.

23.4. Bringing observations together

Although it contains two ingredients—dark matter and dark energy—which have not yet been verified by laboratory experiments, the Λ CDM model is almost universally accepted by cosmologists as the best description of the present data. The basic ingredients are given by the parameters listed in Sec. 23.1.4, with approximate values of some of the key parameters being $\Omega_b \approx 0.05$, $\Omega_{\text{cdm}} \approx 0.23$, $\Omega_\Lambda \approx 0.72$, and a Hubble constant $h \approx 0.70$. The spatial geometry is very close to flat (and usually assumed to be precisely flat), and the initial perturbations Gaussian, adiabatic, and nearly scale-invariant.

The most powerful single experiment is WMAP7, which on its own supports all these main tenets. Values for some parameters, as given in Larson *et al.* [2] and Komatsu *et al.* [3], are reproduced in Table 23.2. These particular results presume a flat Universe. The

constraints are somewhat strengthened by adding additional data-sets, as shown in the Table, though most of the constraining power resides in the WMAP7 data.

Table 23.2: Parameter constraints reproduced from Larson *et al.* [2] and Komatsu *et al.* [3], with some additional rounding. All columns assume the Λ CDM cosmology with a power-law initial spectrum, no tensors, spatial flatness, and a cosmological constant as dark energy. Above the line are the six parameter combinations actually fit to the data; those below the line are derived from these. Two different data combinations are shown to highlight the extent to which this choice matters. The first column is WMAP7 alone, while the second column shows a combination of WMAP7 with BAO and H_0 data as described in Ref. 3. The perturbation amplitude $\Delta_{\mathcal{R}}^2$ is specified at the scale 0.002 Mpc^{-1} . Uncertainties are shown at 68% confidence.

	WMAP7 alone	WMAP7 + BAO + H_0
$\Omega_b h^2$	0.0225 ± 0.0006	0.0226 ± 0.0005
$\Omega_{\text{cdm}} h^2$	0.112 ± 0.006	0.113 ± 0.004
Ω_Λ	0.73 ± 0.03	0.725 ± 0.016
n	0.967 ± 0.014	0.968 ± 0.012
τ	0.088 ± 0.015	0.088 ± 0.014
$\Delta_{\mathcal{R}}^2 \times 10^9$	2.43 ± 0.11	2.43 ± 0.09
h	0.704 ± 0.025	0.702 ± 0.014
σ_8	0.81 ± 0.03	0.816 ± 0.024
$\Omega_m h^2$	0.134 ± 0.006	0.135 ± 0.004

If the assumption of spatial flatness is lifted, it turns out that WMAP7 on its own only weakly constrains the spatial curvature, due to a parameter degeneracy in the angular-diameter distance. However inclusion of other data readily removes this, *e.g.*, inclusion of BAO and H_0 data, plus the assumption that the dark energy is a cosmological constant, yields a constraint on $\Omega_{\text{tot}} \equiv \sum \Omega_i + \Omega_\Lambda$ of $\Omega_{\text{tot}} = 1.002 \pm 0.011$ [3]. Results of this type are normally taken as justifying the restriction to flat cosmologies.

The baryon density Ω_b is now measured with quite high accuracy from the CMB and large-scale structure, and is consistent with the determination from BBN; Fields and Sarkar in this volume quote the range $0.019 \leq \Omega_b h^2 \leq 0.024$ (95% confidence).

While Ω_Λ is measured to be non-zero with very high confidence, there is no evidence of evolution of the dark energy density. The WMAP team find the constraint $w = -0.98 \pm 0.05$ on a constant equation of state from a compilation of data including SNe Ia, with the cosmological constant case $w = -1$ giving an excellent fit to the data. Allowing more complicated forms of dark energy weakens the limits.

The data provide strong support for the main predictions of the simplest inflation models: spatial flatness and adiabatic, Gaussian, nearly scale-invariant density perturbations. But it is disappointing that there is no sign of primordial gravitational waves, with WMAP7 alone providing only an upper limit $r < 0.36$ at 95% confidence [2] (this assumes no running, weakening to 0.49 if running is allowed). The spectral index n is placed in an interesting position, with indications that $n < 1$ is required by the data. However, the confidence with which $n = 1$ is ruled out is still rather weak, and in our view it is premature to conclude that $n = 1$ is no longer viable.

Tests have been made for various types of non-Gaussianity, a particular example being a parameter f_{NL} which measures a quadratic contribution to the perturbations. Various non-gaussianity shapes are possible (see Ref. 3 for details), and current constraints on the popular ‘local’, ‘equilateral’, and ‘orthogonal’ types are $-10 < f_{\text{NL}}^{\text{local}} < 74$,

$-210 < f_{\text{NL}}^{\text{equil}} < 270$, and $-410 < f_{\text{NL}}^{\text{orthog}} < 6$ at 95% confidence (these look weak, but prominent non-Gaussianity requires the product $f_{\text{NL}} \Delta_{\mathcal{R}}$ to be large, and $\Delta_{\mathcal{R}}$ is of order 10^{-5}). There is presently no secure indication of primordial non-gaussianity.

One parameter which is very robust is the age of the Universe, as there is a useful coincidence that for a flat Universe the position of the first peak is strongly correlated with the age. The WMAP7 result is 13.77 ± 0.13 Gyr (assuming flatness). This is in good agreement with the ages of the oldest globular clusters and radioactive dating.

23.5. Outlook for the future

The concordance model is now well established, and there seems little room left for any dramatic revision of this paradigm. A measure of the strength of that statement is how difficult it has proven to formulate convincing alternatives.

Should there indeed be no major revision of the current paradigm, we can expect future developments to take one of two directions. Either the existing parameter set will continue to prove sufficient to explain the data, with the parameters subject to ever-tightening constraints, or it will become necessary to deploy new parameters. The latter outcome would be very much the more interesting, offering a route towards understanding new physical processes relevant to the cosmological evolution. There are many possibilities on offer for striking discoveries, for example:

- The cosmological effects of a neutrino mass may be unambiguously detected, shedding light on fundamental neutrino properties;
- Compelling detection of deviations from scale-invariance in the initial perturbations would indicate dynamical processes during perturbation generation by, for instance, inflation;
- Detection of primordial non-Gaussianities would indicate that non-linear processes influence the perturbation generation mechanism;
- Detection of variation in the dark-energy density (*i.e.*, $w \neq -1$) would provide much-needed experimental input into the nature of the properties of the dark energy.

These provide more than enough motivation for continued efforts to test the cosmological model and improve its accuracy.

Over the coming years, there are a wide range of new observations which will bring further precision to cosmological studies. Indeed, there are far too many for us to be able to mention them all here, and so we will just highlight a few areas.

The CMB observations will improve in several directions. A current frontier is the study of polarization, first detected in 2002 by DASI and for which power spectrum measurements have now been made by several experiments. Future measurements may be able to separately detect the two modes of polarization. Another area of development is pushing accurate power spectrum measurements to smaller angular scales, currently well underway with ACT and SPT. Finally, we mention the *Planck* satellite, launched in 2009, which is making high-precision all-sky maps of temperature and polarization, utilizing a very wide frequency range to improve understanding of foreground contaminants, and to compile a large sample of clusters via the Sunyaev–Zel’dovich effect. Its main cosmological results will be published in early 2013.

An impressive array of ground-based dark energy surveys are also already operational, under construction, or proposed, including ground-based imaging surveys the Dark Energy Survey, Pan-STARRS, and LSST, spectroscopic surveys such as BigBOSS and DESpec, and proposed space missions Euclid and WFIRST.

An exciting new area for the future will be radio surveys of the redshifted 21-cm line of hydrogen. Because of the intrinsic narrowness of this line, by tuning of the bandpass the emission from narrow redshift slices of the Universe will be measured to extremely high redshift, probing the details of the reionization process at redshifts up to perhaps 20. LOFAR is the first instrument able to do this and is at an advanced construction and commissioning stage. In the longer term, the Square Kilometer Array (SKA) will take these studies to a precision level.

The above future surveys will address fundamental questions of physics well beyond just testing the ‘concordance’ Λ CDM model and minor variations. By learning about both the geometry of the universe and the growth of perturbations, it will be possible to test theories of modified gravity and inhomogeneous universes.

The development of the first precision cosmological model is a major achievement. However, it is important not to lose sight of the motivation for developing such a model, which is to understand the underlying physical processes at work governing the Universe’s evolution. On that side, progress has been much less dramatic. For instance, there are many proposals for the nature of the dark matter, but no consensus as to which is correct. The nature of the dark energy remains a mystery. Even the baryon density, now measured to an accuracy of a few percent, lacks an underlying theory able to predict it even within orders of magnitude. Precision cosmology may have arrived, but at present many key questions remain to motivate and challenge the cosmology community.

24. DARK MATTER

Revised September 2011 by M. Drees (Bonn University) and G. Gerbier (Saclay, CEA).

24.1. Theory

24.1.1. Evidence for Dark Matter :

The existence of Dark (*i.e.*, non-luminous and non-absorbing) Matter (DM) is by now well established [1,2]. The earliest, and perhaps still most convincing, evidence for DM came from the observation that various luminous objects (stars, gas clouds, globular clusters, or entire galaxies) move faster than one would expect if they only felt the gravitational attraction of other visible objects. An important example is the measurement of galactic rotation curves. The rotational velocity v of an object on a stable Keplerian orbit with radius r around a galaxy scales like $v(r) \propto \sqrt{M(r)/r}$, where $M(r)$ is the mass inside the orbit. If r lies outside the visible part of the galaxy and mass tracks light, one would expect $v(r) \propto 1/\sqrt{r}$. Instead, in most galaxies one finds that v becomes approximately constant out to the largest values of r where the rotation curve can be measured; in our own galaxy, $v \simeq 240$ km/s at the location of our solar system, with little change out to the largest observable radius. This implies the existence of a *dark halo*, with mass density $\rho(r) \propto 1/r^2$, *i.e.*, $M(r) \propto r$; at some point ρ will have to fall off faster (in order to keep the total mass of the galaxy finite), but we do not know at what radius this will happen. This leads to a lower bound on the DM mass density, $\Omega_{\text{DM}} \gtrsim 0.1$, where $\Omega_X \equiv \rho_X/\rho_{\text{crit}}$, ρ_{crit} being the critical mass density (*i.e.*, $\Omega_{\text{tot}} = 1$ corresponds to a flat Universe).

The observation of clusters of galaxies tends to give somewhat larger values, $\Omega_{\text{DM}} \simeq 0.2$. These observations include measurements of the peculiar velocities of galaxies in the cluster, which are a measure of their potential energy if the cluster is virialized; measurements of the *X-ray* temperature of hot gas in the cluster, which again correlates with the gravitational potential felt by the gas; and—most directly—studies of (weak) gravitational lensing of background galaxies on the cluster.

A particularly compelling example involves the bullet cluster (1E0657-558) which recently (on cosmological time scales) passed through another cluster. As a result, the hot gas forming most of the clusters' baryonic mass was shocked and decelerated, whereas the galaxies in the clusters proceeded on ballistic trajectories. Gravitational lensing shows that most of the total mass also moved ballistically, indicating that DM self-interactions are indeed weak [1].

The currently most accurate, if somewhat indirect, determination of Ω_{DM} comes from global fits of cosmological parameters to a variety of observations; see the Section on Cosmological Parameters for details. For example, using measurements of the anisotropy of the cosmic microwave background (CMB) and of the spatial distribution of galaxies, Ref. 3 finds a density of cold, non-baryonic matter

$$\Omega_{\text{nbm}} h^2 = 0.112 \pm 0.006, \quad (24.1)$$

where h is the Hubble constant in units of 100 km/(s·Mpc). Some part of the baryonic matter density [3],

$$\Omega_{\text{b}} h^2 = 0.022 \pm 0.001, \quad (24.2)$$

may well contribute to (baryonic) DM, *e.g.*, MACHOs [4] or cold molecular gas clouds [5].

The DM density in the “neighborhood” of our solar system is also of considerable interest. This was first estimated as early as 1922 by J.H. Jeans, who analyzed the motion of nearby stars transverse to the galactic plane [2]. He concluded that in our galactic neighborhood, the average density of DM must be roughly equal to that of luminous matter (stars, gas, dust). Remarkably enough, the most recent estimate, based on a detailed model of our galaxy constrained by a host of observables including the galactic rotation curve, finds a quite similar result for the smooth component of the local Dark Matter density [6]:

$$\rho_{\text{DM}}^{\text{local}} = (0.39 \pm 0.03) \frac{\text{GeV}}{\text{cm}^3}. \quad (24.3)$$

This value may have to be increased by a factor of 1.2 ± 0.2 since the baryons in the galactic disk, in which the solar system is located, also increase the local DM density [7]. Small substructures (minihaloes, streams) are not likely to change the local DM density significantly [1].

24.1.2. Candidates for Dark Matter :

Analyses of structure formation in the Universe indicate that most DM should be “cold” or “cool”, *i.e.*, should have been non-relativistic at the onset of galaxy formation (when there was a galactic mass inside the causal horizon) [1]. This agrees well with the upper bound [3] on the contribution of light neutrinos to Eq. (24.1),

$$\Omega_{\nu} h^2 \leq 0.0062 \quad 95\% \text{ CL}. \quad (24.4)$$

Candidates for non-baryonic DM in Eq. (24.1) must satisfy several conditions: they must be stable on cosmological time scales (otherwise they would have decayed by now), they must interact very weakly with electromagnetic radiation (otherwise they wouldn't qualify as *dark matter*), and they must have the right relic density. Candidates include primordial black holes, axions, sterile neutrinos, and weakly interacting massive particles (WIMPs).

Primordial black holes must have formed before the era of Big-Bang nucleosynthesis, since otherwise they would have been counted in Eq. (24.2) rather than Eq. (24.1). Such an early creation of a large number of black holes is possible only in certain somewhat contrived cosmological models [8].

The existence of axions [9] was first postulated to solve the strong *CP* problem of QCD; they also occur naturally in superstring theories. They are pseudo Nambu-Goldstone bosons associated with the (mostly) spontaneous breaking of a new global “Peccei-Quinn” (PQ) $U(1)$ symmetry at scale f_a ; see the Section on Axions in this *Review* for further details. Although very light, axions would constitute cold DM, since they were produced non-thermally. At temperatures well above the QCD phase transition, the axion is massless, and the axion field can take any value, parameterized by the “misalignment angle” θ_i . At $T \lesssim 1$ GeV, the axion develops a mass m_a due to instanton effects. Unless the axion field happens to find itself at the minimum of its potential ($\theta_i = 0$), it will begin to oscillate once m_a becomes comparable to the Hubble parameter H . These coherent oscillations transform the energy originally stored in the axion field into physical axion quanta. The contribution of this mechanism to the present axion relic density is [1]

$$\Omega_a h^2 = \kappa_a \left(f_a / 10^{12} \text{ GeV} \right)^{1.175} \theta_i^2, \quad (24.5)$$

where the numerical factor κ_a lies roughly between 0.5 and a few. If $\theta_i \sim \mathcal{O}(1)$, Eq. (24.5) will saturate Eq. (24.1) for $f_a \sim 10^{11}$ GeV, comfortably above laboratory and astrophysical constraints [9]; this would correspond to an axion mass around 0.1 meV. However, if the post-inflationary reheat temperature $T_R > f_a$, cosmic strings will form during the PQ phase transition at $T \simeq f_a$. Their decay will give an additional contribution to Ω_a , which is often bigger than that in Eq. (24.5) [1], leading to a smaller preferred value of f_a , *i.e.*, larger m_a . On the other hand, values of f_a near the Planck scale become possible if θ_i is for some reason very small.

“Sterile” $SU(2) \times U(1)_Y$ singlet neutrinos with keV masses [10] could alleviate the “cusp/core problem” [1] of cold DM models. If they were produced non-thermally through mixing with standard neutrinos, they would eventually decay into a standard neutrino and a photon.

Weakly interacting massive particles (WIMPs) χ are particles with mass roughly between 10 GeV and a few TeV, and with cross sections of approximately weak strength. Within standard cosmology, their present relic density can be calculated reliably if the WIMPs were in thermal and chemical equilibrium with the hot “soup” of Standard Model (SM) particles after inflation. In this case, their density would become exponentially (Boltzmann) suppressed at $T < m_\chi$. The WIMPs therefore drop out of thermal equilibrium (“freeze out”) once the rate of reactions that change SM particles into WIMPs or vice

versa, which is proportional to the product of the WIMP number density and the WIMP pair annihilation cross section into SM particles σ_A times velocity, becomes smaller than the Hubble expansion rate of the Universe. After freeze out, the co-moving WIMP density remains essentially constant; if the Universe evolved adiabatically after WIMP decoupling, this implies a constant WIMP number to entropy density ratio. Their present relic density is then approximately given by (ignoring logarithmic corrections) [11]

$$\Omega_\chi h^2 \simeq \text{const.} \cdot \frac{T_0^3}{M_{\text{Pl}}^3 \langle \sigma_A v \rangle} \simeq \frac{0.1 \text{ pb} \cdot c}{\langle \sigma_A v \rangle}. \quad (24.6)$$

Here T_0 is the current CMB temperature, M_{Pl} is the Planck mass, c is the speed of light, σ_A is the total annihilation cross section of a pair of WIMPs into SM particles, v is the relative velocity between the two WIMPs in their cms system, and $\langle \dots \rangle$ denotes thermal averaging. Freeze out happens at temperature $T_F \simeq m_\chi/20$ almost independently of the properties of the WIMP. This means that WIMPs are already non-relativistic when they decouple from the thermal plasma; it also implies that Eq. (24.6) is applicable if $T_R > T_F$. Notice that the 0.1 pb in Eq. (24.6) contains factors of T_0 and M_{Pl} ; it is, therefore, quite intriguing that it “happens” to come out near the typical size of weak interaction cross sections.

The seemingly most obvious WIMP candidate is a heavy neutrino. However, an SU(2) doublet neutrino will have too small a relic density if its mass exceeds $M_Z/2$, as required by LEP data. One can suppress the annihilation cross section, and hence increase the relic density, by postulating mixing between a heavy SU(2) doublet and some sterile neutrino. However, one also has to require the neutrino to be stable; it is not obvious why a massive neutrino should not be allowed to decay.

The currently best motivated WIMP candidate is, therefore, the lightest superparticle (LSP) in supersymmetric models [12] with exact R-parity (which guarantees the stability of the LSP). Searches for exotic isotopes [13] imply that a stable LSP has to be neutral. This leaves basically two candidates among the superpartners of ordinary particles, a sneutrino, and a neutralino. The negative outcome of various WIMP searches (see below) rules out “ordinary” sneutrinos as primary component of the DM halo of our galaxy. (In models with gauge-mediated SUSY breaking, the lightest “messenger sneutrino” could make a good WIMP [14].) The most widely studied WIMP is therefore the lightest neutralino. Detailed calculations [1] show that the lightest neutralino will have the desired thermal relic density Eq. (24.1) in at least four distinct regions of parameter space. χ could be (mostly) a bino or photino (the superpartner of the $U(1)_Y$ gauge boson and photon, respectively), if both χ and some sleptons have mass below ~ 150 GeV, or if m_χ is close to the mass of some sfermion (so that its relic density is reduced through co-annihilation with this sfermion), or if $2m_\chi$ is close to the mass of the CP-odd Higgs boson present in supersymmetric models. Finally, Eq. (24.1) can also be satisfied if χ has a large higgsino or wino component.

Many non-supersymmetric extensions of the Standard Model also contain viable WIMP candidates [1]. Examples are the lightest T -odd particle in “Little Higgs” models with conserved T -parity, or “techni-baryons” in scenarios with an additional, strongly interacting (“technicolor” or similar) gauge group.

There also exist models where the DM particles, while interacting only weakly with ordinary matter, have quite strong interactions within an extended “dark sector” of the theory. These were motivated by measurements by the PAMELA, ATIC and Fermi satellites indicating excesses in the cosmic e^+ and/or e^- fluxes at high energies. However, these excesses are relative to background estimates that are clearly too simplistic (*e.g.*, neglecting primary sources of electrons and positrons, and modeling the galaxy as a homogeneous cylinder). Moreover, the excesses, if real, are far too large to be due to usual WIMPs, but can be explained by astrophysical sources. It therefore seems unlikely that they are due to Dark Matter [15]. Similarly, claims of positive signals for direct WIMP detection by the DAMA and, more recently, CoGeNT and CRESST collaborations (see below) led to the development of tailor-made models to alleviate tensions with null experiments. Since we are not convinced that these data indeed signal WIMP detection, and these models (some of which were quickly

excluded by improved measurements) lack independent motivation, we will not discuss them any further in this Review.

Although thermally produced WIMPs are attractive DM candidates because their relic density naturally has at least the right order of magnitude, non-thermal production mechanisms have also been suggested, *e.g.*, LSP production from the decay of some moduli fields [16], from the decay of the inflaton [17], or from the decay of “ Q -balls” (non-topological solitons) formed in the wake of Affleck-Dine baryogenesis [18]. Although LSPs from these sources are typically highly relativistic when produced, they quickly achieve kinetic (but not chemical) equilibrium if T_R exceeds a few MeV [19] (but stays below $m_\chi/20$). They therefore also contribute to cold DM. Finally, if the WIMPs aren’t their own antiparticles, an asymmetry between WIMPs and antiWIMPs might have been created in the early Universe, possibly by the same (unknown) mechanism that created the baryon antibaryon asymmetry. In such “asymmetric DM” models [20] the WIMP antiWIMP annihilation cross section $\langle \sigma_A v \rangle$ should be significantly larger than $1 \text{ pb} \cdot c$, cf Eq. (24.6).

Primary black holes (as MACHOs), axions, sterile neutrinos, and WIMPs are all (in principle) detectable with present or near-future technology (see below). There are also particle physics DM candidates which currently seem almost impossible to detect, unless they decay; the present lower limit on their lifetime is of order 10^{25} to 10^{26} s for 100 GeV particles. These include the gravitino (the spin-3/2 superpartner of the graviton) [1], states from the “hidden sector” thought responsible for supersymmetry breaking [14], and the axino (the spin-1/2 superpartner of the axion) [1].

24.2. Experimental detection of Dark Matter

24.2.1. The case of baryonic matter in our galaxy :

The search for hidden galactic baryonic matter in the form of MAssive Compact Halo Objects (MACHOs) has been initiated following the suggestion that they may represent a large part of the galactic DM and could be detected through the microlensing effect [4]. The MACHO, EROS, and OGLE collaborations have performed a program of observation of such objects by monitoring the luminosity of millions of stars in the Large and Small Magellanic Clouds for several years. EROS concluded that MACHOs cannot contribute more than 8% to the mass of the galactic halo [21], while MACHO observed a signal at 0.4 solar mass and put an upper limit of 40%. Overall, this strengthens the need for non-baryonic DM, also supported by the arguments developed above.

24.2.2. Axion searches :

Axions can be detected by looking for $a \rightarrow \gamma$ conversion in a strong magnetic field [1]. Such a conversion proceeds through the loop-induced $a\gamma\gamma$ coupling, whose strength $g_{a\gamma\gamma}$ is an important parameter of axion models. There currently are two experiments searching for axionic DM. They both employ high quality cavities. The cavity “Q factor” enhances the conversion rate on resonance, *i.e.*, for $m_a(c^2 + v_a^2/2) = \hbar\omega_{\text{res}}$. One then needs to scan the resonance frequency in order to cover a significant range in m_a or, equivalently, f_a . The bigger of the two experiments, the ADMX experiment [22], originally situated at the LLNL in California but now running at the University of Washington, started taking data in the first half of 1996. It now uses SQUIDs as first-stage amplifiers; their extremely low noise temperature (1.2 K) enhances the conversion signal. Published results [23], combining data taken with conventional amplifiers and SQUIDs, exclude axions with mass between 1.9 and 3.53 μeV , corresponding to $f_a \simeq 4 \cdot 10^{13}$ GeV, for an assumed local DM density of 0.45 GeV/cm^3 , if $g_{a\gamma\gamma}$ is near the upper end of the theoretically expected range. An about five times better limit on $g_{a\gamma\gamma}$ was achieved [24] for $1.98 \mu\text{eV} \leq m_a \leq 2.18 \mu\text{eV}$, if a large fraction of the local DM density is due to a single flow of axions with very low velocity dispersion. The ADMX experiment is being upgraded by reducing the cavity and SQUID temperature from the current 1.2 K to about 0.1 K. This should increase the frequency scanning speed for given sensitivity by more than two orders of magnitude, or increase the sensitivity for fixed observation time.

The smaller “CARRACK” experiment now being developed in Kyoto, Japan [25] uses Rydberg atoms (atoms excited to a very high state, $n = 111$) to detect the microwave photons that would result from axion conversion. This allows almost noise-free detection of single photons. Their ultimate goal is to probe the range between 2 and 50 μeV with sensitivity to all plausible axion models, if axions form most of DM.

24.2.3. Searches for keV Neutrinos :

Relic keV neutrinos ν_s can only be detected if they mix with the ordinary neutrinos. This mixing leads to radiative $\nu_s \rightarrow \nu\gamma$ decays, with lifetime $\tau_{\nu_s} \simeq 1.8 \cdot 10^{21} \text{ s} \cdot (\sin\theta)^{-2} \cdot (1 \text{ keV}/m_{\nu_s})^5$, where θ is the mixing angle [10]. This gives rise to a flux of mono-energetic photons with $E_\gamma = m_{\nu_s}/2$, which might be observable by *X-ray* satellites. In the simplest case the relic ν_s are produced only by oscillations of standard neutrinos. Assuming that all lepton-antilepton asymmetries are well below 10^{-3} , the ν_s relic density can then be computed uniquely in terms of the mixing angle θ and the mass m_{ν_s} . The combination of lower bounds on m_{ν_s} from analyses of structure formation (in particular, the Ly α “forest”) and upper bounds on *X-ray* fluxes from various (clusters of) galaxies exclude this scenario if ν_s forms all of DM. This conclusion can be evaded if ν_s forms only part of DM, and/or if there is a lepton asymmetry $\geq 10^{-3}$ (i.e. some 7 orders of magnitude above the observed baryon-antibaryon asymmetry), and/or if there is an additional source of ν_s production in the early Universe, e.g. from the decay of heavier particles [10].

24.2.4. Basics of direct WIMP search :

As stated above, WIMPs should be gravitationally trapped inside galaxies and should have the adequate density profile to account for the observed rotational curves. These two constraints determine the main features of experimental detection of WIMPs, which have been detailed in the reviews in [1].

Their mean velocity inside our galaxy relative to its center is expected to be similar to that of stars, *i.e.*, a few hundred kilometers per second at the location of our solar system. For these velocities, WIMPs interact with ordinary matter through elastic scattering on nuclei. With expected WIMP masses in the range 10 GeV to 10 TeV, typical nuclear recoil energies are of order of 1 to 100 keV.

The shape of the nuclear recoil spectrum results from a convolution of the WIMP velocity distribution, usually taken as a Maxwellian distribution in the galactic rest frame, shifted into the Earth rest frame, with the angular scattering distribution, which is isotropic to first approximation but forward-peaked for high nuclear mass (typically higher than Ge mass) due to the nuclear form factor. Overall, this results in a roughly exponential spectrum. The higher the WIMP mass, the higher the mean value of the exponential. This points to the need for low nuclear recoil energy threshold detectors.

On the other hand, expected interaction rates depend on the product of the local WIMP flux and the interaction cross section. The first term is fixed by the local density of dark matter, taken as 0.39 GeV/cm³ [see Eq. (24.3)], the mean WIMP velocity, typically 220 km/s, the galactic escape velocity, typically 544 km/s [26] and the mass of the WIMP. The expected interaction rate then mainly depends on two unknowns, the mass and cross section of the WIMP (with some uncertainty [6] due to the halo model). This is why the experimental observable, which is basically the scattering rate as a function of energy, is usually expressed as a contour in the WIMP mass–cross section plane.

The cross section depends on the nature of the couplings. For non-relativistic WIMPs, one in general has to distinguish spin-independent and spin-dependent couplings. The former can involve scalar and vector WIMP and nucleon currents (vector currents are absent for Majorana WIMPs, *e.g.*, the neutralino), while the latter involve axial vector currents (and obviously only exist if χ carries spin). Due to coherence effects, the spin-independent cross section scales approximately as the square of the mass of the nucleus, so higher mass nuclei, from Ge to Xe, are preferred for this search. For spin-dependent coupling, the cross section depends on the nuclear spin factor; used target nuclei include ¹⁹F, ²³Na, ⁷³Ge, ¹²⁷I, ¹²⁹Xe, ¹³¹Xe, and ¹³³Cs.

Cross sections calculated in MSSM models [27] induce rates of at most 1 evt day⁻¹ kg⁻¹ of detector, much lower than the usual radioactive backgrounds. This indicates the need for underground laboratories to protect against cosmic ray induced backgrounds, and for the selection of extremely radio-pure materials.

The typical shape of exclusion contours can be anticipated from this discussion: at low WIMP mass, the sensitivity drops because of the detector energy threshold, whereas at high masses, the sensitivity also decreases because, for a fixed mass density, the WIMP flux decreases $\propto 1/m_\chi$. The sensitivity is best for WIMP masses near the mass of the recoiling nucleus.

Two important points are to be kept in mind when comparing exclusion curves from various experiments between them or with positive indications of a signal.

For an experiment with a fixed nuclear recoil energy threshold, the lower is the considered WIMP mass, the lower is the fraction of the spectrum to which the experiment is sensitive. This fraction may be extremely small in some cases. For instance CoGeNT [28], using a Germanium detector with an energy threshold of around 2 keV, is sensitive to about 10 % of the total recoil spectrum of a 7 GeV WIMP, while for XENON100 [29], using a liquid Xenon detector with a threshold of 8.4 keV, this fraction is only 0.05 % (that is the extreme tail of the distribution), for the same WIMP mass. The two experiments are then sensitive to very different parts of the WIMP velocity distribution.

A second important point to consider is the energy resolution of the detector. Again at low WIMP mass, the expected roughly exponential spectrum is very steep and when the characteristic energy of the exponential becomes of the same order as the energy resolution, the energy smearing becomes important. In particular, a significant fraction of the expected spectrum below effective threshold is smeared above threshold, increasing artificially the sensitivity. For instance, a Xenon detector with a threshold of 8 keV and infinitely good resolution is actually insensitive to a 7 GeV mass WIMP, because the expected energy distribution has a cut-off at roughly 5 keV. When folding in the experimental resolution of XENON100 (corresponding to a photostatistics of 0.5 photoelectron per keV), then around 1 % of the signal is smeared above 5 keV and 0.05 % above 8 keV. Setting reliable cross section limits in this mass range thus requires a complete understanding of the response of the detector at energies well below the nominal threshold.

In order to homogenize the reliability of the presented exclusion curves, and save the reader the trouble of performing tedious (though easy to do) calculations, we propose to set cross section limits only for WIMP mass above a “WIMP safe” minimal mass value defined as the maximum of 1) the mass where the increase of sensitivity from infinite resolution to actual experimental resolution is not more than a factor two, and 2) the mass where the experiment is sensitive to at least 1 % of the total WIMP signal recoil spectrum. These recommendations are irrespective of the content of the experimental data obtained by the experiments.

24.2.5. Status and prospects of direct WIMP searches :

Given the intense activity of the field, readers interested in more details than the ones given below may refer to [1], as well as to presentations at recent conferences [30].

The first searches have been performed with ultra-pure semiconductors installed in pure lead and copper shields in underground environments. Combining a priori excellent energy resolutions and very pure detector material, they produced the first limits on WIMP searches (Heidelberg-Moscow, IGEX, COSME-II, HDMS) [1]. Planned experiments using several tens of kg to a ton of Germanium run at liquid nitrogen temperature (designed for double-beta decay search)—GERDA, MAJORANA—are based in addition on passive reduction of the external and internal electromagnetic and neutron background by using segmented detectors, minimal detector housing, close electronics, pulse shape discrimination and large liquid nitrogen or argon shields. Their sensitivity to WIMP interactions will depend on their ability to lower the energy threshold sufficiently, while keeping the background rate small.

The use of so called Point Contact Germanium detectors, with a very small capacitance allowing to reach sub-keV thresholds, has given rise to new results. The CoGeNT collaboration [31] has operated a single 440 g Germanium detector with an effective threshold of 400 eV in the Soudan Underground Laboratory for 56 days [28]. After applying a rise time cut on the pulse shapes in order to remove the surface interactions known to suffer from incomplete charge collection, the resulting spectrum below 4 keV is said by the authors to exhibit an irreducible excess of events, with energy spectrum roughly exponential, compatible with a light mass WIMP in the 7-11 GeV range, and cross section around 10^{-4} pb. However, this conclusion crucially depends on the energy dependent rise time cut applied to the data and a sizeable leaking of surface events into the kept spectrum cannot be excluded. The authors acknowledge themselves that a possible instrumental effect, leading to such an excess, is worth investigating. Nevertheless, considerable attention has been paid to the WIMP interpretation, largely due to the temptation to consider it as a confirmation of the low mass WIMP DAMA/LIBRA solution, without channeling (see below). A recent unpublished analysis, presented at the TAUP 2011 conference, indicates a reduction of the claimed signal by a factor 10. Further results [32] based on data accumulated during one year led to the claim of a 2.8 sigma modulation said to be compatible with a WIMP. Here again, the claim is considerably weakened by the fact that the amplitude of the curve describing the expected WIMP modulation in the 0.5-3 keV bin is too high by roughly a factor 2 (or more, if the unmodulated “signal” has to be reduced) and wrongly leads to the conclusion that the modulation is compatible with a standard WIMP in a standard halo. This is also noted in [33].

A new consortium, CDEX/TEXONO, plans to build a 10 kg array of small and very low (200 eV) threshold detectors, and to operate them in the new Chinese Jinping underground laboratory, the deepest in the world.

In order to make further progress in the reliability of any claimed signal, active background rejection and signal identification questions have to be addressed. This is the focus of a growing number of investigations and improvements. Active background rejection in detectors relies on the relatively small ionization in nuclear recoils due to their low velocity. This induces a reduction (“quenching”) of the ionization/scintillation signal for nuclear recoil signal events relative to e or γ induced backgrounds. Energies calibrated with gamma sources are then called “electron equivalent energies” (keVee unit used below). This effect has been both calculated and measured [1]. It is exploited in cryogenic detectors described later. In scintillation detectors, it induces in addition a difference in decay times of pulses induced by e/γ events vs nuclear recoils. In most cases, due to the limited resolution and discrimination power of this technique at low energies, this effect allows only a statistical background rejection. It has been used in NaI(Tl) (DAMA, LIBRA, NAIAD, Saclay NaI), in CsI(Tl) (KIMS), and Xe (ZEPLIN-I) [1,30]. Pulse shape discrimination is particularly efficient in liquid argon. Using a high energy threshold, it has been used for an event by event discrimination by the WARP experiment, but the high threshold also leads to a moderate signal sensitivity. No observation of nuclear recoils has been reported by these experiments.

Two experimental signatures are predicted for true WIMP signals. One is a strong daily forward/backward asymmetry of the nuclear recoil direction, due to the alternate sweeping of the WIMP cloud by the rotating Earth. Detection of this effect requires gaseous detectors or anisotropic response scintillators (stilbene). The second is a few percent annual modulation of the recoil rate due to the Earth speed adding to or subtracting from the speed of the Sun. This tiny effect can only be detected with large masses; nuclear recoil identification should also be performed, as the otherwise much larger background may also be subject to seasonal modulation.

The DAMA collaboration has reported results from a total of 6 years exposure with the LIBRA phase involving 250 kg of detectors, plus the earlier 6 years exposure of the original DAMA/NaI experiment with 100 kg of detectors [34], for a cumulated exposure of 1.17 t-y. They observe an annual modulation of the signal in the 2 to 6 keVee bin, with the expected period (1 year) and phase (maximum around June 2), at 8.9σ level. If interpreted within the standard halo model described above, two possible explanations have been proposed: a

WIMP with $m_\chi \simeq 50$ GeV and $\sigma_{\chi p} \simeq 7 \cdot 10^{-6}$ pb (central values) or at low mass, in the 6 to 10 GeV range with $\sigma_{\chi p} \sim 10^{-3}$ pb; the cross section could be somewhat lower if there is a significant channeling effect [1].

Interpreting these observations as positive WIMP signal raises several issues of internal consistency. First, the proposed WIMP solutions would induce a sizeable fraction of nuclear recoils in the total measured rate in the 2 to 6 keVee bin. No pulse shape analysis has been reported by the authors to check whether the unmodulated signal was detectable this way. Secondly, the residual e/γ -induced background, inferred by subtracting the signal predicted by the WIMP interpretation from the data, has an unexpected shape [35], starting near zero at threshold and quickly rising to reach its maximum near 3 to 3.5 keVee; from general arguments one would expect the background (e.g. due to electronic noise) to increase towards the threshold. Finally, the amplitude of the annual modulation shows a somewhat troublesome tendency to decrease with time. The original DAMA data, taken 1995 to 2001, gave an amplitude of the modulation of 20.0 ± 3.2 in units of 10^{-3} counts/(kg·day·keVee), in the 2-6 keVee bin. During the first phase of DAMA/LIBRA, covering data taken between 2003 and 2007, this amplitude became 10.7 ± 1.9 , and in the second phase of DAMA/LIBRA, covering data taken between 2007 and 2009, it further decreased to 8.5 ± 2.2 . The ratio of amplitudes inferred from the DAMA/LIBRA phase 2 and original DAMA data is 0.43 ± 0.13 , differing from the expected value of 1 by more than 4 standard deviations. (The results for the DAMA/LIBRA phase 2 have been calculated by us using published results for the earlier data alone [36] as well as for the latest grand total [34].) Similar conclusions can be drawn from analyses of the 2-4 and 2-5 keVee bins.

Concerning compatibility with other experiments (see below), the high mass solution is clearly excluded by several null observations (CDMS, EDELWEISS, XENON), while possibly a small parameter space remains available for the low mass solution (according to [35] this possibility is excluded if the energy spectrum measured by DAMA/LIBRA is taken into account). It should be noted that these comparisons have to make assumptions about the WIMP velocity distribution (see above), but varying this within reasonable limits does not resolve the tension [35]. Moreover, one usually assumes that the WIMP scatters elastically, and that the spin-independent cross section for scattering off protons and neutrons is roughly the same. These assumptions are satisfied by all models we know that are either relatively simple (i.e. do not introduce many new particles) or have independent motivation (e.g. attempting to solve the hierarchy problem). As noted earlier, recently models have been constructed where these assumptions do not hold, but at least some of these are no longer able to make the WIMP interpretation of the DAMA(/LIBRA) observations compatible with all null results from other experiments. Finally, appealing to spin-dependent interactions does not help, either [37], in view of null results from direct searches as well as limits on neutrino fluxes from the Sun (see the subsection on indirect WIMP detection below).

No other annual modulation analysis with comparable sensitivity has been reported by any experiment. ANAIS [30], a 100 kg NaI(Tl) project planned to be run at the Canfranc lab, is in the phase of crystal selection and purification. DM-ice is a new project with the aim of checking the DAMA/LIBRA modulation signal in the southern hemisphere. It will consist of 250 kg of NaI(Tl) installed in the heart of the IceCube array. The counting rate of crystals from the previous NAIAD array recently measured in situ is currently dominated by internal radioactivity.

KIMS [38], an experiment operating 12 crystals of CsI(Tl) with a total mass of 104.4 kg in the Yang Yang laboratory in Korea, has accumulated several years of continuous operation. They should soon be able to set an upper limit on annual modulation amplitude lower than DAMA value if no annual modulation is present, or confirm the DAMA value at 3σ .

At mK temperature, the simultaneous measurement of the phonon and ionization signals in semiconductor detectors permits event by event discrimination between nuclear and electronic recoils down to 5 to 10 keV recoil energy. This feature is being used by the CDMS [30] and EDELWEISS [30] collaborations. Surface interactions,

exhibiting incomplete charge collection, are an important residual background, which is treated by two different techniques: CDMS uses the timing information of the phonon pulse, while EDELWEISS uses the ionization pulses in an interleaved electrodes scheme. New limits on the spin-independent coupling of WIMPs were obtained by CDMS, after operating 19 Germanium cryogenic detectors at the Soudan mine during new runs involving a total exposure of around 612 kg·d (around 300 kg·d fiducial) [39]. Two events were found in the pre-defined signal region, while 0.9 background event were expected. Given these figures, no observation of a signal is claimed. While this data set alone provided a worse limit than the previous runs, the combined data sets provide an improved upper limit on the spin-independent cross section for the scattering of a 70 GeV/ c^2 WIMP on a nucleon of 3.8×10^{-8} pb, at 90% CL. The “WIMP safe” minimal mass (see the discussion at the end of sec. 1.2.4) of this analysis is about 12 GeV.

An independent analysis of data at low energy (i.e. above 2 keV recoil energy) has also been performed by CDMS [40]. From the knowledge of the quenching factor of Germanium recoils down to 2 keV recoil energy, the energy spectrum is reconstructed using only the measured phonon energy. The obtained spectrum, once corrected for quenching, has a shape somewhat similar to that reported by CoGeNT, but with a lower amplitude (especially for one of the detector modules, which was used to set the limit) so that CDMS concludes that their data are inconsistent with the original WIMP interpretation of the CoGeNT data (note that both detectors use the same target material, so this comparison really is model-independent), as well as with the standard WIMP interpretation of the DAMA data. New detectors with interleaved electrode schemes are being built.

EDELWEISS has operated ten 400 g Germanium detectors equipped with different thermal sensors and an interdigitised charge collection electrode scheme, during one year at the Laboratoire Souterrain de Modane [41]. A total of 5 events were observed in the signal region for a fiducial exposure of 384 kg·d, while 3 events were expected from backgrounds. No WIMP signal was claimed. A similar sensitivity to CDMS is obtained at high mass, while the high 20 keV analysis threshold induces a somewhat poorer limit at masses lower than 50 GeV. New larger detectors with a complete coverage of the crystal with annular electrodes, and better rejection of non-recoil events are being built.

Given their similar sensitivities, the two collaborations combined their data sets. Using a simple combination method, a gain of 1.6 relative to the best limit has been obtained at WIMP masses larger than 700 GeV, and an improved limit of 3.3×10^{-8} pb for a 90 GeV WIMP mass [42].

The cryogenic experiment CRESST [30] uses the scintillation of CaWO_4 as second variable for background discrimination. CRESST has recently submitted for publication [43] the result of the analysis of 730 kg·d exposure performed with 8 detectors. The observation of 67 events in the signal region does not match the about 40 expected background events, originating from e/γ leakage, neutron recoils, as well as leakage from α and Pb recoils. The event excess is said to be compatible with WIMPs. A likelihood method provides two solutions, respectively for 12 and 25 GeV masses, stating also that the background hypothesis alone is more than 4 sigma away from the observed data. However, some other potential sources of background are insufficiently addressed, like “no-light” events, a category of events which previously plagued the sensitivity of this experiment.

Other inorganic scintillators are also being explored, e.g. by the ROSEBUD collaboration [30].

The experimental programs of CDMS II, EDELWEISS II and CRESST II aim at an increase of sensitivity by a factor of 10, by operating around 40 kg of detectors. The next stage SuperCDMS and EURECA-I (a combination of EDELWEISS and CRESST) projects will involve typically 150 kg of detectors. Then GEODM and EURECA-2 will turn to 1 t goals.

Noble gas detectors for dark matter detection are now being developed rapidly by several groups [1]. Dual (liquid and gas) phase detectors allow to measure both the primary scintillation and the ionization electrons drifted through the liquid and amplified in the gas, which is used for background rejection.

The XENON collaboration [30] has successfully operated the 161 kg XENON100 setup at Gran Sasso laboratory during a 100 day data taking period. Within a fiducial mass of 48 kg, 3 events were observed in the signal region, while 1.8 were expected, out of which 1.2 originate from a sizeable contamination of Krypton 85 in the liquid [29]. This allowed to set the best limits at all masses on spin-independent interactions of WIMPs, with a minimum of cross section at 7.0×10^{-9} pb for a mass of 50 GeV. However, the reliability of limits set at masses lower than 10 GeV, especially wrt the relative light efficiency factor, have been discussed in the community. Moreover, as underlined near the end of section 1.2.4, the limits at low mass can be set *only* thanks to the poor energy resolution at threshold -8.4 keV— due to the low photoelectron yield of 0.5 pe/keV. With infinite energy resolution, a Xe detector *with the same threshold of 8.4 keV* is not sensitive to a WIMP mass of 7 GeV. Folding in the XENON100 resolution, the expected fraction of a 7 GeV WIMP signal above 8.4 keV is around 0.05 % (in strong contrast with the 10 % to which CoGeNT is sensitive). If one follows the recommendation made above, the “WIMP safe” minimal mass for XENON100 is around 12 GeV.

A reanalysis of part of the XENON10 data [44], using the ionization signal only, with an ionization yield of around 3.5 electron/keV at a threshold of 1.4 keV, sets a more convincing limit in the 7 GeV range, about one order of magnitude below the original CoGeNT claim (see above). The “WIMP safe” minimal mass for this XENON10 analysis is around 5 GeV. The XENON10 limit for spin dependent WIMPs with pure neutron couplings is still the best published limit at all masses [45] (but likely to be soon superseded by an analysis of XENON100 data). XENON1t, the successor of XENON100 planned to be run at Gran Sasso lab, is in its preparation phase. One should note that, presumably, the planned increase of distance between planes of PMT’s will lead to a lower photoelectron yield for scintillation light than at XENON100. This was the case when going from XENON10 (around 1 pe/keV) to XENON100 (around 0.5 pe/keV). For comparison, a 0.25 pe yield per keV would correspond to a “WIMP safe” mass of order of 20 GeV.

A new liquid Xenon based project, PANDA-X, with pancake geometry, planned to be housed in the new Jinping lab, will perform a dedicated low mass WIMP search.

ZEPLIN III [30], using a similar principle and with an active mass of 12 kg of Xenon, operated in the Boulby laboratory, has been upgraded for a lower background, has acquired new data, and is now stopped. XMASS [30] in Japan is close to operate a single-phase 800 kg detector (100 kg fiducial mass) installed in a large pure water shield at the SuperKamiokande site. With no pulse shape analysis, the expected performance relies heavily on the self-shielding effect to lower the background [1].

The LUX detector [1], a 300 kg double phase Xenon detector, planned to be operated in the new SURF (previous Sanford) laboratory in US, is in the commissioning phase, in a water shield at surface, before transport underground to the 4850 level.

The WARP collaboration [30] is currently installing a 100 l Argon detector at the Gran Sasso laboratory. Thanks to a double-background rejection method based on the asymmetry between scintillating and ionizing pulses and extremely efficient pulse shape discrimination of scintillating pulses, it looks possible to achieve very high background rejection, even in the presence of the radioactive isotope ^{39}Ar . The ArDM project [30] is using a similar technique with a much larger (1,100 kg) mass. It should be installed soon and take data at the newly opened Canfranc laboratory. MiniCLEAN and DEAP-3600 [30], both measuring only scintillation signals in spherical geometries in single phase mode, are being assembled at SNOLab and will operate respectively 500 kg of Ar/Ne and 3600 kg of Ar [1]. DARK SIDE [30], is another Argon based, double phase project, involving in a first step about 50 kg of ^{39}Ar depleted Argon, to be installed in Gran Sasso lab.

The low pressure Time Projection Chamber technique is the only convincing way to measure the direction of nuclear recoils and prove the galactic origin of a possible signal [1]. The DRIFT collaboration [30] has operated a 1 m^3 volume detector in the UK Boulby mine. Though the background due to internal radon contamination was lowered, no new competitive limit has yet been

set. The MIMAC collaboration [30] is investigating a sub-keV energy threshold TPC detector. Additional sensitive measurements of Fluor nuclei quenching factor and recoil imaging have been performed recently by this group down to few keV. A 2.5 l 1000 channel prototype is going to be operated soon in the Fréjus laboratory. Other groups developing similar techniques, though with lower sensitivity, are DMTPC in the US and NewAge in Japan.

The following more unconventional detectors use ^{19}F nuclei to set limits on the spin dependent coupling of WIMPs, with less than kg mass detectors. The bubble chamber like detector, COUPP [30], run at Fermilab, has provided a new limit [46] for spin dependent proton coupling WIMPs for masses above 20 GeV, superseding an earlier KIMS result. PICASSO [30], a superheated droplet detector run at SNOLAB, obtained a better limit below 20 GeV on the same type of WIMPs [47]. Finally, SIMPLE [30], a similar experiment run at Laboratoire Souterrain de Rustrel, submitted results for publication that claim to provide the currently best limit on the spin-dependent WIMP-proton cross section for all WIMP masses [48].

Figure 24.1: Cross sections (normalised to nucleon assuming A^2 dependence, see section 1.2.4) for spin independent coupling versus mass diagrams. References to the experimental results are given in the text. The big dots on some curves show the “WIMP safe” minimal mass for the corresponding experimental result (see details in text). DAMA candidates region (no channeling) are from [50], shaded 68% and 95% regions are SUSY predictions by [51], together with recent constraints (crosshatched 68% and 95% regions) set by LHC experiments (CMSSM) [52]. Here equal cross sections for scattering from protons and neutrons have been assumed.

Figures 24.1 and 24.2 illustrate the limits and positive claims for cross sections, normalised to nucleon, for spin independent and spin dependent couplings, respectively, as functions of WIMP mass, where only the two currently best limits are presented. Also shown are constraints from indirect observations (see the next section) and typical regions of SUSY models, before and after recent LHC results. These figures have been made with the `dmtools` web page, thanks to the very efficient collaboration of `dmtools` team [55].

Sensitivities down to $\sigma_{\chi p}$ of 10^{-10} pb, as needed to probe large regions of MSSM parameter space [27], will be reached with detectors of typical masses of 1 ton, assuming nearly perfect background discrimination capabilities. Note that the expected WIMP rate is then 5 evts/ton/year for Ge. The ultimate neutron background will only be identified by its multiple interactions in a finely segmented or multiple-interaction-sensitive detector, and/or by operating detectors containing different target materials within the same set-up. Larger mass projects are envisaged by the DARWIN European consortium

Figure 24.2: Cross sections for spin dependent coupling versus mass diagrams. References to the experimental results are given in the text. The DAMA candidates region (no channeling) are from [50]: (a) interactions on neutron; (b) interactions on proton.

and the MAX project in the US (liquid Xe and Ar multiton project) [30].

24.2.6. Status and prospects of indirect WIMP searches :

WIMPs can annihilate and their annihilation products can be detected; these include neutrinos, gamma rays, positrons, antiprotons, and antinuclei [1]. These methods are complementary to direct detection and might be able to explore higher masses and different coupling scenarios. “Smoking gun” signals for indirect detection are GeV neutrinos coming from the center of the Sun or Earth, and monoenergetic photons from WIMP annihilation in space.

WIMPs can be slowed down, captured, and trapped in celestial objects like the Earth or the Sun, thus enhancing their density and their probability of annihilation. This is a source of muon neutrinos which can interact in the Earth. Upward going muons can then be detected in large neutrino telescopes such as MACRO, BAKSAN, SuperKamiokande, Baikal, AMANDA, ANTARES, NESTOR, and the large sensitive area IceCube [1]. The best upper limit for relatively soft muons, of ≈ 1000 muons/km²/year for muons with energy above ~ 2 GeV [53], comes from SuperKamiokande [30] using through-going muons. For more energetic muons a slightly more stringent limit

has been set by IceCube22 (using 22 strings), e.g. excluding a flux above 610 muons/km²/year from the Sun for a WIMP model with average muon energy of 150 GeV [54]. In the framework of the MSSM and with standard halo velocity profiles, only the limits from the Sun, which mostly probe spin-dependent couplings, are competitive with direct WIMP search limits. IceCube80 [30] will increase this sensitivity by a factor $\simeq 5$ at masses higher than 200 GeV while IceCube Deep Core will allow to reach masses down to 50 GeV [1].

WIMP annihilation in the halo can give a continuous spectrum of gamma rays and (at one-loop level) also monoenergetic photon contributions from the $\gamma\gamma$ and γZ channels. These channels also allow to search for WIMPs for which direct detection experiments have little sensitivity, e.g., almost pure higgsinos. However, the size of this signal depends very strongly on the halo model, but is expected to be most prominent near the galactic center. The central region of our galaxy hosts a strong TeV point source discovered [56] by the H.E.S.S. Cherenkov telescope [57]. Moreover, FERMI/LAT [30] data revealed a new extended source of GeV photons near the galactic center above and below the galactic plane [58]. Both of these sources are most likely of astrophysical origin. The presence of these unexpected backgrounds makes it more difficult to discover WIMPs in this channel, and no convincing signal has been claimed. FERMI/LAT observations of the galactic halo are in agreement with predictions based on purely astrophysical sources (in contrast to a re-analysis of earlier EGRET data [59]), and rule out many WIMP models that were constructed to explain the PAMELA and FERMI/LAT excesses in the e^\pm channel [60]. Similarly, Cherenkov telescope and FERMI/LAT observations of nearby dwarf galaxies, globular clusters, and clusters of galaxies only yielded upper limits on photon fluxes from WIMP annihilation. While limits from individual observations are still above the predictions of most WIMP models, a very recent combination [61] of limits from dwarf galaxies excludes WIMPs annihilating hadronically with the standard cross section needed for thermal relics, if the WIMP mass is below 25 GeV; assumptions are annihilation from an S -wave initial state, and a dark matter density distribution scaling like the inverse of the distance from the center of the dwarf galaxy at small radii.

Antiparticles arise as additional WIMP annihilation products in the halo. To date the best measurement of the antiproton flux comes from the PAMELA satellite [30], and covers kinetic energies between 60 MeV and 180 GeV [62]. The result is in good agreement with secondary production and propagation models. These data exclude WIMP models that attempt to explain the e^\pm excesses via annihilation into W^\pm or Z^0 boson pairs; however, largely due to systematic uncertainties they do not significantly constrain conventional WIMP models.

The best measurements of the positron (and electron) flux at (tens of) GeV energies again comes from PAMELA [63], showing a rather marked rise of the positron fraction between 10 and 100 GeV. The observed spectrum falls within the one order of magnitude span (largely due to differences in the propagation model used) of positron fraction values predicted by secondary production models [64]. Measurements of the total electron+positrons energy spectrum by ATIC [65], FERMI/LAT [66] and H.E.S.S. [67] between 100 and 1000 GeV also exceed the predicted purely secondary spectrum, but with very large dispersion of the magnitude of these excesses. While it has been recognized that astrophysical sources may account for all these features, many ad-hoc Dark Matter models have been built to account for these excesses. As mentioned in section 1, given the amount of jerking and twisting needed to build such models not to contradict any observation, it seems very unlikely that Dark Matter is at the origin of these excesses.

Last but not least, an antideuteron signal [1], as potentially observable by AMS2 or PAMELA, could constitute a signal for WIMP annihilation in the halo.

An interesting comparison of respective sensitivities to MSSM parameter space of future direct and various indirect searches has been performed with the DARKSUSY tool [68]. A web-based up-to-date collection of results from direct WIMP searches, theoretical predictions, and sensitivities of future experiments can be found in [55]. Also, the web page [69] allows to make predictions for WIMP

signals in various experiments, within a variety of SUSY models and to extract limits from simply parametrised data. Integrated analysis of all data from direct and indirect WIMP detection, and also from LHC experiments should converge to a comprehensive approach, required to fully unravel the mysteries of dark matter.

25. COSMIC MICROWAVE BACKGROUND

Revised August 2011 by D. Scott (University of British Columbia) and G.F. Smoot (UCB/LBNL).

25.1. Introduction

The energy content in radiation from beyond our Galaxy is dominated by the cosmic microwave background (CMB), discovered in 1965 [1]. The spectrum of the CMB is well described by a blackbody function with $T = 2.7255$ K, this spectral form being one of the main pillars of the hot Big Bang model for the early Universe. The lack of any observed deviations from a blackbody spectrum constrains physical processes over cosmic history at redshifts $z \lesssim 10^7$ (see earlier versions of this review). All viable cosmological models predict a very nearly Planckian spectrum inside the current observational limits.

Another observable quantity inherent in the CMB is the variation in temperature (or intensity) from one part of the microwave sky to another [2]. Since the first detection of these anisotropies by the COBE satellite [3], there has been intense activity to map the sky at increasing levels of sensitivity and angular resolution by ground-based and balloon-borne measurements. These were joined in 2003 by the first results from NASA's Wilkinson Microwave Anisotropy Probe (WMAP) [4], which were improved upon by analysis of the 3-year, 5-year, and 7-year WMAP data [5,6,7]. Together these observations have led to a stunning confirmation of the 'Standard Model of Cosmology.' In combination with other astrophysical data, the CMB anisotropy measurements place quite precise constraints on a number of cosmological parameters, and have launched us into an era of precision cosmology. This is expected to continue with the improved capabilities of ESA's *Planck* satellite [8,9].

25.2. Description of CMB Anisotropies

Observations show that the CMB contains anisotropies at the 10^{-5} level, over a wide range of angular scales. These anisotropies are usually expressed by using a spherical harmonic expansion of the CMB sky:

$$T(\theta, \phi) = \sum_{\ell m} a_{\ell m} Y_{\ell m}(\theta, \phi).$$

The vast majority of the cosmological information is contained in the temperature 2-point function, *i.e.*, the variance as a function only of angular separation, since we notice no preferred direction. Equivalently, the power per unit $\ln \ell$ is $\ell \sum_m |a_{\ell m}|^2 / 4\pi$.

25.2.1. The Monopole :

The CMB has a mean temperature of $T_\gamma = 2.7255 \pm 0.0006$ K (1σ) [10], which can be considered as the monopole component of CMB maps, a_{00} . Since all mapping experiments involve difference measurements, they are insensitive to this average level. Monopole measurements can only be made with absolute temperature devices, such as the FIRAS instrument on the COBE satellite [11]. Such measurements of the spectrum are consistent with a blackbody distribution over more than three decades in frequency (with some recent evidence for deviation at low frequencies [12]). A blackbody of the measured temperature corresponds to $n_\gamma = (2\zeta(3)/\pi^2) T_\gamma^3 \simeq 411 \text{ cm}^{-3}$ and $\rho_\gamma = (\pi^2/15) T_\gamma^4 \simeq 4.64 \times 10^{-34} \text{ g cm}^{-3} \simeq 0.260 \text{ eV cm}^{-3}$.

25.2.2. The Dipole :

The largest anisotropy is in the $\ell = 1$ (dipole) first spherical harmonic, with amplitude 3.355 ± 0.008 mK [6]. The dipole is interpreted to be the result of the Doppler shift caused by the solar system motion relative to the nearly isotropic blackbody field, as broadly confirmed by measurements of the radial velocities of local galaxies (although with some debate [13]). The motion of an observer with velocity $\beta \equiv v/c$ relative to an isotropic Planckian radiation field of temperature T_0 produces a Doppler-shifted temperature pattern

$$\begin{aligned} T(\theta) &= T_0(1 - \beta^2)^{1/2} / (1 - \beta \cos \theta) \\ &\simeq T_0 \left(1 + \beta \cos \theta + \left(\beta^2/2 \right) \cos 2\theta + O(\beta^3) \right). \end{aligned}$$

At every point in the sky, one observes a blackbody spectrum, with temperature $T(\theta)$. The spectrum of the dipole is the differential of a blackbody spectrum, as confirmed by Ref. 14.

The implied velocity for the solar system barycenter is $v = 369.0 \pm 0.9 \text{ km s}^{-1}$, assuming a value $T_0 = T_\gamma$, towards $(\ell, b) = (263.99^\circ \pm 0.14^\circ, 48.26^\circ \pm 0.03^\circ)$ [6,15]. Such a solar system motion implies a velocity for the Galaxy and the Local Group of galaxies relative to the CMB. The derived value is $v_{\text{LG}} = 627 \pm 22 \text{ km s}^{-1}$ towards $(\ell, b) = (276^\circ \pm 3^\circ, 30^\circ \pm 3^\circ)$, where most of the error comes from uncertainty in the velocity of the solar system relative to the Local Group.

The dipole is a frame-dependent quantity, and one can thus determine the 'absolute rest frame' as that in which the CMB dipole would be zero. Our velocity relative to the Local Group, as well as the velocity of the Earth around the Sun, and any velocity of the receiver relative to the Earth, is normally removed for the purposes of CMB anisotropy study.

25.2.3. Higher-Order Multipoles :

The variations in the CMB temperature maps at higher multipoles ($\ell \geq 2$) are interpreted as being mostly the result of perturbations in the density of the early Universe, manifesting themselves at the epoch of the last scattering of the CMB photons. In the hot Big Bang picture, the expansion of the Universe cools the plasma so that by a redshift $z \simeq 1100$ (with little dependence on the details of the model), the hydrogen and helium nuclei can bind electrons into neutral atoms, a process usually referred to as recombination [16]. Before this epoch, the CMB photons are tightly coupled to the baryons, while afterwards they can freely stream towards us.

Theoretical models generally predict that the $a_{\ell m}$ modes are Gaussian random fields to high precision, *e.g.*, standard slow-roll inflation's non-Gaussian contribution is expected to be one or two orders of magnitude below current observational limits [17]. Although non-Gaussianity of various forms is possible in early Universe models, tests show that Gaussianity is an extremely good simplifying approximation [18], with only some relatively weak indications of non-Gaussianity or statistical anisotropy at large scales. Such signatures found in existing WMAP data are generally considered to be subtle foreground or instrumental artifacts [19].

A statistically isotropic sky means that all m 's are equivalent, *i.e.*, there is no preferred axis. Together with the assumption of Gaussian statistics, the variance of the temperature field (or equivalently the power spectrum in ℓ) then fully characterizes the anisotropies. The power summed over all m 's at each ℓ is $(2\ell + 1)C_\ell / (4\pi)$, where $C_\ell \equiv \langle |a_{\ell m}|^2 \rangle$. Thus averages of $a_{\ell m}$'s over m can be used as estimators of the C_ℓ 's to constrain their expectation values, which are the quantities predicted by a theoretical model. For an idealized full-sky observation, the variance of each measured C_ℓ (*i.e.*, the variance of the variance) is $[2/(2\ell + 1)]C_\ell^2$. This sampling uncertainty (known as 'cosmic variance') comes about because each C_ℓ is χ^2 distributed with $(2\ell + 1)$ degrees of freedom for our observable volume of the Universe. For fractional sky coverage, f_{sky} , this variance is increased by $1/f_{\text{sky}}$ and the modes become partially correlated.

It is important to understand that theories predict the expectation value of the power spectrum, whereas our sky is a single realization. Hence the cosmic variance is an unavoidable source of uncertainty when constraining models; it dominates the scatter at lower ℓ 's, while the effects of instrumental noise and resolution dominate at higher ℓ 's [20].

25.2.4. Angular Resolution and Binning :

There is no one-to-one conversion between multipole ℓ and the angle subtended by a particular spatial scale projected onto the sky. However, a single spherical harmonic $Y_{\ell m}$ corresponds to angular variations of $\theta \sim \pi/\ell$. CMB maps contain anisotropy information from the size of the map (or in practice some fraction of that size) down to the beam-size of the instrument, σ . One can think of the effect of a Gaussian beam as rolling off the power spectrum with the function $e^{-\ell(\ell+1)\sigma^2}$.

For less than full sky coverage, the ℓ modes become correlated. Hence, experimental results are usually quoted as a series of 'band powers', defined as estimators of $\ell(\ell + 1)C_\ell / 2\pi$ over different ranges of ℓ . Because of the strong foreground signals in the Galactic Plane, even 'all-sky' surveys, such as WMAP and *Planck* involve a cut sky. The amount of binning required to obtain uncorrelated estimates of power also depends on the map size.

25.3. Cosmological Parameters

The current ‘Standard Model’ of cosmology contains around 10 free parameters (see The Cosmological Parameters—Sec. 23 of this *Review*). The basic framework is the Friedmann-Robertson-Walker (FRW) metric (*i.e.*, a universe that is approximately homogeneous and isotropic on large scales), with density perturbations laid down at early times and evolving into today’s structures (see Big-Bang cosmology—Sec. 21 of this *Review*). The most general possible set of density variations is a linear combination of an adiabatic density perturbation and some isocurvature perturbations. Adiabatic means that there is no change to the entropy per particle for each species, *i.e.*, $\delta\rho/\rho$ for matter is $(3/4)\delta\rho/\rho$ for radiation. Isocurvature means that the set of individual density perturbations adds to zero, for example, matter perturbations compensate radiation perturbations so that the total energy density remains unperturbed, *i.e.*, $\delta\rho$ for matter is $-\delta\rho$ for radiation. These different modes give rise to distinct (temporal) phases during growth, with those of the adiabatic scenario being strongly preferred by the data. Models that generate mainly isocurvature type perturbations (such as most topological defect scenarios) are no longer considered to be viable. However, an admixture of the adiabatic mode with up to about 10% isocurvature contribution is still allowed [21].

Within the adiabatic family of models, there is, in principle, a free function describing the variation of comoving curvature perturbations, $\mathcal{R}(\mathbf{x}, t)$. The great virtue of \mathcal{R} is that it is constant in time for a purely adiabatic perturbation. There are physical reasons to anticipate that the variance of these perturbations will be described well by a power-law in scale, *i.e.*, in Fourier space $\langle |\mathcal{R}|_k^2 \rangle \propto k^{n-4}$, where k is wavenumber and n is the usual definition of spectral index. So-called ‘scale-invariant’ initial conditions (meaning gravitational potential fluctuations which are independent of k) correspond to $n = 1$. In inflationary models [22], perturbations are generated by quantum fluctuations, which are set by the energy scale of inflation, together with the slope and higher derivatives of the inflationary potential. One generally expects that the Taylor series expansion of $\ln \mathcal{R}_k(\ln k)$ has terms of steadily decreasing size. For the simplest models, there are thus two parameters describing the initial conditions for density perturbations: the amplitude and slope of the power spectrum. These can be explicitly defined, for example, through:

$$\Delta_{\mathcal{R}}^2 \equiv (k^3/2\pi^2) \langle |\mathcal{R}|_k^2 \rangle = A (k/k_0)^{n-1},$$

with $A \equiv \Delta_{\mathcal{R}}^2(k_0)$ and $k_0 = 0.002 \text{ Mpc}^{-1}$, say. There are many other equally valid definitions of the amplitude parameter (see also Sec. 21 and Sec. 23 of this *Review*), and we caution that the relationships between some of them can be cosmology-dependent. In ‘slow roll’ inflationary models, this normalization is proportional to the combination $V^3/(V')^2$, for the inflationary potential $V(\phi)$. The slope n also involves V'' , and so the combination of A and n can, in principle, constrain potentials.

Inflation generates tensor (gravitational wave) modes, as well as scalar (density perturbation) modes. This fact introduces another parameter, measuring the amplitude of a possible tensor component, or equivalently the ratio of the tensor to scalar contributions. The tensor amplitude is $A_T \propto V$, and thus one expects a larger gravitational wave contribution in models where inflation happens at higher energies. The tensor power spectrum also has a slope, often denoted n_T , but since this seems unlikely to be measured in the near future, it is sufficient for now to focus only on the amplitude of the gravitational wave component. It is most common to define the tensor contribution through r , the ratio of tensor to scalar perturbation spectra at some small value of k (although sometimes it is defined in terms of the ratio of contributions at $\ell = 2$). Different inflationary potentials will lead to different predictions, *e.g.*, for $\lambda\phi^4$ inflation with 50 e-folds, $r = 0.32$, and for $m^2\phi^2$ inflation $r \simeq 0.15$, while other models can have arbitrarily small values of r . In any case, whatever the specific definition, and whether they come from inflation or something else, the ‘initial conditions’ give rise to a minimum of 3 parameters: A , n , and r .

The background cosmology requires an expansion parameter (the Hubble Constant, H_0 , often represented through $H_0 = 100 h \text{ km s}^{-1} \text{ Mpc}^{-1}$) and several parameters to describe the matter

Figure 25.1: The theoretical CMB anisotropy power spectrum, using a standard Λ CDM model from CMBFAST. The x -axis is logarithmic here. The regions, each covering roughly a decade in ℓ , are labeled as in the text: the ISW rise; Sachs-Wolfe plateau; acoustic peaks; and damping tail. Also shown is the shape of the tensor (gravitational wave) contribution, with an arbitrary normalization.

and energy content of the Universe. These are usually given in terms of the critical density, *i.e.*, for species ‘ x ’, $\Omega_x \equiv \rho_x/\rho_{\text{crit}}$, where $\rho_{\text{crit}} \equiv 3H_0^2/8\pi G$. Since physical densities $\rho_x \propto \Omega_x h^2 \equiv \omega_x$ are what govern the physics of the CMB anisotropies, it is these ω ’s that are best constrained by CMB data. In particular CMB, observations constrain $\Omega_b h^2$ for baryons and $\Omega_m h^2$ for baryons plus cold dark matter.

The contribution of a cosmological constant Λ (or other form of dark energy) is usually included via a parameter which quantifies the curvature, $\Omega_K \equiv 1 - \Omega_{\text{tot}}$, where $\Omega_{\text{tot}} = \Omega_m + \Omega_\Lambda$. The radiation content, while in principle a free parameter, is precisely enough determined by the measurement of T_γ , and makes a $< 10^{-4}$ contribution to Ω_{tot} today.

The main effect of astrophysical processes on the C_ℓ ’s comes through reionization. The Universe became reionized at some redshift z_i , long after recombination, affecting the CMB through the integrated Thomson scattering optical depth:

$$\tau = \int_0^{z_i} \sigma_T n_e(z) \frac{dt}{dz} dz,$$

where σ_T is the Thomson cross-section, $n_e(z)$ is the number density of free electrons (which depends on astrophysics), and dt/dz is fixed by the background cosmology. In principle, τ can be determined from the small-scale matter power spectrum, together with the physics of structure formation and feedback processes. However, this is a sufficiently intricate calculation that τ needs to be considered as a free parameter.

Thus, we have eight basic cosmological parameters: A , n , r , h , $\Omega_b h^2$, $\Omega_m h^2$, Ω_{tot} , and τ . One can add additional parameters to this list, particularly when using the CMB in combination with other data sets. The next most relevant ones might be: $\Omega_\nu h^2$, the massive neutrino contribution; w ($\equiv p/\rho$), the equation of state parameter for the dark energy; and $dn/d \ln k$, measuring deviations from a constant spectral index. To these 11 one could of course add further parameters describing additional physics, such as details of the reionization process, features in the initial power spectrum, a sub-dominant contribution of isocurvature modes, *etc.*

As well as these underlying parameters, there are other quantities that can be obtained from them. Such derived parameters include the actual Ω ’s of the various components (*e.g.*, Ω_m), the variance of density perturbations at particular scales (*e.g.*, σ_8), the age of the Universe today (t_0), the age of the Universe at recombination, reionization, *etc.*

25.4. Physics of Anisotropies

The cosmological parameters affect the anisotropies through the well understood physics of the evolution of linear perturbations within a background FRW cosmology. There are very effective, fast, and publicly available software codes for computing the CMB anisotropy, polarization, and matter power spectra, *e.g.*, CMBFAST [23] and CAMB [24]. These have been tested over a wide range of cosmological parameters and are considered to be accurate to better than the 1% level [25].

A description of the physics underlying the C_ℓ 's can be separated into three main regions, as shown in Fig. 25.1.

25.4.1. The ISW rise, $\ell \lesssim 10$, and Sachs-Wolfe plateau, $10 \lesssim \ell \lesssim 100$:

The horizon scale (or more precisely, the angle subtended by the Hubble radius) at last scattering corresponds to $\ell \simeq 100$. Anisotropies at larger scales have not evolved significantly, and hence directly reflect the ‘initial conditions’. $\delta T/T = -(1/5)\mathcal{R}(\mathbf{x}_{\text{LSS}}) \simeq (1/3)\delta\phi/c^2$, here $\delta\phi$ is the perturbation to the gravitational potential, evaluated on the last scattering surface (LSS). This is a result of the combination of gravitational redshift and intrinsic temperature fluctuations and is usually referred to as the Sachs-Wolfe effect [26].

Assuming that a nearly scale-invariant spectrum of curvature and corresponding density perturbations was laid down at early times (*i.e.*, $n \simeq 1$, meaning equal power per decade in k), then $\ell(\ell+1)C_\ell \simeq \text{constant}$ at low ℓ 's. This effect is hard to see unless the multipole axis is plotted logarithmically (as in Fig. 25.1, but not Fig. 25.2).

Time variation of the potentials (*i.e.*, time-dependent metric perturbations) leads to an upturn in the C_ℓ 's in the lowest several multipoles; any deviation from a total equation of state $w = 0$ has such an effect. So the dominance of the dark energy at low redshift makes the lowest ℓ 's rise above the plateau. This is sometimes called the integrated Sachs-Wolfe effect (or ISW rise), since it comes from the line integral of $\dot{\phi}$; it has been confirmed through correlations between the large-angle anisotropies and large-scale structure [27]. Specific models can also give additional contributions at low ℓ (*e.g.*, perturbations in the dark energy component itself [28]), but typically these are buried in the cosmic variance.

In principle, the mechanism that produces primordial perturbations could generate scalar, vector, and tensor modes. However, the vector (vorticity) modes decay with the expansion of the Universe. The tensors (transverse trace-free perturbations to the metric) generate temperature anisotropies through the integrated effect of the locally anisotropic expansion of space. Since the tensor modes also redshift away after they enter the horizon, they contribute only to angular scales above about 1° (see Fig. 25.1). Hence some fraction of the low ℓ signal could be due to a gravitational wave contribution, although small amounts of tensors are essentially impossible to discriminate from other effects that might raise the level of the plateau. However, the tensors *can* be distinguished using polarization information (see Sec. 25.6).

25.4.2. The acoustic peaks, $100 \lesssim \ell \lesssim 1000$:

On sub-degree scales, the rich structure in the anisotropy spectrum is the consequence of gravity-driven acoustic oscillations occurring before the atoms in the Universe became neutral. Perturbations inside the horizon at last scattering have been able to evolve causally and produce anisotropy at the last scattering epoch, which reflects this evolution. The frozen-in phases of these sound waves imprint a dependence on the cosmological parameters, which gives CMB anisotropies their great constraining power.

The underlying physics can be understood as follows. Before the Universe became neutral, the proton-electron plasma was tightly coupled to the photons, and these components behaved as a single ‘photon-baryon fluid.’ Perturbations in the gravitational potential, dominated by the dark matter component, were steadily evolving. They drove oscillations in the photon-baryon fluid, with photon pressure providing most of the restoring force and baryons giving some additional inertia. The perturbations were quite small in amplitude, $O(10^{-5})$, and so evolved linearly. That means each Fourier mode developed independently, and hence can be described by a driven harmonic oscillator, with frequency determined by the sound speed in

the fluid. Thus the fluid density underwent oscillations, giving time variations in temperature. These combine with a velocity effect which is $\pi/2$ out of phase and has its amplitude reduced by the sound speed.

After the Universe recombined, the radiation decoupled from the baryons and could travel freely towards us. At that point, the phases of the oscillations were frozen-in, and became projected on the sky as a harmonic series of peaks. The main peak is the mode that went through $1/4$ of a period, reaching maximal compression. The even peaks are maximal *under*-densities, which are generally of smaller amplitude because the rebound has to fight against the baryon inertia. The troughs, which do not extend to zero power, are partially filled by the Doppler effect because they are at the velocity maxima.

The physical length scale associated with the peaks is the sound horizon at last scattering, which can be straightforwardly calculated. This length is projected onto the sky, leading to an angular scale that depends on the geometry of space, as well as the distance to last scattering. Hence the angular position of the peaks is a sensitive probe of the spatial curvature of the Universe (*i.e.*, Ω_{tot}), with the peaks lying at higher ℓ in open universes and lower ℓ in closed geometry.

One additional effect arises from reionization at redshift z_1 . A fraction of photons (τ) will be isotropically scattered at $z < z_1$, partially erasing the anisotropies at angular scales smaller than those subtended by the Hubble radius at z_1 . This corresponds typically to ℓ 's above about a few 10s, depending on the specific reionization model. The acoustic peaks are therefore reduced by a factor $e^{-2\tau}$ relative to the plateau.

These peaks were a clear theoretical prediction going back to about 1970 [29]. One can think of them as a snapshot of stochastic standing waves. Since the physics governing them is simple and their structure rich, then one can see how they encode extractable information about the cosmological parameters. Their empirical existence started to become clear around 1994 [30], and the emergence, over the following decade, of a coherent series of acoustic peaks and troughs is a triumph of modern cosmology. This picture has received further confirmation with the detection in the power spectrum of galaxies (at redshifts close to zero) of the imprint of these same acoustic oscillations in the baryon component [33–33].

25.4.3. The damping tail, $\ell \gtrsim 1000$:

The recombination process is not instantaneous, which imparts a thickness to the last scattering surface. This leads to a damping of the anisotropies at the highest ℓ 's, corresponding to scales smaller than that subtended by this thickness. One can also think of the photon-baryon fluid as having imperfect coupling, so that there is diffusion between the two components, and hence the amplitudes of the oscillations decrease with time. These effects lead to a damping of the C_ℓ 's, sometimes called Silk damping [34], which cuts off the anisotropies at multipoles above about 2000.

An extra effect at high ℓ 's comes from gravitational lensing, caused mainly by non-linear structures at low redshift. The C_ℓ 's are convolved with a smoothing function in a calculable way, partially flattening the peaks, generating a power-law tail at the highest multipoles, and complicating the polarization signal [35]. The effects of lensing on the CMB have recently been detected by correlating temperature gradients and small-scale filtered anisotropies from WMAP with lensing potentials traced using galaxies [36], as well as through the effect on the shape of the C_ℓ 's [37] and directly through the CMB 4-point function [38]. This is an example of a ‘secondary effect,’ *i.e.*, the processing of anisotropies due to relatively nearby structures (see Sec. 25.7.2). Galaxies and clusters of galaxies give several such effects; all are expected to be of low amplitude and typically affect only the highest ℓ 's, but they carry additional cosmological information and will be increasingly important as experiments push to higher sensitivity and angular resolution [39].

25.5. Current Anisotropy Data

There has been a steady improvement in the quality of CMB data that has led to the development of the present-day cosmological model. Probably the most robust constraints currently available come from the combination of the WMAP 7-year data [40] with smaller scale results from the ACT [41] and SPT [42] experiments (together with constraints from other cosmological data-sets). We plot power spectrum estimates from these experiments, as well as ACBAR [43] and QUAD [44] in Fig. 25.2. Other recent experiments also give powerful constraints, which are quite consistent with what we describe below. There have been some comparisons among data-sets [45], which indicate very good agreement, both in maps and in derived power spectra (up to systematic uncertainties in the overall calibration for some experiments). This makes it clear that systematic effects are largely under control. However, a fully self-consistent joint analysis of all the current data-sets has not been attempted, one of the reasons being that it would require a careful treatment of the overlapping sky coverage.

Figure 25.2: Band-power estimates from the WMAP, ACBAR, ACT, QUAD, and SPT experiments (omitting some band-powers which have larger error bars). Note that the widths of the ℓ -bands vary between experiments and have not been plotted. This figure represents only a selection of available experimental results, with some other data-sets being of similar quality. The multipole axis here is linear, so the Sachs-Wolfe plateau is hard to see. However, the acoustic peaks and damping region are very clearly observed, with no need for a theoretical curve to guide the eye; the curve plotted is a best-fit model from WMAP plus other CMB data. At high ℓ there is some departure from the model due to secondary anisotropies.

The band-powers shown in Fig. 25.2 are in very good agreement with a ‘ Λ CDM’ model. As described earlier, several of the peaks and troughs are quite apparent. For details of how these estimates were arrived at, the strength of any correlations between band-powers and other information required to properly interpret them, the original papers should be consulted.

25.6. CMB Polarization

Since Thomson scattering of an anisotropic radiation field also generates linear polarization, the CMB is predicted to be polarized at the level of roughly 5% of the temperature anisotropies [46]. Polarization is a spin-2 field on the sky, and the algebra of the modes in ℓ -space is strongly analogous to spin-orbit coupling in quantum mechanics [47]. The linear polarization pattern can be decomposed in a number of ways, with two quantities required for each pixel in a map, often given as the Q and U Stokes parameters. However, the most intuitive and physical decomposition is a geometrical one, splitting the polarization pattern into a part that comes from a

divergence (often referred to as the ‘ E -mode’) and a part with a curl (called the ‘ B -mode’) [48]. More explicitly, the modes are defined in terms of second derivatives of the polarization amplitude, with the Hessian for the E -modes having principle axes in the same sense as the polarization, while the B -mode pattern can be thought of as a 45° rotation of the E -mode pattern. Globally one sees that the E -modes have $(-1)^\ell$ parity (like the spherical harmonics), while the B -modes have $(-1)^{\ell+1}$ parity.

The existence of this linear polarization allows for six different cross power spectra to be determined from data that measure the full temperature and polarization anisotropy information. Parity considerations make two of these zero, and we are left with four potential observables: C_ℓ^{TT} , C_ℓ^{TE} , C_ℓ^{EE} , and C_ℓ^{BB} . Because scalar perturbations have no handedness, the B -mode power spectrum can only be sourced by vectors or tensors. Moreover, since inflationary scalar perturbations give only E -modes, while tensors generate roughly equal amounts of E - and B -modes, then the determination of a non-zero B -mode signal is a way to measure the gravitational wave contribution (and thus potentially derive the energy scale of inflation), even if it is rather weak. However, one must first eliminate the foreground contributions and other systematic effects down to very low levels.

The oscillating photon-baryon fluid also results in a series of acoustic peaks in the polarization C_ℓ ’s. The main ‘EE’ power spectrum has peaks that are out of phase with those in the ‘TT’ spectrum, because the polarization anisotropies are sourced by the fluid velocity. The ‘TE’ part of the polarization and temperature patterns comes from correlations between density and velocity perturbations on the last scattering surface, which can be both positive and negative, and is of larger amplitude than the EE signal. There is no polarization Sachs-Wolfe effect, and hence no large-angle plateau. However, scattering during a recent period of reionization can create a polarization ‘bump’ at large angular scales.

Figure 25.3: Cross power spectrum of the temperature anisotropies and E -mode polarization signal from WMAP, together with estimates from BICEP, BOOMERANG, CBI, DASI, and QUAD, several of which extend to higher ℓ . Note that the y -axis here is not multiplied by the additional ℓ , which helps to show both the large and small angular scale features.

Because the polarization anisotropies have only a fraction of the amplitude of the temperature anisotropies, they took longer to detect. The first measurement of a polarization signal came in 2002 from the DASI experiment [49], which provided a convincing detection, confirming the general paradigm, but of low enough significance that it lent little constraint to models. As well as the E -mode signal, DASI also made a statistical detection of the TE correlation.

The TE signal has now been mapped out quite accurately through data from WMAP [50], together with the BICEP [51], BOOMERANG [52], CBI [53], DASI [54], and QUAD [55] experiments, which are shown in Fig. 25.3. The anti-correlation

at $\ell \simeq 150$ and the peak at $\ell \simeq 300$ are now quite distinct. The measured shape of the cross-correlation power spectrum provides supporting evidence for the adiabatic nature of the perturbations, as well as directly constraining the thickness of the last scattering surface. Since the polarization anisotropies are generated in this scattering surface, the existence of correlations at angles above about a degree demonstrates that there were super-Hubble fluctuations at the recombination epoch. The sign of this correlation also confirms the adiabatic paradigm.

Figure 25.4: Power spectrum of E -mode polarization from several different experiments, plotted along with a theoretical model which fits WMAP plus other CMB data. Note that the widths of the bands have been suppressed for clarity, but that in some cases they are almost as wide as the features in the power spectrum.

Experimental band-powers for C_ℓ^{EE} from WMAP plus BICEP [51], BOOMERANG [56], CAPMAP [57], CBI [53], DASI [54], QUAD [55] and QUIET [58] are shown in Fig. 25.4. Without the benefit of correlating with the temperature anisotropies (*i.e.*, measuring C_ℓ^{TE}), the polarization anisotropies are very weak and challenging to measure. Nevertheless, there is a highly significant overall detection which is consistent with expectation. The data convincingly show the peak at $\ell \simeq 140$ (hard to see on this scale), the next peak at $\ell \simeq 400$ (corresponding to the first trough in C_ℓ^{TT}) and the generally oscillatory structure.

Several experiments have reported upper limits on C_ℓ^{BB} , but they are currently not very constraining. This situation should change as increasingly ambitious experiments report results.

The most distinctive novel from the polarization measurements is at the largest angular scales ($\ell < 10$) in C_ℓ^{TE} , where there is an excess signal compared to that expected from the temperature power spectrum alone. This is precisely the signal anticipated from an early period of reionization, arising from Doppler shifts during the partial scattering at $z < z_i$. The effect is also confirmed in the WMAP C_ℓ^{EE} results at $\ell = 2-7$ [50]. The amplitude of the signal indicates that the first stars, presumably the source of the ionizing radiation, formed around $z \simeq 10$ (although the uncertainty is still quite large). Since this corresponds to scattering optical depth $\tau \simeq 0.1$, then roughly 10% of CMB photons were re-scattered at the reionization epoch, with the other 90% last scattering at $z \simeq 1100$.

25.7. Complications

There are a number of issues which complicate the interpretation of CMB anisotropy data (and are considered to be *signal* by many astrophysicists), some of which we sketch out below.

25.7.1. Foregrounds :

The microwave sky contains significant emission from our Galaxy and from extra-galactic sources [59,60]. Fortunately, the frequency dependence of these various sources is in general substantially different from that of the CMB anisotropy signals. The combination of Galactic synchrotron, bremsstrahlung, and dust emission reaches a minimum at a wavelength of roughly 3 mm (or about 100 GHz). As one moves to greater angular resolution, the minimum moves to slightly higher frequencies, but becomes more sensitive to unresolved (point-like) sources.

At frequencies around 100 GHz, and for portions of the sky away from the Galactic Plane, the foregrounds are typically 1 to 10% of the CMB anisotropies. By making observations at multiple frequencies, it is relatively straightforward to separate the various components and determine the CMB signal to the few per cent level. For greater sensitivity, it is necessary to use the spatial information and statistical properties of the foregrounds to separate them from the CMB.

The foregrounds for CMB polarization follow a similar pattern, but are less well studied, and are intrinsically more complicated. WMAP has shown that the polarized foregrounds dominate at large angular scales, and that they must be well characterized in order to be discriminated [60]. Whether it is possible to achieve sufficient separation to detect B -mode CMB polarization is still an open question. However, for the time being, foreground contamination is not a fundamental limit for CMB experiments.

25.7.2. Secondary Anisotropies :

With increasingly precise measurements of the primary anisotropies, there is growing theoretical and experimental interest in ‘secondary anisotropies,’ pushing experiments to higher angular resolution and sensitivity. These secondary effects arise from the processing of the CMB due to ionization history and the evolution of structure, including gravitational lensing and patchy reionization effects [61]. Additional information can thus be extracted about the Universe at $z \ll 1000$. This tends to be most effectively done through correlating CMB maps with other cosmological probes of structure. Secondary signals are also typically non-Gaussian, unlike the primary CMB anisotropies.

A secondary signal of great current interest is the Sunyaev-Zeldovich (SZ) effect [62], which is Compton scattering ($\gamma e \rightarrow \gamma' e'$) of the CMB photons by hot electron gas. This creates spectral distortions by transferring energy from the electrons to the photons. It is particularly important for clusters of galaxies, through which one observes a partially Comptonized spectrum, resulting in a decrement at radio wavelengths and an increment in the submillimeter.

The imprint on the CMB sky is of the form $\Delta T/T = y f(x)$, with the y -parameter being the integral of Thomson optical depth times $kT_e/m_e c^2$ through the cluster, and $f(x)$ describing the frequency dependence. This is simply $x \coth(x/2) - 4$ for a non-relativistic gas (the electron temperature in a cluster is typically a few keV), where the dimensionless frequency $x \equiv h\nu/kT_e$. As well as this ‘thermal’ SZ effect, there is also a smaller ‘kinetic’ effect due to the bulk motion of the cluster gas, giving $\Delta T/T \sim \tau(v/c)$, with either sign, but having the same spectrum as the primary CMB anisotropies.

A significant advantage in finding galaxy clusters this way is that the SZ effect is largely independent of redshift, so in principle clusters can be found to arbitrarily large distances. The SZ effect can be used to find and study individual clusters, and to obtain estimates of the Hubble constant. There is also the potential to constrain the equation of state of the dark energy through counts of detected clusters as a function of redshift [63]. Many experiments are currently in operation which will probe clusters in this way. The promise of the method has been realized through detections of clusters purely through the SZ effect, by SPT [64], ACT [65] and *Planck* [66].

25.7.3. Higher-order Statistics :

Although most of the CMB anisotropy information is contained in the power spectra, there will also be weak signals present in higher-order statistics. These can measure any primordial non-Gaussianity in the perturbations, as well as non-linear growth of the fluctuations on small scales and other secondary effects (plus residual foreground contamination of course). Although there are an infinite variety of ways in which the CMB could be non-Gaussian [17], there is a

generic form to consider for the initial conditions, where a quadratic contribution to the curvature perturbations is parameterized through a dimensionless number f_{NL} . This weakly non-linear component can be constrained using measurements of the bispectrum or Minkowski functionals, for example. The constraints depend on the shape of the triangles in harmonic space, and it has become common to distinguish the ‘local’ or ‘squeezed’ configuration (in which one side is much smaller than the other two) from the ‘equilateral’ configuration. The results from the WMAP team are $-10 < f_{\text{NL}} < 74$ (95% confidence region), for the local mode and $-214 < f_{\text{NL}} < 266$ for the equilateral mode [40]. Different estimators used by other authors give results of similar magnitude [67].

The level of f_{NL} expected is small, so that a detection of $f_{\text{NL}} \gtrsim 10$ would rule out all single field, slow-roll inflationary models. However, with the capabilities of *Planck* and other future experiments, it seems that a measurement of primordial non-Gaussianity may be feasible for a wide class of models, and therefore much effort is expected to be devoted to predictions and measurements in the coming years.

25.8. Constraints on Cosmologies

The most striking outcome of the newer experimental results is that the standard cosmological paradigm is in very good shape. A large amount of high precision data on the power spectrum is adequately fit with fewer than 10 free parameters. The framework is that of FRW models, which have nearly flat geometry, containing dark matter and dark energy, and with adiabatic perturbations having close to scale invariant initial conditions.

Within this basic picture, the values of the cosmological parameters can be constrained. Of course, much more stringent bounds can be placed on models which cover a restricted parameter space, *e.g.*, assuming that $\Omega_{\text{tot}} = 1$, $n = 1$ or $r = 0$. More generally, the constraints depend upon the adopted prior probability distributions, even if they are implicit, for example by restricting the parameter freedom or their ranges (particularly where likelihoods peak near the boundaries), or by using different choices of other data in combination with the CMB. When the data become even more precise, these considerations will be less important, but for now we caution that restrictions on model space and choice of priors need to be kept in mind when adopting specific parameter values and uncertainties.

There are some combinations of parameters that fit the CMB anisotropies almost equivalently. For example, there is a nearly exact geometric degeneracy, where any combination of Ω_{m} and Ω_{Λ} that gives the same angular diameter distance to last scattering will give nearly identical C_{ℓ} 's. There are also other less exact degeneracies among the parameters. Such degeneracies can be broken when using the CMB results in combination with other cosmological data-sets. Particularly useful are complementary constraints from galaxy clustering, the abundance of galaxy clusters, baryon acoustic oscillations, weak gravitational lensing measurements, Type Ia supernova distances, and the distribution of Lyman α forest clouds. For an overview of some of these other cosmological constraints, see The Cosmological Parameters—Sec. 23 of this *Review*.

The 7-year WMAP data alone, within the context of a six parameter family of models (which fixes $\Omega_{\text{tot}} = 1$ and $r = 0$), yield the following results [50]: $A = (2.43 \pm 0.11) \times 10^{-9}$; $n = 0.967 \pm 0.014$; $h = 0.704 \pm 0.025$; $\Omega_{\text{b}} h^2 = 0.0225 \pm 0.0006$; $\Omega_{\text{m}} h^2 = 0.134 \pm 0.006$; and $\tau = 0.088 \pm 0.015$. There has been little substantive change compared with earlier results, although it is now possible to obtain this 6-parameter set without using additional cosmological data-sets. Compared with the earliest WMAP results, the better measurement of the third acoustic peak, together with improved understanding of calibration issues has led to tighter error bars on dark matter density and overall normalization. The evidence for non-zero reionization optical depth is now very compelling, while the evidence for $n < 1$ is still only at the roughly 3σ level.

Other combinations of data, *e.g.*, including additional CMB measurements, or using other cosmological data-sets, lead to consistent results to those given above, sometimes with smaller error bars, and with the precise values depending on data selection [33,55,68,42] (see Sec. 23 of this *Review*). Note that for h , the CMB data alone provide only a very weak constraint, unless spatial flatness or some other cosmological data are used. For $\Omega_{\text{b}} h^2$, the precise value depends

sensitively on how much freedom is allowed in the shape of the primordial power spectrum (see Sec. 22 of this *Review*). The addition of other data-sets also allows for constraints to be placed on further parameters.

For Ω_{tot} , perhaps the best WMAP constraint is 1.002 ± 0.006 [40], from the combination with Hubble constant [22] and baryon acoustic oscillation [33] constraints (and setting $w = -1$). The 95% confidence upper limit on r is 0.36 using WMAP alone [50], tightening to $r < 0.17$ with the addition of other data [42]. This limit depends on how the slope n is restricted and whether $dn/d \ln k \neq 0$ is allowed. Nevertheless, it is clear that $\lambda\phi^4$ (sometimes called self-coupled) inflation is disfavored by the data, while the $m^2\phi^2$ (sometimes called mass term) inflationary model is still allowed [40]. Gravitational wave constraints coming directly from B -mode limits are at the level of $r < 0.73$ [51].

There are also constraints on parameters over and above the basic eight that we have described, usually requiring extra cosmological data to break degeneracies. For example, the addition of the dark energy equation of state w adds the partial degeneracy of being able to fit a ridge in (w, h) space, extending to low values of both parameters. This degeneracy is broken when the CMB is used in combination with independent H_0 limits, or other data. For example, WMAP plus baryon acoustic oscillation and supernova data [70] yields $w = -1.00 \pm 0.06$, even without assuming flatness.

For the optical depth τ , the best-fit corresponds to a reionization redshift centered on 10.5 in the best-fit cosmology, and assuming instantaneous reionization. This redshift appears to be higher than that suggested from studies of absorption in high- z quasar spectra [71], perhaps indicating that the process of reionization was complex. The important constraint provided by CMB polarization, in combination with astrophysical measurements, allows us to investigate how the first stars formed and brought about the end of the cosmic dark ages.

25.9. Particle Physics Constraints

CMB data are beginning to put limits on parameters which are directly relevant for particle physics models. For example, there is a limit on the neutrino contribution $\Omega_{\nu} h^2 < 0.0062$ (95% confidence) from a combination of WMAP and other data [18]. This directly implies a limit on neutrino mass, $\sum m_{\nu} < 0.58$ eV, assuming the usual number density of fermions which decoupled when they were relativistic. Some tighter constraints can be derived using the CMB in combination with other data-sets [72].

The current suite of data suggests that $n < 1$, with a best-fitting value about 0.03 below unity. If borne out, this would be quite constraining for inflationary models. Moreover, it gives a real target for B -mode searches, since the value of r in simple models may be in the range of detectability, *e.g.*, $r \sim 0.12$ for $m^2\phi^2$ inflation if $n \simeq 0.97$. In addition, a combination of the WMAP data with other data-sets constrains the running of the spectral index, although at the moment there is no evidence for $dn/d \ln k \neq 0$ [40].

One other possible hint of new physics lies in the fact that the quadrupole seems anomalously low and also appears remarkably well aligned with the octupole. Additionally there is some weak evidence for a large scale modulation of the smaller-scale power [73]. These effects might be expected in a universe which has a large-scale cut-off, or anisotropy in the initial power spectrum, or is topologically non-trivial. However, cosmic variance, a posteriori statistics, possible foregrounds, apparent correlations between modes (as mentioned in Sec. 25.2), *etc.*, limit the significance of these anomalies, and for now the general view is that such features are not unreasonably unlikely within the Λ CDM paradigm [19].

It is also possible to put limits on other pieces of physics [74], for example the neutrino chemical potentials, contribution of warm dark matter, decaying particles, parity violation, time variation of the fine-structure constant, topological defects, or physics beyond general relativity. Further particle physics constraints will follow as the anisotropy measurements increase in precision.

Careful measurement of the CMB power spectra and non-Gaussianity can in principle put constraints on physics at the highest energies, including ideas of string theory, extra dimensions, colliding branes, *etc.* At the moment any calculation of predictions appears to be far from definitive. However, there is a great deal of activity on

implications of string theory for the early Universe, and hence a very real chance that there might be observational implications for specific scenarios.

25.10. Fundamental Lessons

More important than the precise values of parameters is what we have learned about the general features which describe our observable Universe. Beyond the basic hot Big Bang picture, the CMB has taught us that:

- The Universe recombined at $z \simeq 1100$ and started to become ionized again at $z \simeq 10$.
- The geometry of the Universe is close to flat.
- Both dark matter and dark energy are required.
- Gravitational instability is sufficient to grow all of the observed large structures in the Universe.
- Topological defects were not important for structure formation.
- There are ‘synchronized’ super-Hubble modes generated in the early Universe.
- The initial perturbations were predominantly adiabatic in nature.
- The perturbations had close to Gaussian (*i.e.*, maximally random) initial conditions.

It is very tempting to make an analogy between the status of the cosmological ‘Standard Model’ and that of particle physics (see earlier Sections of this *Review*). In cosmology there are about 10 free parameters, each of which is becoming well determined, and with a great deal of consistency between different measurements. However, none of these parameters can be calculated from a fundamental theory, and so hints of the bigger picture, ‘physics beyond the Standard Model,’ are being searched for with ever more ambitious experiments.

Despite this analogy, there are some basic differences. For one thing, many of the cosmological parameters change with cosmic epoch, and so the measured values are simply the ones determined today, and hence they are not ‘constants,’ like particle masses for example (although they *are* deterministic, so that if one knows their values at one epoch, they can be calculated at another). Moreover, the parameter set is not as well defined as it is in the particle physics Standard Model; different researchers will not necessarily agree on which parameters should be considered as free, and the set can be extended as the quality of the data improves. In addition, parameters like τ , which come from astrophysics, are in principle calculable from known physical processes. On top of all this, other parameters might be ‘stochastic’ in that they may be fixed only in our observable patch of the Universe or among certain vacuum states in the ‘Landscape’ [76].

In a more general sense, the cosmological ‘Standard Model’ is much further from the underlying ‘fundamental theory,’ which will ultimately provide the values of the parameters from first principles. Nevertheless, any genuinely complete ‘theory of everything’ must include an explanation for the values of these cosmological parameters as well as the parameters of the Standard Model of particle physics.

25.11. Future Directions

Given the significant progress in measuring the CMB sky, which has been instrumental in tying down the cosmological model, what can we anticipate for the future? There will be a steady improvement in the precision and confidence with which we can determine the appropriate cosmological parameters. Ground-based experiments operating at smaller angular scales will continue to place tighter constraints on the damping tail. New polarization experiments will push down the limits on primordial B -modes. The third generation CMB satellite mission, *Planck*, was launched successfully in May 2009, and has already led to many papers on foregrounds and secondary anisotropies [9]. Cosmological results from the primary CMB anisotropies are expected from *Planck* in early 2013 and are keenly anticipated.

Despite the increasing improvement in the results, the addition of the latest experiments has not significantly changed the established cosmological model. It is, therefore, appropriate to ask: what should we expect to come from *Planck* and from other future experiments? *Planck* certainly has the advantage of high sensitivity and a full-sky survey. A precise measurement of the third acoustic peak provides

a good determination of the matter density; this can only be done by measurements which are accurate relative to the first two peaks (which themselves constrain the curvature and the baryon density). A detailed measurement of the damping tail region will also significantly improve the determination of n and any running of the slope. *Planck* should be capable of measuring C_ℓ^{EE} quite well, providing both a strong check on the cosmological Standard Model and extra constraints that will improve parameter estimation.

A set of cosmological parameters is now known to roughly 10% accuracy, and that may seem sufficient for many people. However, we should certainly demand more of measurements which describe *the entire observable Universe!* Hence a lot of activity in the coming years will continue to focus on determining those parameters with increasing precision. This necessarily includes testing for consistency among different predictions of the cosmological Standard Model, and searching for signals which might require additional physics.

A second area of focus will be the smaller scale anisotropies and ‘secondary effects.’ There is a great deal of information about structure formation at $z \ll 1000$ encoded in the CMB sky. This may involve higher-order statistics as well as spectral signatures, with many new experiments targeting the galaxy cluster SZ effect. Such investigations can also provide constraints on the dark energy equation of state, for example. *Planck*, as well as new telescopes aimed at the highest ℓ ’s, should be able to make a lot of progress in this arena.

A third direction is increasingly sensitive searches for specific signatures of physics at the highest energies. The most promising of these may be the primordial gravitational wave signals in C_ℓ^{BB} , which could be a probe of the $\sim 10^{16}$ GeV energy range. As well as *Planck*, there are several ground- and balloon-based experiments underway which are designed to search for the polarization B -modes. Whether the amplitude of the effect coming from inflation will be detectable is unclear, but the prize makes the effort worthwhile, and the indications that $n \simeq 0.95$ give some genuine optimism that r (the tensor to scalar ratio) may be of order 0.1, and hence within reach soon.

Anisotropies in the CMB have proven to be the premier probe of cosmology and the early Universe. Theoretically the CMB involves well understood physics in the linear regime, and is under very good calculational control. A substantial and improving set of observational data now exists. Systematics appear to be under control and not a limiting factor. And so for the next few years we can expect an increasing amount of cosmological information to be gleaned from CMB anisotropies, with the prospect also of some genuine surprises.

26. COSMIC RAYS

Revised August 2011 by J.J. Beatty (Ohio State Univ.) and J. Matthews (Louisiana State Univ. and Southern Univ.); revised August 2009 by T.K. Gaisser and T. Stanev (Bartol Research Inst., Univ. of Delaware).

26.1. Primary spectra

The cosmic radiation incident at the top of the terrestrial atmosphere includes all stable charged particles and nuclei with lifetimes of order 10^6 years or longer. Technically, “primary” cosmic rays are those particles accelerated at astrophysical sources and “secondaries” are those particles produced in interaction of the primaries with interstellar gas. Thus electrons, protons and helium, as well as carbon, oxygen, iron, and other nuclei synthesized in stars, are primaries. Nuclei such as lithium, beryllium, and boron (which are not abundant end-products of stellar nucleosynthesis) are secondaries. Antiprotons and positrons are also in large part secondary. Whether a small fraction of these particles may be primary is a question of current interest.

Apart from particles associated with solar flares, the cosmic radiation comes from outside the solar system. The incoming charged particles are “modulated” by the solar wind, the expanding magnetized plasma generated by the Sun, which decelerates and partially excludes the lower energy galactic cosmic rays from the inner solar system. There is a significant anticorrelation between solar activity (which has an alternating eleven-year cycle) and the intensity of the cosmic rays with energies below about 10 GeV. In addition, the lower-energy cosmic rays are affected by the geomagnetic field, which they must penetrate to reach the top of the atmosphere. Thus the intensity of any component of the cosmic radiation in the GeV range depends both on the location and time.

There are four different ways to describe the spectra of the components of the cosmic radiation: (1) By particles per unit rigidity. Propagation (and probably also acceleration) through cosmic magnetic fields depends on gyroradius or *magnetic rigidity*, R , which is gyroradius multiplied by the magnetic field strength:

$$R = \frac{pc}{Ze} = r_L B. \quad (26.1)$$

(2) By particles per energy-per-nucleon. Fragmentation of nuclei propagating through the interstellar gas depends on energy per nucleon, since that quantity is approximately conserved when a nucleus breaks up on interaction with the gas. (3) By nucleons per energy-per-nucleon. Production of secondary cosmic rays in the atmosphere depends on the intensity of nucleons per energy-per-nucleon, approximately independently of whether the incident nucleons are free protons or bound in nuclei. (4) By particles per energy-per-nucleus. Air shower experiments that use the atmosphere as a calorimeter generally measure a quantity that is related to total energy per particle.

The units of differential intensity I are $[\text{m}^{-2} \text{s}^{-1} \text{sr}^{-1} \mathcal{E}^{-1}]$, where \mathcal{E} represents the units of one of the four variables listed above.

The intensity of primary nucleons in the energy range from several GeV to somewhat beyond 100 TeV is given approximately by

$$I_N(E) \approx 1.8 \times 10^4 (E/1 \text{ GeV})^{-\alpha} \frac{\text{nucleons}}{\text{m}^2 \text{ s sr GeV}}, \quad (26.2)$$

where E is the energy-per-nucleon (including rest mass energy) and α ($\equiv \gamma + 1$) = 2.7 is the differential spectral index of the cosmic ray flux and γ is the integral spectral index. About 79% of the primary nucleons are free protons and about 70% of the rest are nucleons bound in helium nuclei. The fractions of the primary nuclei are nearly constant over this energy range (possibly with small but interesting variations). Fractions of both primary and secondary incident nuclei are listed in Table 26.1. Figure 26.1 shows the major components for energies greater than 2 GeV/nucleon.

Figure 26.1: Fluxes of nuclei of the primary cosmic radiation in particles per energy-per-nucleus are plotted vs energy-per-nucleus using data from Refs. [1–12]. The figure was created by P. Boyle and D. Muller.

The composition and energy spectra of nuclei are typically interpreted in the context of propagation models, in which the sources of the primary cosmic radiation are located within the galaxy [16]. The ratio of secondary to primary nuclei is observed to decrease with increasing energy, a fact interpreted to mean that the lifetime of cosmic rays in the galaxy decreases with energy. Measurements of radioactive “clock” isotopes in the low energy cosmic radiation are consistent with a lifetime in the galaxy of about 15 Myr.

Table 26.1: Relative abundances F of cosmic-ray nuclei at 10.6 GeV/nucleon normalized to oxygen ($\equiv 1$) [6]. The oxygen flux at kinetic energy of 10.6 GeV/nucleon is $3.26 \times 10^{-2} (\text{m}^2 \text{ s sr GeV/nucleon})^{-1}$. Abundances of hydrogen and helium are from Refs. [2,3]. Note that one can not use these values to extend the cosmic ray flux to high energy because the power law indices for each element may differ slightly.

Z	Element	F	Z	Element	F
1	H	540	13–14	Al-Si	0.19
2	He	26	15–16	P-S	0.03
3–5	Li-B	0.40	17–18	Cl-Ar	0.01
6–8	C-O	2.20	19–20	K-Ca	0.02
9–10	F-Ne	0.30	21–25	Sc-Mn	0.05
11–12	Na-Mg	0.22	26–28	Fe-Ni	0.12

Cosmic rays are nearly isotropic at most energies due to diffusive propagation in the galactic magnetic field. Milagro [13], IceCube [14], and The Tibet-III air shower array [15] have observed anisotropy at the level of about 10^{-3} for cosmic rays with energy of a few TeV, possibly due to nearby sources.

The spectrum of electrons and positrons incident at the top of the atmosphere is expected to steepen by one power of E at an energy of ~ 5 GeV because of the strong synchrotron energy loss in the galactic magnetic fields. The ATIC experiment [21] measured an excess of electrons above 100 GeV followed by a steepening above 1,000 GeV. The Fermi/LAT γ -ray observatory confirmed the relatively

flat electron spectrum [23] without confirming the peak of the ATIC excess at ~ 800 GeV.

The PAMELA satellite experiment [24] measured the positron to electron ratio to increase above 10 GeV instead of the expected decrease [25] at higher energy. The structure in the electron spectrum as well as the increase in the positron fraction could be related to contributions from individual nearby sources emerging above a background suppressed at high energy by synchrotron losses [26]. The low positron to electron ratio below 10 GeV is due to the new solar magnetic field polarity after the year 2001.

Figure 26.2: Differential spectrum of electrons plus positrons multiplied by E^3 (data from [17–23]). The line shows the proton spectrum multiplied by 0.01. The inset shows the positron to electron ratio measured by PAMELA [24] compared to the expected decrease [25].

The ratio of antiprotons to protons is $\sim 2 \times 10^{-4}$ [27] at around 10–20 GeV, and there is clear evidence [28] for the kinematic suppression at lower energy that is the signature of secondary antiprotons. The \bar{p}/p ratio also shows a strong dependence on the phase and polarity of the solar cycle [29] in the opposite sense to that of the positron fraction. There is at this time no evidence for a significant primary component of antiprotons. No antihelium or antideuteron has been found in the cosmic radiation. The best measured upper limit on the ratio antihelium/helium is currently approximately 1×10^{-7} [30]. The upper limit on the flux of antideuterons around 1 GeV/nucleon is approximately $2 \times 10^{-4} (\text{m}^2 \text{ s sr GeV/nucleon})^{-1}$ [31].

26.2. Cosmic rays in the atmosphere

Figure 26.3 shows the vertical fluxes of the major cosmic ray components in the atmosphere in the energy region where the particles are most numerous (except for electrons, which are most numerous near their critical energy, which is about 81 MeV in air). Except for protons and electrons near the top of the atmosphere, all particles are produced in interactions of the primary cosmic rays in the air. Muons and neutrinos are products of the decay chain of charged mesons, while electrons and photons originate in decays of neutral mesons.

Most measurements are made at ground level or near the top of the atmosphere, but there are also measurements of muons and electrons from airplanes and balloons. Fig. 26.3 includes recent measurements of negative muons [32–36]. Since $\mu^+(\mu^-)$ are produced in association with $\nu_\mu(\bar{\nu}_\mu)$, the measurement of muons near the maximum of the intensity curve for the parent pions serves to calibrate the atmospheric ν_μ beam [37]. Because muons typically lose almost 2 GeV in passing through the atmosphere, the comparison near the production altitude is important for the sub-GeV range of $\nu_\mu(\bar{\nu}_\mu)$ energies.

The flux of cosmic rays through the atmosphere is described by a set of coupled cascade equations with boundary conditions at the

Figure 26.3: Vertical fluxes of cosmic rays in the atmosphere with $E > 1$ GeV estimated from the nucleon flux of Eq. (26.2). The points show measurements of negative muons with $E_\mu > 1$ GeV [32–36].

top of the atmosphere to match the primary spectrum. Numerical or Monte Carlo calculations are needed to account accurately for decay and energy-loss processes, and for the energy-dependences of the cross sections and of the primary spectral index γ . Approximate analytic solutions are, however, useful in limited regions of energy [38,39]. For example, the vertical intensity of charged pions with energy $E_\pi \ll \epsilon_\pi = 115$ GeV is

$$I_\pi(E_\pi, X) \approx \frac{Z_{N\pi}}{\lambda_N} I_N(E_\pi, 0) e^{-X/\Lambda} \frac{X E_\pi}{\epsilon_\pi}, \quad (26.3)$$

where Λ is the characteristic length for exponential attenuation of the parent nucleon flux in the atmosphere. This expression has a maximum at $X = \Lambda \approx 121 \pm 4 \text{ g cm}^{-2}$ [40], which corresponds to an altitude of 15 kilometers. The quantity $Z_{N\pi}$ is the spectrum-weighted moment of the inclusive distribution of charged pions in interactions of nucleons with nuclei of the atmosphere. The intensity of low-energy pions is much less than that of nucleons because $Z_{N\pi} \approx 0.079$ is small and because most pions with energy much less than the critical energy ϵ_π decay rather than interact.

26.3. Cosmic rays at the surface

26.3.1. Muons: Muons are the most numerous charged particles at sea level (see Fig. 26.3). Most muons are produced high in the atmosphere (typically 15 km) and lose about 2 GeV to ionization before reaching the ground. Their energy and angular distribution reflect a convolution of the production spectrum, energy loss in the atmosphere, and decay. For example, 2.4 GeV muons have a decay length of 15 km, which is reduced to 8.7 km by energy loss. The mean energy of muons at the ground is ≈ 4 GeV. The energy spectrum is almost flat below 1 GeV, steepens gradually to reflect the primary spectrum in the 10–100 GeV range, and steepens further at higher energies because pions with $E_\pi > \epsilon_\pi$ tend to interact in the atmosphere before they decay. Asymptotically ($E_\mu \gg 1$ TeV), the energy spectrum of atmospheric muons is one power steeper than the primary spectrum.

The integral intensity of vertical muons above 1 GeV/c at sea level is $\approx 70 \text{ m}^{-2}\text{s}^{-1}\text{sr}^{-1}$ [41,42], with recent measurements [43–45] favoring a lower normalization by 10–15%. Experimentalists are familiar with this number in the form $I \approx 1 \text{ cm}^{-2} \text{ min}^{-1}$ for horizontal detectors. The overall angular distribution of muons at the ground is $\propto \cos^2 \theta$, which is characteristic of muons with $E_\mu \sim 3 \text{ GeV}$. At lower energy the angular distribution becomes increasingly steep, while at higher energy it flattens, approaching a $\sec \theta$ distribution for $E_\mu \gg \epsilon_\pi$ and $\theta < 70^\circ$.

Figure 26.4 shows the muon energy spectrum at sea level for two angles. At large angles low energy muons decay before reaching the surface and high energy pions decay before they interact, thus the average muon energy increases. An approximate extrapolation formula valid when muon decay is negligible ($E_\mu > 100/\cos \theta \text{ GeV}$) and the curvature of the Earth can be neglected ($\theta < 70^\circ$) is

$$\frac{dN_\mu}{dE_\mu d\Omega} \approx \frac{0.14 E_\mu^{-2.7}}{\text{cm}^2 \text{ s sr GeV}} \times \left\{ \frac{1}{1 + \frac{1.1 E_\mu \cos \theta}{115 \text{ GeV}}} + \frac{0.054}{1 + \frac{1.1 E_\mu \cos \theta}{850 \text{ GeV}}} \right\}, \quad (26.4)$$

where the two terms give the contribution of pions and charged kaons. Eq. (26.4) neglects a small contribution from charm and heavier flavors which is negligible except at very high energy [50].

Figure 26.4: Spectrum of muons at $\theta = 0^\circ$ (\blacklozenge [41], \blacksquare [46], \blacktriangledown [47], \blacktriangle [48], \times , $+$ [43], \circ [44], and \bullet [45] and $\theta = 75^\circ$ \diamond [49]). The line plots the result from Eq. (26.4) for vertical showers.

Figure 26.5: Muon charge ratio as a function of the muon momentum from Refs. [44,45,51].

The muon charge ratio reflects the excess of π^+ over π^- and K^+ over K^- in the forward fragmentation region of proton initiated interactions together with the fact that there are more protons than neutrons in the primary spectrum. The increase with energy of μ^+/μ^- shown in Fig. 26.5 reflects the increasing importance of kaons in the TeV range [51] and indicates a significant contribution of associated production by cosmic-ray protons ($p \rightarrow \Lambda + K^+$). The same process is even more important for atmospheric neutrinos at high energy.

26.3.2. Electromagnetic component: At the ground, this component consists of electrons, positrons, and photons primarily from cascades initiated by decay of neutral and charged mesons. Muon decay is the dominant source of low-energy electrons at sea level. Decay of neutral pions is more important at high altitude or when the energy threshold is high. Knock-on electrons also make a small contribution at low energy [52]. The integral vertical intensity of electrons plus positrons is very approximately 30, 6, and $0.2 \text{ m}^{-2}\text{s}^{-1}\text{sr}^{-1}$ above 10, 100, and 1000 MeV respectively [42,53], but the exact numbers depend sensitively on altitude, and the angular dependence is complex because of the different altitude dependence of the different sources of electrons [52–54]. The ratio of photons to electrons plus positrons is approximately 1.3 above 1 GeV and 1.7 below the critical energy [54].

26.3.3. Protons: Nucleons above 1 GeV/c at ground level are degraded remnants of the primary cosmic radiation. The intensity is approximately $I_N(E, 0) \times \exp(-X/\cos \theta \Lambda)$ for $\theta < 70^\circ$. At sea level, about 1/3 of the nucleons in the vertical direction are neutrons (up from $\approx 10\%$ at the top of the atmosphere as the n/p ratio approaches equilibrium). The integral intensity of vertical protons above 1 GeV/c at sea level is $\approx 0.9 \text{ m}^{-2}\text{s}^{-1}\text{sr}^{-1}$ [42,55].

26.4. Cosmic rays underground

Only muons and neutrinos penetrate to significant depths underground. The muons produce tertiary fluxes of photons, electrons, and hadrons.

26.4.1. Muons: As discussed in Section 30.6 of this *Review*, muons lose energy by ionization and by radiative processes: bremsstrahlung, direct production of e^+e^- pairs, and photonuclear interactions. The total muon energy loss may be expressed as a function of the amount of matter traversed as

$$-\frac{dE_\mu}{dX} = a + b E_\mu, \quad (26.5)$$

where a is the ionization loss and b is the fractional energy loss by the three radiation processes. Both are slowly varying functions of energy. The quantity $\epsilon \equiv a/b$ ($\approx 500 \text{ GeV}$ in standard rock) defines a critical energy below which continuous ionization loss is more important than radiative losses. Table 26.2 shows a and b values for standard rock, and b for ice, as a function of muon energy. The second column of Table 26.2 shows the muon range in standard rock ($A = 22$, $Z = 11$, $\rho = 2.65 \text{ g cm}^{-3}$). These parameters are quite sensitive to the chemical composition of the rock, which must be evaluated for each location.

Table 26.2: Average muon range R and energy loss parameters a and b calculated for standard rock [56] and the total energy loss parameter b for ice. Range is given in km-water-equivalent, or 10^5 g cm^{-2} .

E_μ GeV	R km.w.e.	a MeV $\text{g}^{-1} \text{cm}^2$	b_{brems}	b_{pair}	b_{nucl}	$\sum b_i$	$\sum b(\text{ice})$
			—	$10^{-6} \text{ g}^{-1} \text{cm}^2$	—	—	—
10	0.05	2.17	0.70	0.70	0.50	1.90	1.66
100	0.41	2.44	1.10	1.53	0.41	3.04	2.51
1000	2.45	2.68	1.44	2.07	0.41	3.92	3.17
10000	6.09	2.93	1.62	2.27	0.46	4.35	3.78

The intensity of muons underground can be estimated from the muon intensity in the atmosphere and their rate of energy loss. To the extent that the mild energy dependence of a and b can be neglected, Eq. (26.5) can be integrated to provide the following relation between the energy $E_{\mu,0}$ of a muon at production in the atmosphere and its average energy E_{μ} after traversing a thickness X of rock (or ice or water):

$$E_{\mu,0} = (E_{\mu} + \epsilon) e^{bX} - \epsilon. \quad (26.6)$$

Especially at high energy, however, fluctuations are important and an accurate calculation requires a simulation that accounts for stochastic energy-loss processes [57].

There are two depth regimes for which Eq. (26.6) can be simplified. For $X \ll b^{-1} \approx 2.5$ km water equivalent, $E_{\mu,0} \approx E_{\mu}(X) + aX$, while for $X \gg b^{-1}$ $E_{\mu,0} \approx (\epsilon + E_{\mu}(X)) \exp(bX)$. Thus at shallow depths the differential muon energy spectrum is approximately constant for $E_{\mu} < aX$ and steepens to reflect the surface muon spectrum for $E_{\mu} > aX$, whereas for $X > 2.5$ km.w.e. the differential spectrum underground is again constant for small muon energies but steepens to reflect the surface muon spectrum for $E_{\mu} > \epsilon \approx 0.5$ TeV. In the deep regime the shape is independent of depth although the intensity decreases exponentially with depth. In general the muon spectrum at slant depth X is

$$\frac{dN_{\mu}(X)}{dE_{\mu}} = \frac{dN_{\mu}}{dE_{\mu,0}} \frac{dE_{\mu,0}}{dE_{\mu}} = \frac{dN_{\mu}}{dE_{\mu,0}} e^{bX}, \quad (26.7)$$

where $E_{\mu,0}$ is the solution of Eq. (26.6) in the approximation neglecting fluctuations.

Fig. 26.6 shows the vertical muon intensity versus depth. In constructing this “depth-intensity curve,” each group has taken account of the angular distribution of the muons in the atmosphere, the map of the overburden at each detector, and the properties of the local medium in connecting measurements at various slant depths and zenith angles to the vertical intensity. Use of data from a range of angles allows a fixed detector to cover a wide range of depths. The flat portion of the curve is due to muons produced locally by charged-current interactions of ν_{μ} . The inset shows the vertical intensity curve for water and ice published in Refs. [59–62]. It is not as steep as the one for rock because of the lower muon energy loss in water.

26.4.2. Neutrinos:

Because neutrinos have small interaction cross sections, measurements of atmospheric neutrinos require a deep detector to avoid backgrounds. There are two types of measurements: contained (or semi-contained) events, in which the vertex is determined to originate inside the detector, and neutrino-induced muons. The latter are muons that enter the detector from zenith angles so large (*e.g.*, nearly horizontal or upward) that they cannot be muons produced in the atmosphere. In neither case is the neutrino flux measured directly. What is measured is a convolution of the neutrino flux and cross section with the properties of the detector (which includes the surrounding medium in the case of entering muons).

Contained and semi-contained events reflect neutrinos in the sub-GeV to multi-GeV region where the product of increasing cross section and decreasing flux is maximum. In the GeV region the neutrino flux and its angular distribution depend on the geomagnetic location of the detector and, to a lesser extent, on the phase of the solar cycle. Naively, we expect $\nu_{\mu}/\nu_e = 2$ from counting neutrinos of the two flavors coming from the chain of pion and muon decay. Contrary to expectation, however, the numbers of the two classes of events are similar rather than different by a factor of two. This is now understood to be a consequence of neutrino flavor oscillations [70]. (See the article on neutrino properties in this *Review*.)

Two well-understood properties of atmospheric cosmic rays provide a standard for comparison of the measurements of atmospheric neutrinos to expectation. These are the “ $\sec\theta$ effect” and the “east-west effect” [69]. The former refers originally to the enhancement of the flux of > 10 GeV muons (and neutrinos) at large zenith angles because the parent pions propagate more in the low density

Figure 26.6: Vertical muon intensity vs depth (1 km.w.e. = 10^5 g cm^{-2} of standard rock). The experimental data are from: \diamond : the compilations of Crouch [58], \square : Baksan [63], \circ : LVD [64], \bullet : MACRO [65], \blacksquare : Frejus [66], and \triangle : SNO [67]. The shaded area at large depths represents neutrino-induced muons of energy above 2 GeV. The upper line is for horizontal neutrino-induced muons, the lower one for vertically upward muons. Darker shading shows the muon flux measured by the SuperKamiokande experiment. The inset shows the vertical intensity curve for water and ice published in Refs. [59–62].

upper atmosphere where decay is enhanced relative to interaction. For neutrinos from muon decay, the enhancement near the horizontal becomes important for $E_{\nu} > 1$ GeV and arises mainly from the increased pathlength through the atmosphere for muon decay in flight. Fig. 26.7 from Ref. 68 shows a comparison between measurement and expectation for the zenith angle dependence of multi-GeV electron-like (mostly ν_e) and muon-like (mostly ν_{μ}) events separately. The ν_e show an enhancement near the horizontal and approximate equality for nearly upward ($\cos\theta \approx -1$) and nearly downward ($\cos\theta \approx 1$) events. There is, however, a very significant deficit of upward ($\cos\theta < 0$) ν_{μ} events, which have long pathlengths comparable to the radius of the Earth. This feature is the principal signature for oscillations [70].
