Abstract

Aim of the study:

Predicting outcome of unconscious patients after successful resuscitation is challenging and better prognostic markers are highly needed. Ischemic heart disease is a common cause of out-of-hospital cardiac arrest (OHCA). Whether or not high-sensitivity troponin T (hs-TnT) is a prognostic marker among survivors of OHCA with both ischemic and non-ischemic aetiologies remains to be determined. We sought to evaluate the ability of hs-TnT to prognosticate all-cause mortality, death due to cardiovascular causes or multi-organ failure and death due to cerebral causes after OHCA. The influence of the level of target temperature management on hs-TnT as a marker of infarct size was also assessed.

Methods:

A total of 699 patients from the Targeted Temperature Management (TTM) trial were included and hs-TnT was analysed in blood samples from 24, 48 and 72 h after return of spontaneous circulation (ROSC). The endpoints were 180 day all-cause mortality, death due to cardiovascular causes or multi-organ failure and death due to cerebral causes. Subgroups based on the initial ECG after ROSC (STEMI vs all other ECG presentations) were analysed.

Results:

Hs-TnT was independently associated with all-cause mortality which was driven by death due to cardiovascular causes or multi-organ failure and not cerebral causes (at 48h: OR 1.10, CI 1.01-1.20, $p < 0.05$). Hs-TnT was also an independent predictor of death due to cardiovascular causes or multi-organ failure (at 48h: OR 1.13, CI 1.01-1.26, $p < 0.05$). In patients with STEMI, hs-TnT was independently associated with death due to cardiovascular causes or multi-organ failure (at 48h: OR 1.47, CI 1.10-1.95, $p < 0.01$). Targeted temperature management at 33 °C was not associated with hs-TnT compared to 36 °C.

Conclusions:

After OHCA due to both ischemic and non-ischemic causes, hs-TnT is an independent marker of both all-cause mortality and death due to cardiovascular causes or multi-organ failure. Targeted temperature management at

33 °C did not reduce hs-TnT compared to 36 °C. Hs-TnT may be a marker of poor prognosis after OHCA and this should be taken into consideration in patients that present with high troponin levels.

Trial Registration

The TTM-trial is registered and accessible at [Clinicaltrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT01020916) (identifier: NCT01020916)

Keywords

Out-of-hospital cardiac arrest, hypothermia, prognosis, high-sensitivity Troponin T, TTM-trial

Introduction

Ischemic heart disease is a common cause of out-of-hospital cardiac arrest (OHCA), with an estimated 60-70% of OHCA caused by coronary heart disease [1, 2]. Troponin T (TnT) is both a diagnostic and prognostic marker in ST-elevation myocardial infarction (STEMI) as well as in non ST-elevation myocardial infarction (NSTEMI) [3, 4]. Since shock and myocardial infarction are frequently encountered among survivors of OHCA, it is therefore plausible that troponin might contribute to additional prognostic information. However, whether or not high-sensitivity troponin T (hs-TnT) is a prognostic marker among survivors of OHCA with both ischemic and non-ischemic aetiologies remains to be established. In a recent study including survivors of OHCA with ventricular fibrillation as the primary rhythm, hs-TnT was not associated with neurological outcome and mortality after adjustment for established risk factors [5]. Although high sensitivity troponins at admission are independently associated with acute coronary occlusions, they do not seem to aid in the decision regarding coronary angiography when added to other risk factors [6, 7].

Even though acute coronary syndromes are common in patients with OHCA, acute coronary angiography among OHCA patients without STEMI is still a matter of debate. The issue is further complicated by difficulties interpreting symptoms as well as the ECG in the post cardiac arrest setting since the post resuscitation ECG seem to be a poor predictor of an acute coronary occlusion [8, 9]. No randomized trials have evaluated the potential benefit of immediate coronary angiography in patients without STEMI and register studies have shown diverging results [10-12]. A recent sub study of the Targeted Temperature Management (TTM) trial revealed no survival benefit of coronary angiography within 6 hours of cardiac arrest among patients without STEMI at presentation [13].

In the present study we hypothesized that hs-TnT would be an independent prognostic marker of all-cause mortality as well as death due to cardiovascular causes or multi organ failure (MOF) at 6 months after OHCA. Furthermore, the relationship between hs-TnT and cerebral causes of death as well as targeted temperature management level, 33 °C vs 36 °C, was assessed.

Methods

Patient selection

The current study is a pre-defined observational substudy of the TTM-trial that investigated the effects of 33 °C versus 36 °C treatment among 939 unconscious survivors of OHCA [14]. The TTM trial included all primary ECG rhythms as well as both ischemic and non-ischemic cardiac arrest aetiologies. There was no difference in outcome between the two temperature groups. The present study is a part of a pre-defined biomarker substudy of the TTM trial. A total of 699 patients were included and serum blood samples were obtained at 24, 48 and 72 h after return of spontaneous circulation (ROSC). Out of the 36 participating sites, 29 took part in the biomarker substudy. All samples were pre-analytically processed, aliquoted and frozen to - 80 °C at the different sites before shipment to the integrated biobank in Luxembourg for analysis.

We pre-specified subgroups based on the initial ECG after ROSC (STEMI vs all other ECG presentations). Information about ECG at admission was available for 691 patients (99%). Two hundred eighty two (282) patients (40%) had STEMI at admission whereas 409 (59%) had other ECG presentations. For 8 patients, no information about ECG at admission was available. Since a previous unrecognized left bundle branch block (LBBB) is rarely associated with acute ischemia, it was not treated as a STEMI-equivalent [15].

Acute coronary angiography and PCI was defined as being performed within 6 hours from the cardiac arrest. In total, acute coronary angiography was performed in 398 patients (57%) with ad-hoc PCI in 69% of cases (N=270). In the group without STEMI, 164 patients (40%) underwent acute coronary angiography with ad-hoc PCI in 41% of cases (N=67). Among STEMI patients, acute coronary angiography was performed in 222 patients (79%) with ad-hoc PCI in 93% of cases (N=192). The decision to perform acute angiography or PCI was made by the treating cardiologist.

Endpoints

Mortality and causes of death 180 days after OHCA were assessed by using public- and hospital health registries as well as direct contact with patients and relatives at the end of the TTM-trial [14]. Autopsies were not systematically performed, but may in some cases have been part of the adjudication of most likely cause of death. As it can be difficult to differentiate between death due to multi-organ failure or cardiovascular causes, these two entities were treated as one in the analysis.

TnT-assay

The Roche Cobas e601, high sensitivity Troponin T assay (Basel, Switzerland) was used for the troponin analyses, with the detection limit 5 ng/l and with a 99th percentile conforming to the universal definition of myocardial infarction of 14 ng/l [16]. These troponin data were not available to the treating physicians.

Statistical analysis

Data are presented as medians, interquartile range, counts and proportions (%). Since the distribution of hs-TnT was skewed it was logarithmically transformed prior to analysis. Missing values were replaced with 5-fold multiple imputations using the MCMC method with 10 iterations per imputation. Continuous variables with normal distribution were compared using ANOVA. Non-parametric continuous data were compared using the Mann-Whitney U test. Pearson's chi Square test with the z-test as post-test were used for comparing differences between categorical data. All confidence intervals were analysed at the 95% confidence level. The overall ability of hs-TnT to discriminate between outcomes was described by receiving operating characteristic (ROC) curves. Unadjusted mortality between quartiles of hs-TnT was compared using the Kaplan-Meier estimator with the log rank test for significance testing. Troponin T at 24 h, 48 h and 72 h were added to a logistic regression model containing temperature allocation, age, sex, bystander CPR, first prehospital rhythm, time from cardiac arrest (CA) to return of spontaneous circulation (ROSC), pH at admission and shock at admission as covariates. There was no multicollinearity as assessed with condition indices. As hs-TnT was expressed in the log₂ scale, the odds ratio corresponds to a 2-fold increase in hs-TnT. When the logistic regression model was used to analyse specific causes of death, competing risk of dying was handled by censoring patients with other causes of death. All p-values $P < 0.05$ were considered statistically significant. IBM SPSS Statistics 22 (Foster City, USA) and GraphPad Prism 6 (La Jolla, USA) were used for the analyses.

Results

Background demographics in the whole patient cohort

A total of 699 patients entered the study. Hs-TnT was available for 646 patients (92%) at 24h, 618 patients (88%) at 48h and 573 patients (82%) at 72h. Hs-TnT peaked at 24 h after admission (848 ng/l (IQR 2685 ng/l)). Median

values at 48h were 695 ng/l (IQR 2039 ng/l) and at 72h 756 ng/l (IQR 1786 ng/l)) (figure 1a). Non-survivors 180 days after OHCA were older, had more often PEA or asystole as the primary rhythm and longer duration between cardiac arrest and ROSC. Moreover, comorbidities such as a history of heart disease, arterial hypertension and diabetes were significantly more prevalent among non-survivors. Baseline characteristics for survivors compared to non-survivors can be found in table 1.

All-cause mortality in the whole patient cohort

At follow up 6 months after OHCA, 322 patients (46%) had died. Hs-TnT was significantly higher among non-survivors compared to survivors at the 48 h ($p<0.05$) and 72 h ($p<0.01$) after ROSC (Figure 1b). The Kaplan-Meier analysis did not indicate a significant association between hs-TnT at any time point and all-cause mortality. ROC curve analysis did not show significant AUC:s for predicting all-cause mortality (AUC 0.54-0.56; at 24h and 48h $p=ns$, at 72h $p<0.05$). However, in the logistic regression model, hs-TnT at 48h and 72h were independently associated with all-cause mortality (at 48h: OR 1.10, CI: 1.01-1.20, $p<0.05$; at 72h: OR 1.11, CI: 1.02-1.21, $p<0.05$) (Table 2a). The relative hs-TnT change between 24h and 48h was not associated with all-cause mortality (OR: 1.05, CI: 0.97-1.15, $p=ns$).

Death from cardiovascular causes or multi-organ failure in the whole patient cohort

In total, 104 patients (14.9%) died due cardiovascular causes and multi-organ failure, which corresponded to 34% of all deaths. Time to death was available for 309 patients (96%). The median duration from CA to death was 147 h (IQR:161 h) for the cohort as a whole. Among patients that died due to CV/MOF the duration from CA to death was 138 h (IQR: 332 h) and for patients that died from cerebral causes 144 h (IQR:118 h) ($p=ns$).

Hs-TnT was significantly elevated at 48h and 72h in patients that died due to cardiovascular causes or multi-organ failure compared to survivors ($p<0.05$) (figure 1c). The Kaplan-Meier analysis indicated a significant unadjusted association between hs-TnT at 48h and 72h and cardiovascular death or multi-organ failure. ROC curve analysis at 24, 48 and 72 h did not show significant AUC:s (0.54-0.59, $p=ns$) for predicting death due to

cardiovascular causes or multi-organ failure. However, in the logistic regression model, hs-TnT at 24, 48 and 72h were independently associated with death from cardiovascular causes and multi-organ failure (at 24h: OR 1.11, CI:1.00-1.23, $p<0.05$; at 48h: OR 1.13, CI: 1.01-1.26, $p<0.05$; at 72h: OR 1.16, CI:1.03-1.30, $p<0.05$) (table 2b). The relative hs-TnT change between 24h and 48h was not associated with death from cardiovascular causes and multi-organ failure (OR: 0.98, CI: 0.88-1.09, $p=ns$).

Death from cerebral causes in the whole patient cohort

In total, 194 patients died due to cerebral causes, which corresponded to 28% of all deaths. Hs-TnT was significantly elevated at 72h in patients that died due to cerebral causes compared to survivors ($p<0.05$). The Kaplan-Meier analysis could not detect an association between hs-TnT and death due to cerebral causes. In concordance, the logistic regression could not detect any association between hs-TnT and death due to cerebral causes at any time point. The relative hs-TnT change between 24h and 48h was borderline significantly associated with death from cerebral causes (OR: 1.13, CI: 1.00-1.09, $p=0.05$).

Background demographics in patients with STEMI vs patients without STEMI

The STEMI group was slightly younger and had *less* prevalence of previous coronary artery bypass graft surgery (CABG) and heart failure compared to the group without STEMI. STEMI was present in 282 patients (40%) at admission and among those 216 (77%) underwent acute PCI compared to 86 patients (21%) without STEMI. The STEMI group had significantly higher hs-TnT at 24h, 48h and 72h compared to the group without STEMI ($p<0.001$) (figure 1d). Patients without STEMI that were selected for acute angiography had significantly higher hs-TnT than the ones who did not (at 24 h: 718 vs 276 ng/l , $p<0.001$; at 48h: 449 vs 238 ng/l, $p<0.05$: at 72h 492 vs 224 ng/l, $p<0.01$) Furthermore, patients without STEMI that were treated with PCI had significantly higher hs-TnT at 48 h

and 72 h compared to the ones that only underwent acute angiography (at 48h: 899 ng/l vs 131 ng/l, $p<0.05$; at 72h: 918 ng/l vs 103 ng/l, $p<0.05$).

All-cause mortality in patients with STEMI vs patients without STEMI.

Patients with an ECG without STEMI at admission had higher all-cause mortality at follow up compared to the STEMI group (49% vs 40%, $p<0.05$). The Kaplan-Meier curves revealed significant unadjusted correlations between hs-TnT at 24h and 48h and all-cause mortality ($p<0.05$), but only among patients without STEMI. However, adjusted analyses using a logistic regression model showed no association between hs-TnT and all-cause mortality regardless of ECG presentation.

Death from cardiovascular causes or multi-organ failure in patients with STEMI vs patients without STEMI.

Death due to cardiovascular causes or multi-organ failure was significantly more prevalent among patients without STEMI compared to the STEMI cohort (36% vs 25% of all deaths, $p<0.05$). The Kaplan-Meier analysis indicated a significant unadjusted association between hs-TnT at 48h and 72h and cardiovascular death or multi-organ failure in both groups. However, only in the STEMI group was hs-TnT predictive of death due to cardiovascular causes or multi-organ failure when analysed in the logistic regression model (at 24h: OR 1.31, CI: 1.03-1.66, $p<0.05$; at 48h: OR 1.47, CI: 1.10-1.95, $p<0.01$; at 72h: OR 1.52, CI: 1.10-2.11, $p<0.05$).

Troponin T levels according to targeted temperature

Temperature assignment (33°C vs 36°C) was not associated with differences in hs-TnT levels and there was no interaction between temperature allocation and hs-TnT in our logistic regression model (at 48h: the 33°C-group 782 ng/l (IQR 2192 ng/l); the 36°C-group 618 ng/l (IQR 1904 ng/l) (figure 2). This remained unchanged when subgroups with and without STEMI were analysed separately.

Discussion

Treatment of patients who remain comatose after OHCA is challenging and novel markers to help guiding treatment are highly desirable. In this study of patients with OHCA due to both ischemic and non-ischemic aetiologies, hs-TnT was independently associated with all-cause mortality in the entire patient cohort. Hs-TnT was also an independent predictor of death due to cardiovascular causes or multi-organ failure in the whole patient cohort. In patients with STEMI, hs-TnT was independently associated with death due to cardiovascular causes or multi-organ failure. In patients without STEMI, hs-TnT did not provide prognostic information. Targeted temperature management at 33 °C did not reduce hs-TnT compared to 36 °C.

The association between hs-TnT and all-cause mortality is in line with the increased mortality observed with elevated troponin in other critically ill populations [17]. It is tempting to speculate that hs-TnT reflect the severity of the cardiac arrest syndrome and could be regarded as a marker of general hypo perfusion and systemic inflammation. However, hs-TnT was not predictive of cerebral death at any time point and the prognostic properties of hs-TnT seem primarily to be related to cardiovascular death and multi organ failure.

The correlation between hs-TnT and death due to cardiovascular causes or multi-organ failure corresponds with previous findings in patients with and without acute coronary syndromes [18, 19]. Furthermore, Troponin within the first days after STEMI without OHCA is associated with infarct size, left ventricular function as well as mortality in several studies [20-22]. However, in the present study hs-TnT did not predict death due to cardiovascular causes or multi-organ failure in the group without STEMI. This is interesting since death due to cardiovascular causes or multi-organ failure was significantly more common in these patients. One might hypothesize that this increase in cardiovascular mortality amongst patients without STEMI might be due less acute revascularization in this group. Thus, an ad-hoc analysis was performed focusing on the patients without STEMI that did not undergo PCI within 6 hours from admission. Still, no correlation between hs-TnT and death due to cardiovascular causes or multi-organ failure was found. This might indicate that acute PCI was not underutilized in the TTM trial and complements a recent TTM substudy that could not find a benefit from acute PCI in patients without STEMI [13]. The issue of whether or not patients without STEMI benefit from acute PCI needs to be addressed in a randomized trial and a pilot trial is currently underway (DISCO, ClinicalTrials.gov Identifier: NCT02309151).

There was no association between hs-TnT and the level of TTM. Since experimental studies show that hypothermia decrease myocardial reperfusion damage [23], one would assume that the 33°C group should have lower hs-TnT levels than the 36 °C group. Clinical and experimental results have previously shown the importance of achieving a body temperature below 35 °C before reperfusion to reduce myocardial injury [24]. This requirement was met by the 33 °C group in the TTM-trial as it reached a body temperature below 35 °C shortly after randomization. However, the experimental models investigating the protective properties of hypothermia have focused on coronary occlusion and reperfusion. In contrast, only 39% of the patients underwent acute PCI making it difficult to extrapolate occlusion-reperfusion findings to our cohort.

Strengths of the present study include the use of a fourth generation high sensitivity troponin T assay that is widely used in contemporary care. Furthermore, the relatively large sample size in combination with inclusion of a wide range of cardiac arrest aetiologies and clinical characteristics increases its validity. Moreover, both 33°C and 36°C TTM was assessed. Limitations to the study include potential selection bias as not the whole TTM-cohort was included in this biomarker substudy. For example, the median time to death of 147 hours is longer than expected and could indicate that patients with shorter survival times are underrepresented. Some values of hs-TnT were missing, although compensated for with multiple imputations. As with all post-hoc and subgroups analysis, our results can only be regarded as hypothesis generating since they might suffer from potential bias and confounding. Although hs-TnT is an independent predictor of all-cause mortality, it is important to emphasize that there exists a considerable overlap of hs-TnT between the outcome groups. Hence, hs-TnT should only be regarded as one of many variables to consider when assessing the prognosis of an individual patient.

Conclusion

In this study of patients with OHCA due to both ischemic and non-ischemic aetiologies, hs-TnT was independently associated with all-cause mortality which was driven by higher risk of death due to cardiovascular causes or multi organ failure and not cerebral causes. In patients with STEMI, hs-TnT was independently associated with death

due to cardiovascular causes or multi organ failure, however this could not be seen for patients without STEMI. Therapeutic hypothermia treatment at 33 °C did not reduce hs-TnT compared to 36 °C. Hs-TnT may be a marker of poor prognosis after OHCA and special care should be given to patients that present with high troponin levels regardless of initial ECG. The upcoming DISCO trial will assess whether or not patients without STEMI benefit from acute revascularization (ClinicalTrials.gov Identifier: NCT02309151).

Table 1

	Survivors	Non-survivors	p-value
Age (years)	61 (16)	68 (14)	<0.001
Sex (female)	62 (16%)	72 (22%)	<0.05
Previous AMI (yes)	62 (16%)	78 (24%)	<0.05
Arterial hypertension (yes)	130 (35%)	150 (47%)	<0.01
Diabetes (yes)	42 (11%)	60 (19%)	<0.05
Previous heart failure (yes)	14 (3.7%)	28 (9%)	<0.01
Previous PCI (yes)	37 (10%)	48 (15%)	ns
Previous CABG (yes)	20 (5%)	43 (13%)	<0.01
Bystander CPR (yes)	301 (80%)	203 (63%)	<0.001
First rhythm VT or VF	350 (94%)	204 (65%)	<0.001
Time CA to ROSC (min)	20 (15)	31 (27)	<0.001
pH at admission	7.27 (0.16)	7.18 (0.22)	<0.001
Hs-troponin T day 1 (ng/l)	786 (2390)	996 (3014)	ns
Hs-troponin T day 2 (ng/l)	602 (1895)	789 (2505)	<0.01
Hs-troponin T day 3 (ng/l)	590 (1693)	859 (2124)	<0.01
STEMI at admision (yes)	168 (45%)	114 (36%)	<0.05
Acute coronary angiography (yes)	217 (58%)	156 (48%)	<0.05
Acute PCI (yes)	161 (43%)	109 (34%)	<0.05

Table 2a		
At 24h	Odds ratio (95% CI)	p-value
