Nonhematopoietic bone marrow mesenchymal stem cells (BM-MSCs) are of central importance for bone marrow stroma and the hematopoietic environment. However, the exact phenotype and anatomical distribution of specified MSC populations in the marrow are unknown. We characterized the phenotype of primary human BM-MSCs and found that all assayable colony-forming units-fibroblast (CFU-Fs) were highly and exclusively enriched not only in the lin-/CD271+/CD45-/CD146+ stem-cell fraction, but also in lin-/CD271+/CD45-/CD146+/low cells. Both populations, regardless of CD146 expression, shared a similar phenotype and genotype, gave rise to typical cultured stromal cells, and formed bone and hematopoietic stroma in vivo. Interestingly, CD146 was up-regulated in normoxia and down-regulated in hypoxia. This was correlated with in situ localization differences, with CD146 coexpressing reticular cells located in perivascular regions, whereas bone-lining MSCs expressed CD271 alone. In both regions, CD34+ hematopoietic stem/progenitor cells were located in close proximity to MSCs. These novel findings show that the expression of CD146 differentiates between perivascular versus endosteal localization of nonhematopoietic BM-MSC populations, which may be useful for the study of the hematopoietic environment. (Blood. 2011; 117(19):5067-5077)

Introduction

Human bone marrow contains a rare population of nonhematopoietic mesenchymal stem cells (BM-MSCs), which are multipotent and can differentiate in vivo toward skeletal lineages such as osteoblasts, adipocytes, and chondrocytes, as well as toward fibroblastic stromal cells.1-3 In vitro, clonogenic cells—denoted as colony-forming units, fibroblast (CFU-Fs)—can be assayed from the bone marrow as plastic adherent cells giving rise to fibroblastic colonies. These CFU-Fs are considered to reflect primary BM-MSCs, and on further proliferation in culture, their descendants make up the well-known and extensively studied cultured mesenchymal stromal cells.4-Bone marrow CFU-Fs express surface markers such as STRO-1,5 CD271 (nerve growth factor receptor [NGFR]),5,7 stage-specific embryonic antigen-4 (SSEA-4),9 GD2 (disialoganglioside 2),9 CD49a (integrin α-1),10 and CD146 (melanoma cell adhesion molecule [MCAM]).3,11 To date, these different CFU-F markers have not been used in combination, and it is therefore not known whether they identify the same cells or whether different subtypes of early nonhematopoietic stem and progenitor cells coexist in the bone marrow.

Culture-expanded CD146+ cells have been demonstrated to reestablish the hematopoietic microenvironment (HME) in a xenotransplantation model, and the transplanted cells colocalized with suggested HSC niches in the bone marrow.3 Therefore, BM-MSCs are likely to be relevant for human HME and stem cell niche anatomy and function. However, a precise phenotypic definition of the human stem cell niche cellular components has thus far been elusive, in contrast to the murine system, in which different niche cell types have been recently described.12-15

We report herein that nonhematopoietic human BM-CFU-Fs are highly and exclusively enriched in lin-/CD271+/CD45-/CD146+ cells and in lin-/CD271+/CD45-/CD146+/low cells. Whereas CD271 expression identifies all assayable BM-CFU-Fs, different expression patterns of CD146 are correlated with in situ localization differences: subendothelial sinusoidal CFU-Fs display the primary CD271+/CD46+ phenotype, whereas bone-lining CD271+ CFU-Fs are predominantly CD146+/low. In both locations, CD34+ hematopoietic stem/progenitor cells are located in close proximity, which might enable for the first time the prospective investigation and dissection of differently localized putative HSC niche cells in human bone marrow.

Methods

BM-MNCs

Sixty milliliters of bone marrow was aspirated from the iliac crest bone of consenting healthy donors. This procedure was approved by the University of Lund ethics committee. Bone marrow mononuclear cells (BM-MNCs) were highly and exclusively enriched in lin-/CD271+/CD45-/CD146+ cells and in lin-/CD271+/CD45-/CD146+/low cells. Both populations, regardless of CD146 expression, shared a similar phenotype and genotype, gave rise to typical cultured stromal cells, and formed bone and hematopoietic stromal stroma in vivo. Interestingly, CD146 was up-regulated in normoxia and down-regulated in hypoxia. This was correlated with in situ localization differences, with CD146 coexpressing reticular cells located in perivascular regions, whereas bone-lining MSCs expressed CD271 alone. In both regions, CD34+ hematopoietic stem/progenitor cells were located in close proximity to MSCs. These novel findings show that the expression of CD146 differentiates between perivascular versus endosteal localization of nonhematopoietic BM-MSC populations, which may be useful for the study of the hematopoietic environment. (Blood. 2011; 117(19):5067-5077)
were isolated by density gradient centrifugation using LSM 1077 Lymphocyte Separation Medium (PAA Laboratories) either with or without prior incubation with RosetteSep Human Mesenchymal Stem Cell Enrichment Cocktail (StemCell Technologies) for lineage depletion (CD3, CD14, CD19, CD38, CD66b, and glycophrin A).

FACS
Lineage-depleted BM-MNCs were incubated in blocking buffer (Dulbecco PBS [DPBS] without Ca\(^{2+}\), Mg\(^{2+}\), and 3.3 mg/mL of human normal immunoglobulin [Gammanorm; Octapharm] and 1% FBS [Invitrogen]) to prevent unspecific binding, followed by staining with monoclonal antibodies against CD45, CD146, and CD271 (see supplemental Methods, available on the Blood Web site; see the Supplemental Materials link at the top of the online article). Sorting gates were set according to the corresponding fluorescence-minus-one (FMO) controls. Cells were sorted on a FACS Aria I or a FACS Diva flow cytometer (both BD Biosciences). Dead cells were excluded by 7-amino-actinomycin (7-AAD; Sigma) staining, and doublets were excluded by gating on forward scatter-height versus forward scatter-width and side scatter-height versus side scatter-width.

Generation of cultured mesenchymal stromal cells
Sorted BM-MNCs were cultured in standard MSC culture medium (NH Expansion Medium [Miltenyi Biotec] plus 1% antibiotic-antimycotic solution [Sigma-Aldrich]). Medium was changed weekly and cells were passaged at 70% confluence after trypsinization (0.05% trypsin/EDTA; Invitrogen). Trypsinized cells were replated at 500-1000 cells/cm\(^2\).

Mesenchymal stromal cells for intra-bone marrow transplantation or subcutaneous transplantation with hydroxyapatite/tricalcium phosphate (HA/TCP) carriers were initiated from sorted CD271\(^+\)/CD45\(^-\)/CD146\(^-\)/H11001 BM-MNCs, respectively. Sorted cells were initially plated at 20-50 cells/cm\(^2\), and adherent cells were culture expanded as described in the beginning of this section. Green fluorescent protein (GFP)-labeled cells for intra-bone marrow transplantation were produced by transducing 0. passage cells (before the first passaging) with a lentiviral vesicular stomatitis virus glycoprotein GFP vector, followed by sorting of GFP\(^+\) cells 2 weeks after transduction and an additional 3 weeks of culture until transplantation.

CFU-F assay
CFU-F frequencies of BM-MNC populations were determined as described previously.\(^{16,17}\) Briefly, FACS-sorted cells were cultured at plating densities of 1-50 cells/cm\(^2\) when assaying CD271\(^+\)/CD45\(^-\)/CD146\(^-\)/H11001 and CD271\(^+\)/CD45\(^-\)/CD146\(^+\)/H11002 BM-MNCs, respectively. Sorted cells were initially plated at 20-50 cells/cm\(^2\), and adherent cells were culture expanded as described in the beginning of this section. Green fluorescent protein (GFP)-labeled cells for intra-bone marrow transplantation were produced by transducing 0. passage cells (before the first passaging) with a lentiviral vesicular stomatitis virus glycoprotein GFP vector, followed by sorting of GFP\(^+\) cells 2 weeks after transduction and an additional 3 weeks of culture until transplantation.

Flow cytometry
Cultured cells were harvested (0.05% trypsin/EDTA) and washed, and unspecific binding was blocked with human normal immunoglobulin. Cells were stained for 45 minutes at 4°C with combinations of antibodies. Samples were analyzed on a FACS Calibur flow cytometer (BD Biosciences).

In vitro differentiation assays
Cultured BM mesenchymal stromal cells were differentiated toward the adipogenic, osteoblastic, and chondrogenic lineage, as described previously.\(^{16,17}\) Briefly, cells were cultured for 14 days in AdipoDiff medium [Miltenyi Biotec], and cells were stained with Oil Red O (Sigma-Aldrich). For osteogenic differentiation, cells were cultured in osteogenesis induction medium (standard MSC medium supplemented with 0.05mM ascorbic acid [Wako Chemicals] and 1.0mL/dexmethasone and 10mM β-glycerophosphate [both from Sigma-Aldrich]) for 21 days, and calcium depositions in the cultures were detected with Alizarin Red (Sigma-Aldrich). Chondrogenic differentiation was accomplished by culturing cell pellets (2.5 × 10\(^5\) cells/pellet) for 28 days in chondrogenesis induction medium (DMEM high-glucose medium supplemented with 0.1mL/dexmethasone, 1mL sodium pyruvate, and 0.35mL/L-proline [all from Sigma-Aldrich], 0.17mM ascorbic acid [Wako Chemicals], 1% ITS plus (insulin transferrin selenium) culture supplements [BD Biosciences], and 0.01 μg/mL of TGF-β3 [R&D Systems]). Pellets were paraformaldehyde fixed and frozen in O.C.T. Compound (Sakura). Cryosections were stained against aggrecan (see supplemental Methods) and toluidine blue and Alcian blue (both Sigma-Aldrich). For aggrecan staining, nuclei were stained with 4’,6-diamidino-2-phenylindole (Invitrogen). Sections were analyzed with a fluorescence microscope (BX51; Olympus) and a digital camera (DP70; Olympus) using DP manager software version 1.1.71 (Olympus).

Hematopoietic progenitor and LTC-IC assays
For long-term culture-initiating cell (LTC-IC) assays, CD271/CD45 populations were sorted from MACS-enriched primary CD271\(^+\) BM-MNCs (CD271 MicroBead kit; Miltenyi Biotec). Cells were resuspended in IMDM plus 2% FBS (both Invitrogen) and seeded into methylcellulose medium (HSC-CFU complete with Epo; Miltenyi Biotec). After 2 weeks of culture, hematopoietic colonies were analyzed under a microscope according to standard criteria.

The stroma-supporting capacities of cultures generated from sorted CD271\(^+\)/CD45\(^-\)/CD146\(^-\)/H11001 and CD271\(^+\)/CD45\(^-\)/CD146\(^+\)/H11002 cells were assessed with standard LTC-IC assays. Briefly, 3 × 10\(^4\) cells were plated in collagen-coated, 35-mm culture dishes and irradiated the following day (16 Gy). Forty-eight hours after irradiation, 3000 MACS-enriched human cord blood CD34\(^+\) cells were seeded and cultured in MyeloCult H5100 medium (StemCell Technologies) with 10\(^{-8}\)mM hydrocortisone (Sigma-Aldrich) with weekly half-medium changes. After 6 weeks, cells were harvested by trypsinization and assayed for hematopoietic colony formation, as described in the beginning of this section.

In vivo transplantation
For orthotopic transplantations, 1 × 10\(^6\) GFP\(^+\) mesenchymal stromal cells generated from sorted CD271\(^+\)/CD45\(^-\)/CD146\(^-\)/H11001 and CD271\(^+\)/CD45\(^-\)/CD146\(^+\)/H11002 BM-MNCs were injected intrafemorally into irradiated (2 Gy) 6- to 8-week-old NOD-Cg-Prkar\(^{cid}\)Il2rg\(^{null}\)/SzJ mice. After 8 weeks,
mice were killed by cervical dislocation and femurs were removed and fixed in paraformaldehyde. After decalcification, permeabilization, and dehydration, specimens were embedded in paraffin for analysis.

For analysis of in vivo bone and stroma formation, cultured MSCs were derived from sorted CD271+/CD45−/CD146low and CD271+/CD45−/CD146+ cells. Cells were loaded overnight on HA/TCP ceramic powder, and 4 × 10⁵ cells were implanted subcutaneously into 8-week-old female NOD/SCID mice (4 implants per culture). Implants were removed after 8 weeks, fixed, decalcified, and paraffin embedded. Sections were stained with hematoxylin/eosin and analyzed as described previously. All animal procedures were approved by the local ethical committees on animal experiments.

**Immunofluorescence staining of bone sections**

Paraffin sections from human bone marrow and mouse femurs were deparaffinized and rehydrated following standard protocols. Heat-induced epitope retrieval was applied using citrate buffer, pH 6 (Target Retrieval Solution; Dako) for 30 minutes at 98°C. Sections were blocked/permeabilized with Dulbecco PBS and 0.3% Triton X-100 (Sigma-Aldrich), and stained for 1 hour at room temperature (for antibodies, see supplemental Methods). TO-PRO-3 (Invitrogen) was used as a nuclear staining was performed for 1 hour at room temperature (for antibodies, see supplemental Methods). TdT-PO-3 (Invitrogen) was used as a nuclear stain. Photographs were taken on a confocal microscope (DMRE; Leica) equipped with green helium/argon, standard helium/argon, and argon lasers using Confocal Software v2.61 (Leica).

**Hypoxia experiments**

Stromal cultures generated from unfractionated bone marrow were cultured with the addition of 100μM deferoxamine mesylate in a standard incubator with daily medium changes. After 1 week, cells were analyzed by FACS for the expression of CD45 and other surface markers.

Cultures generated from unfractionated bone marrow were cultured in a hypoxic chamber set to 1% O₂ in standard MSC medium with weekly medium changes. After 2 weeks, cells were analyzed by FACS for the expression of CD45 and other surface markers (see supplemental Methods).

**Results**

**CFU-Fs are highly and exclusively enriched in CD271+/CD45−**

BM-MNCs expressing either CD146low or CD146+

Human BM-MNCs were stained with antibodies against CD146, CD271, and CD45 (Figure 1A-B). Without CD45 exclusion, CD271+/CD45−/CD146− populations contained large numbers of hematopoietic cells, (43%, 97%, and 88% of CD271+/CD146+, CD271+/CD146−, and CD271−/CD146+ cells, respectively; n = 9). As shown in Figure 1C, we detected 0.02% ± 0.005% CD271+/CD45−/CD146+, 0.01% ± 0.003% CD271+/CD45−/CD146+, and 0.06% ± 0.02% CD271+/CD45+/CD146+ cells within viable human BM-MNCs (data are mean ± SEM; n = 9).

We next assessed the CFU-F frequency of the different CD271+/CD146− cell populations in lineage-depleted bone marrow (Figure 1D-G). CFU-Fs were highly and exclusively enriched in the CD271+/CD45−/CD146low and CD271+/CD45+/CD146− cells. In contrast, colony growth was not observed in either CD45− or the CD271− cell fractions regardless of CD146 expression (Figure 1F). No CFU-Fs were lost by lineage depletion (supplemental Figure 1).

Mean CFU-F frequencies were 4.2 ± 1.6 CFU-Fs per 100 plated CD271+/CD45+/CD146low cells and 2.0 ± 0.7 CFU-Fs per 100 CD271+/CD45+/CD146+ cells compared with 0.005 ± 0.001 CFU-Fs per 100 viable cells in lineage-depleted BM-MNCs (Figure 1F).

The colony-forming potential of the 2 CFU-F-containing populations was confirmed by single-cell assays. CFU-F frequencies were 3.5 ± 0.9 and 1.6 ± 0.7 per 96-well plate for CD271+/CD45+/CD146−/low and CD271+/CD45+/CD146+ cells, respectively (n = 8; Figure 1G). Single-cell sorting accuracy as estimated by bead sorting was 100%.

Whereas CD146+ expression on CD271+ cells did not discriminate between colony-forming and non-colony-forming cells, CD45 expression did; the majority of CD271+ cells coexpressed CD45, and clear morphologic differences were observed between the CD271+/CD45− and CD271+/CD45+ cell populations (supplemental Figure 2B).

In addition to CFU-F potential, sorted bone marrow cell populations were also tested for hematopoietic colony growth in standard methylcellulose assays. Erythroid colonies were observed at low frequencies when CD271+/CD45− cells were plated, but were absent in other sorted cell fractions (supplemental Figure 2).

**Both CD271+/CD45−/CD146low and CD271+/CD45−/CD146+ BM-MNCs give rise to typical cultured mesenchymal stromal cells**

We generated mesenchymal stromal cell cultures from both CD271+/CD45−/CD146low and CD271+/CD45−/CD146+ cells derived from either bulk- or single-sorted cells. Both populations grew in standard MSC medium as typical adherent, spindle-shaped, fibroblastic-like cells (Figure 2A), and no significant differences in colony size between CD146+ cells (2.1 ± 0.1 mm; n = 46) and CD146−/CD45 cells (1.9 ± 0.08 mm; n = 51) could be observed (Figure 2B). In addition, cultured cells from both populations exhibited similar differentiation potential in vitro toward the osteoblastic (Alizarin Red staining; some colonies were additionally stained with von Kossa/ALP), adipogenic (Oil Red O staining), and chondrogenic (aggrecan, toluidine blue, and Alcian blue staining) lineages. This was observed for both single-cell–derived clonal cultures (Figure 2C) and multiclonal cultures from bulk-sorted cells. A sufficient number of cells to test for trilineage differentiation were generated from 14 of 20 clones, 8 of which showed differentiation into all 3 lineages (2 of 3 CD146+ clones and 6 of 11 CD146−/CD45 clones). The remaining 6 clones showed either 2-lineage differentiation capacity (n = 3) or only unilineage differentiation capacity (n = 3). Sufficient cells for testing bilineage differentiation capacity (osteoblasts and adipocytes) could be generated from 2 additional clones, 1 of which showed bilineage capacity and the other unilineage capacity for osteoblastic differentiation. Furthermore, 2 additional clones could be only tested for osteoblastic differentiation and both of them were positive. In general, bilineage or unilineage clones possessed osteoblastic potential but lacked or lost adipogenic and/or chondrogenic potential. Furthermore, stromal cell cultures generated from CD271+/CD45−/CD146low and CD271+/CD45−/CD146+ CFU-Fs (single-cell as well as bulk) exhibited similar surface-marker profiles when analyzed for expression of typical MSC marker profiles (ie, cells were positive for CD105, CD90, CD73, and HLA-class I, and negative for CD34, CD45, CD14, CD19, and HLA-DR; Figure 2D and supplemental Figure 3). Moreover, cultures derived from CD271+/CD45−/CD146low and CD271+/CD45−/CD146+ cells showed no differences in stroma-supporting capacity, as indicated by standard LTC-IC assays (21.0 ± 3.0 vs 20.7 ± 3.5 colonies per 1000 seeded CD34+ cells; n = 3).
Primary CD271+/CD146−/low and CD271+/CD146+ CFU-Fs share a similar phenotype

We compared the uncultured CD271+/CD45−/CD146−/low and CD271+/CD45+/CD146+ CFU-F-containing populations based on morphology, FACS profile, and gene expression. As shown in Figure 3, freshly sorted cells before attachment were round and displayed reticular extensions (Figure 3A-B left). After attachment, cells displayed a large, flat, branched-out fibroblastic morphology (Figure 3A-B right). In addition, cytospin preparations were prepared to study nuclear morphology and cytoplasm properties of freshly isolated cells in more detail (supplemental Figure 4A-C). CD271+/CD45−/CD146−/low and CD271+/CD45+/CD146+ cells were characterized by cytoplasmic vacuoles and large, immature nuclei with an open chromatin pattern, and CD271+/CD146−/low cells were generally smaller than the double-positive cells (supplemental Figure 4A-B). In contrast, CD146 single-positive cells, which did not contain any CFU-Fs, also had immature nuclei but exhibited a more basophilic cytoplasm and perinuclear halos, which clearly distinguished them from CD271+/CD45+/CD146+ CFU-Fs (supplemental Figure 4E). Endothelial markers such as CD271, CD146, and CD45, and analyzed by flow cytometry. Representative contour plots of CD271- and CD146-expressing human bone marrow cells after forward/side scatter and 7-AAD gating are shown. (A) CD271 and CD146 expression in whole viable BM-MNCs. (B) CD271 and CD146 expression after exclusion of CD45+ cells. (C) Percentage of CD271+/CD45+/CD146−, CD271−/CD45+/CD146+, and CD271−/CD45−/CD146− cells in viable, nondepleted human BM-MNCs (n = 9). Horizontal lines indicate mean values. Error bars show SEM. (D) Gates for the CD271+/CD45+/CD146+ sorting from lineage-depleted bone marrow were set according to the appropriate FMO controls for CD45 (top row left plot). The top right plot illustrates the CD45-sorted gating, with P10 and P5 indicating the sorting gates for CD45+ cells and CD45− cells, respectively. Red dots indicate all gated events shown in the CD271+/CD146+ plot (E) after back-gating on CD45. Sorting gate definition based on the FMO controls for CD271 and CD146 are illustrated in the bottom plots. (E) Sorting gates from a representative bone marrow sample for CD271+/CD146− (P8), CD271−/CD45−/CD146− (P9), CD271+/CD146−/low (P7), and CD271+/CD45−/low (P6) after lineage depletion and CD45 exclusion. As shown in this analysis, CD146 expression increased gradually with increasing CD271 expression, and therefore it is impossible to identify a clear-cut CD271+/CD146− cell population within the CD271+ cells. We therefore chose instead to use the term CD271+/CD146−/low for cells sorted on gate P7 to indicate this fact. (F) CFU-F frequencies per 100 freshly isolated BM-MNCs of total sortable cells sorted only based on 7-AAD exclusion (viable, n = 4), sorted total CD45+ cells (n = 4), and the different sorted CD271+/CD45+ populations after CD45 exclusion (n = 5). Each dot represents the mean frequency of CFU-Fs from one bone marrow sample. Horizontal lines indicate mean values of at least 4-5 independent samples. (G) CFU-F frequencies per 96-well plate of single-sorted CD271+/CD45+/CD146−/low and CD271+/CD45+/CD146+ primary cells. Data are shown as mean ± SEM (n = 8).
sufficient amounts were available. Cultures were initiated were measured in the fourth and second passages, when a matching the flow cytometric profile of a gradually increasing Scale bars indicate 200
eoglycans and Alcian blue (far right) for metachromasia. stained with toluidine blue (second from right) for pro-
photograph). In addition, chondrocyte sections were
cyte pellets were stained with an anti-aggrecan plus sec-
ary antibody (third from right). Control sections were
stained with isotype controls. Black open histograms represent the cor-
tograms) FACS-sorted bone marrow cell. Cultured cells
were stained for typical MSC markers and analyzed by
flow cytometry. For protein expression, see supplemental Figure 4F. Interestingly,
CD146 expression could also be detected in approximately 40% of
the flow cytometric profile of cultured cells (Figure 3C). The majority of trans-
planted GFP+ cells were localized in close proximity (ie, within
20 μm, corresponding to approximately 2 cells) of the bone surface
and vasculature, respectively (supplemental Table 1). No differ-
ences in the distribution of transplanted GFP+ cells were observed compared with CD271+/CD45+/CD146−-derived cultures.

### In vivo differentiation capacity of cultured CD271+/CD146−cells and CD271+/CD146+ cells

CD271+/CD146− and CD271+/CD146+ CFU-Fs were culture expanded in standard MSC medium to obtain sufficient cell numbers for heterotopic (subcutaneous) and ortho-
topic (intrafemoral) transplantation into immunodeficient mice. Eight weeks after subcutaneous injection (cultured cells with
HA/TCP carrier particles), bone, adipocytes, fibroblastic tissue,
and capillaries could be detected in both transplants (Figure 4A). In
addition, we detected invading hematopoietic cells in the trans-
plants (Figure 4B).

Orthotopic intrafemoral transplants were performed with GFP-labeled
stromal cultures generated from either CD271+/CD45+/CD146− or
CD271+/CD45+/CD146+ cells. After 8 weeks, GFP+ cells could be detected in the perivascular regions surrounding the endothel-
ium of vessels, as cells lining the surface of cortical and trabecular
bone or surrounding adipocytes, or as reticular cells in the marrow
space (Figure 4C-E). Some of the bone-lining GFP+ cells were
found to express N-cadherin (Figure 4C). The majority of trans-
planted GFP+ cells were localized in close proximity (ie, within
20 μm, corresponding to approximately 2 cells) of the bone surface
and vasculature, respectively (supplemental Table 1). No differ-
ences in the distribution of transplanted cells were observed compared with CD271+/CD45+/CD146−-derived cultures.

In vivo differentiation capacity of cultured CD271+/CD45+/CD146− and CD271+/CD45+/CD146+ cells

CD271+/CD45+/CD146− and CD271+/CD45+/CD146+ cells were culture expanded in standard MSC medium to obtain sufficient cell numbers for heterotopic (subcutaneous) and ortho-
topic (intrafemoral) transplantation into immunodeficient mice. Eight weeks after subcutaneous injection (cultured cells with
HA/TCP carrier particles), bone, adipocytes, fibroblastic tissue,
and capillaries could be detected in both transplants (Figure 4A). In
addition, we detected invading hematopoietic cells in the trans-
plants (Figure 4B).

Orthotopic intrafemoral transplants were performed with GFP-labeled
stromal cultures generated from either CD271+/CD45+/CD146− or
CD271+/CD45+/CD146+ cells. After 8 weeks, GFP+ cells could be detected in the perivascular regions surrounding the endothel-
ium of vessels, as cells lining the surface of cortical and trabecular
bone or surrounding adipocytes, or as reticular cells in the marrow
space (Figure 4C-E). Some of the bone-lining GFP+ cells were
found to express N-cadherin (Figure 4C). The majority of trans-
planted GFP+ cells were localized in close proximity (ie, within
20 μm, corresponding to approximately 2 cells) of the bone surface
and vasculature, respectively (supplemental Table 1). No differ-
ences in the distribution of transplanted cells were observed compared with CD271+/CD45+/CD146−-derived cultures.

In vivo differentiation capacity of cultured CD271+/CD146− and CD271+/CD146+ cells

CD271+/CD45+/CD146− and CD271+/CD45+/CD146+ cells were culture expanded in standard MSC medium to obtain sufficient cell numbers for heterotopic (subcutaneous) and ortho-
topic (intrafemoral) transplantation into immunodeficient mice. Eight weeks after subcutaneous injection (cultured cells with
HA/TCP carrier particles), bone, adipocytes, fibroblastic tissue,
and capillaries could be detected in both transplants (Figure 4A). In
addition, we detected invading hematopoietic cells in the trans-
plants (Figure 4B).

Orthotopic intrafemoral transplants were performed with GFP-labeled
stromal cultures generated from either CD271+/CD45+/CD146− or
CD271+/CD45+/CD146+ cells. After 8 weeks, GFP+ cells could be detected in the perivascular regions surrounding the endothel-
ium of vessels, as cells lining the surface of cortical and trabecular
bone or surrounding adipocytes, or as reticular cells in the marrow
space (Figure 4C-E). Some of the bone-lining GFP+ cells were
found to express N-cadherin (Figure 4C). The majority of trans-
planted GFP+ cells were localized in close proximity (ie, within
20 μm, corresponding to approximately 2 cells) of the bone surface
and vasculature, respectively (supplemental Table 1). No differ-
ences in the distribution of transplanted cells were observed compared with CD271+/CD45+/CD146−-derived cultures.

In vivo differentiation capacity of cultured CD271+/CD146− and CD271+/CD146+ cells

CD271+/CD45+/CD146− and CD271+/CD45+/CD146+ cells were culture expanded in standard MSC medium to obtain sufficient cell numbers for heterotopic (subcutaneous) and ortho-
topic (intrafemoral) transplantation into immunodeficient mice. Eight weeks after subcutaneous injection (cultured cells with
HA/TCP carrier particles), bone, adipocytes, fibroblastic tissue,
and capillaries could be detected in both transplants (Figure 4A). In
addition, we detected invading hematopoietic cells in the trans-
plants (Figure 4B).

Orthotopic intrafemoral transplants were performed with GFP-labeled
stromal cultures generated from either CD271+/CD45+/CD146− or
CD271+/CD45+/CD146+ cells. After 8 weeks, GFP+ cells could be detected in the perivascular regions surrounding the endothel-
ium of vessels, as cells lining the surface of cortical and trabecular
bone or surrounding adipocytes, or as reticular cells in the marrow
space (Figure 4C-E). Some of the bone-lining GFP+ cells were
found to express N-cadherin (Figure 4C). The majority of trans-
planted GFP+ cells were localized in close proximity (ie, within
20 μm, corresponding to approximately 2 cells) of the bone surface
and vasculature, respectively (supplemental Table 1). No differ-
ences in the distribution of transplanted cells were observed compared with CD271+/CD45+/CD146−-derived cultures.

In vivo differentiation capacity of cultured CD271+/CD146− and CD271+/CD146+ cells

CD271+/CD45+/CD146− and CD271+/CD45+/CD146+ cells were culture expanded in standard MSC medium to obtain sufficient cell numbers for heterotopic (subcutaneous) and ortho-
topic (intrafemoral) transplantation into immunodeficient mice. Eight weeks after subcutaneous injection (cultured cells with
HA/TCP carrier particles), bone, adipocytes, fibroblastic tissue,
and capillaries could be detected in both transplants (Figure 4A). In

and vasculature, respectively (supplemental Table 1). No differ-
ences in the distribution of transplanted cells were observed compared with CD271+/CD45+/CD146−-derived cultures.
The principal capacity of transplanted cells to form secondary colonies was investigated qualitatively in first experiments by harvesting bone marrow cells from 2 mice 8 weeks after intramedullar transplantation and plating them for CFU-Fs in standard MSC culture medium. GFP\textsuperscript{+} fibroblastic colonies were detected in the bone marrow of mice transplanted with CD271\textsuperscript{−}/CD45\textsuperscript{−}/CD146\textsuperscript{−}/low or CD271\textsuperscript{+}/CD45\textsuperscript{−}/CD146\textsuperscript{−}/high-derived cells, thus demonstrating the principally colony-forming capacity of transplanted BM-MSC-derived cells. However, these experiments were not designed to allow for a quantitative analysis.

In situ localization of CD271\textsuperscript{+}/CD146\textsuperscript{−}/low and CD271\textsuperscript{+}/CD146\textsuperscript{−}/high cells in human bone marrow

To investigate the in situ localization of BM-CFU-Fs, paraffin sections of normal human bone marrow were stained with antibodies against CD146 and CD271. CD146/CD271 double-positive cells were observed as perivascular cells surrounding the capillary endothelium and larger vessels (Figure 5A-B and supplemental Figure 5B-E). CD271\textsuperscript{−} reticular cells spanned the bone marrow with long extensions, some of which encircled adipocytes. In contrast to these CD146/CD271 double-positive cells, we found that bone-lining cells proximal to the surface of trabecular bone primarily expressed CD271 alone (Figure 5C and supplemental Figure 5A). CD146 coexpression by bone-lining cells was rarely detected. Costaining with CD45 confirmed that no perivascular, reticular, or bone-lining cells were CD45\textsuperscript{−} (Figure 6A). In the marrow space, CD271\textsuperscript{dim} coexpressing hematopoietic CD45\textsuperscript{−} cells were visible as smaller, round cells (Figure 6A right), and these cells could easily be distinguished from CD271\textsuperscript{high} reticular cells based on their morphology. CD146 was not only expressed by perivascular cells, but also by \( \alpha \)-smooth muscle actin (\( \alpha \)-SMA)--positive cells within the vascular tunica media (supplemental Figure 5C), whereas CD271 expression was exclusively confined to the extraluminal cells in the vascular tunica adventitia (Figure 6B and supplemental Figure 5B). CD271\textsuperscript{+} and CD146\textsuperscript{−} cells in the tunica adventitia exhibited weak expression of \( \alpha \)-SMA (Figure 6B and supplemental Figure 5B-C).

We next investigated the colocalization of CD34\textsuperscript{+} hematopoietic stem/progenitor cells with CFU-Fs in bone marrow sections. As illustrated in Figure 6, human, round CD34\textsuperscript{+} cells could be found in proximity to perivascular cells stained with CD271 (Figure 6C). In addition, CD34\textsuperscript{+} cells could be detected in proximity to trabecular bone-lining CD271\textsuperscript{+} cells (Figure 6D), although, as expected, only at very low frequencies.
Figure 4. Ectopic and orthotopic transplantation of cultured cells into immunodeficient mice. Multiclonal cultures generated from CD271⁺/CD146⁻/low and CD271⁺/CD146⁺ primary BM-MNCs were transplanted either subcutaneously (with HA/TCP particles) or intrafemorally into immunodeficient mice. (A-B) Representative section of hematoxylin/eosin–stained transplanted cells and HA/TCP carrier particles. Black square in the left photograph is shown as a magnification (original magnification 10×). (B) Invading hematopoietic cells could be detected in the transplanted cells (black arrow). Original magnification was 10×. Scale bar indicates 50 μm. (C) GFP⁺ cells generated from either CD271⁺/CD145⁻/CD146⁻/low (top row) or CD271⁺/CD145⁻/CD146⁺ (bottom row) cells analyzed 8 weeks after intrafemoral transplantation. GFP⁺ cells (green) could be detected as bone-lining cells, some of which expressed N-cadherin (N-Cad, red) (white arrows, left panels), and in perivascular regions surrounding the endothelium (CD31, red) (white arrowheads, right panels). (D) Reticular GFP⁺ cells (green) could be detected independently from vessels in the marrow space (white arrowheads). The photograph shows reticular GFP⁺ cells generated from CD271⁺/CD145⁻/CD146⁻/low cells. (E) Bone marrow section from a control mouse after sorting of MACS CD45-depleted BM-MNCs. (A) Bone (b), adipocytes (a), fibroblastic tissue (f), and capillaries (c) are indicated. Dark brown areas in the left photograph indicate HA/TCP carrier particles. Black square in the left photograph is shown as a magnification (original magnification 10×). (B) Invading hematopoietic cells could be detected in the transplanted cells (black arrow). Original magnification was 10×. Scale bar indicates 50 μm. The photographs were taken with a confocal microscope (DMRE; Leica).

In vitro CD146 expression is up-regulated during culture and down-regulated under hypoxic conditions

Sorted CD271⁺/CD146⁻/low and CD271⁺/CD146⁺ cells were plated on chamber slides and cultured for 6 days at 21% O₂. Cells that initially were CD146⁻/low continued to express CD146 at lower levels compared with CD146⁺ cells (Figure 7A-B). Conversely, CD271 expression was comparable (Figure 7A-B). The difference in CD146 expression could also be observed flow cytometrically when analyzing lower-passage cultures generated from either CD146⁻/low or CD146⁺ cells. However, the CD146 expression of CD271⁺/CD146⁻/low cells progressively increased over time and attained levels comparable to those observed in cultured CD271⁺/CD146⁺ cells or cultures generated from unfractionated bone marrow by the end of the second passage (Figure 7C).

Because the expression levels of CD146 increased in normoxic culture and was related to the immunodeficient localization of primary CFU-Fs, we examined the influence of oxygen levels on CD146 expression. Established stromal cultures from unsorted bone marrow (third and fourth passage) were cultured with or without deferoxamine mesylate (DFO) (n = 2). FACS analysis on day 7 showed that approximately 25% of the DFO-treated cells had become negative for CD146, compared with approximately 3.5% in untreated controls (Figure 7D). No changes in CD90 and CD271 expression were observed (supplemental Figure 6A). This finding was confirmed in hypoxic chamber experiments (n = 2), which showed that CD146 expression decreased after 2 weeks of culture in 1% O₂ compared with 21% O₂ (Figure 7E). This hypoxia-induced decrease of CD146 expression was reversible when cells were incubated for an additional 2 weeks at 21% O₂ (Figure 7E). No changes in expression levels could be detected for any of the remaining surface markers investigated (CD105, CD73, CD90, HLA class I, and CD271; supplemental Figure 6B).

Discussion

Nonhematopoietic BM-MSCs are capable of generating tissues such as bone, fat, and cartilage. Furthermore, BM-MSCs also give rise to the HME, which provides a niche for HSCs in vivo and plays a pivotal role in regulating, supporting, and maintaining hematopoiesis.3,19,20 Considerable progress has been made regarding the phenotypic description of BM-MSCs, and several surface markers for an effective enrichment of CFU-Fs have been reported. Nonetheless, a comprehensive characterization of the nonhematopoietic stem cell system and its different subpopulations is just beginning to emerge. Furthermore, relatively little is known about BM-MSCs and their role in the HME.

Recently, Sacchetti et al3 identified a population of CD146⁺ subendothelial human bone marrow cells that contained all assayable CFU-Fs and generated bone and HME when transplanted subcutaneously into immunodeficient mice. CD271 is another broadly accepted marker for CFU-Fs,5,6 which stains a population of subendothelial and bone-lining stromal cells in human bone marrow.21 We show herein by co-staining of CD146 and CD271 that all assayable CFU-Fs were highly and exclusively enriched, not only in the CD146⁺ fraction of lin⁻/CD271⁺/CD145⁻ stem cells, but also in the CD146⁻/low fraction, thus complementing the current knowledge.

Whereas Sacchetti et al used CD146⁺ and CD146⁻ FACS sorting of MACS CD45-depleted BM-MNCs, we started with a...
highly enriched population of lin−/CD45−/CD271+ cells for sorting on CD146 expression, which is the likely reason that the very rare population of CD146low CFU-Fs became assayable in our experiments.

In agreement with previous studies, the majority of CD271+ cells coexpressed CD45+. Therefore, even though CD271—in contrast to CD146—identified all human BM-CFU-Fs, it is necessary to also exclude CD45+ hematopoietic cells from the population to reach a high purity of BM-CFU-Fs.

In addition to differences in CD146 expression, both CD271+ populations showed comparable BM-MSC properties (morphology, surface-marker expression, in vitro and in vivo differentiation capacities, stroma-supporting capacities, and secondary colony formation). However, differences in CD146 expression were

Figure 5. In situ localization of CD271 and CD146 bone marrow cells. Immunofluorescence staining for the in situ localization of primary BM-MSCs. Paraffin sections of normal human bone marrow biopsies were stained with antibodies against CD271 and CD146. (A) Double-positive cells were detected as reticular cells surrounding the endothelium of vessels. Photographs in the left and middle panels illustrate staining against one antigen in double-stained specimens; these photographs are merged in the right panel. (B) CD271+ reticular cells, shown as green cells in the left panel and brown cells (black arrowhead) in the immunohistochemical (IHC) panels, were found as perivascular cells surrounding the endothelium, shown as red CD31+ cells in the left panel and black arrow in the middle IHC panel. (C) CD271+ bone-lining cells (white arrowheads in the left panel and black arrowhead in the IHC photograph) showed no expression of CD146 (green in the left panel). (B-C) Right IHC panels show a control for the CD271 staining using an isotype-matched antibody. IHC photographs were counterstained with hematoxylin. For confirming IHC expression analysis of CD146 on bone-lining CD271+ cells, see supplemental Figure 5. Nuclei were stained with TO-PRO3 (blue). Scale bars indicate 25 μm. Asterisk indicates the lumen of a vessel. Trabecular bone (b) is indicated. Immunofluorescence photographs were taken with a confocal microscope (DMRE; Leica); IHC photographs were taken with an upright microscope (BX51; Olympus).

Figure 6. CD45 and α-SMA expression on BM-CFU-Fs and colocalization of BM-CFU-Fs with CD34+ cells. (A) Human bone marrow paraffin sections were stained with antibodies against CD271 and CD45. White arrow indicates a vessel with perivascular CD271+/CD45+ cells (left). White arrowheads indicate round, hematopoietic CD271low/CD45+ cells (right). Bone-lining cells in the right photograph are CD271+/CD45+. (B) A larger vessel costained with CD271 and α-SMA is shown. White arrowheads indicate CD271+/α-SMAlow perivascular cells. (C-D) Bone marrow sections were stained against CD34 to detect hematopoietic stem/progenitor cells and against CD271 to detect CFU-Fs. (C) Round CD34+ cells (green) were found in proximity to the reticular extensions of perivascular CD271+ cells (red). (D) In rare instances, round CD34+ cells (green) were found neighboring CD271+ cells in endosteal regions. White arrowheads indicate CD34− cells. Nuclei were stained with TO-PRO3 (blue). Scale bars indicate 25 μm. Asterisks indicate the lumen of a vessel. Trabecular bone (b) is indicated. For the expression of α-SMA and perivascular localization of CD271+ cells, see supplemental Figure 5.
clearly correlated with in situ localization, and therefore enabled us to identify endosteally localized CD271/H11001/CD146/H11002 cells and perivascular CD271/H11001/CD146/H11001 cells. These observations agree with the findings by Sacchetti et al on the localization of bone marrow CD146/H11001 adventitial reticular cells and with data by Cattoretti et al reporting that CD271/H11001 stromal cells can be found as either perivascular or bone-lining cells.

As a note of caution, it has not been ultimately proven at present whether all of the CD271/H11001/CD45/H11002/CD146/H11002 cells that we identified in situ represent CFU-Fs, because some of the cells could belong to the fraction of non-colony-forming cells that might still be present even in highly purified cell populations (here, an even more precise BM-MSCs phenotype definition would be necessary). From our coexpression analysis, CD105, CD90, CD49a, PDGFR-β, and Stro-1 appear to be potentially useful as additional CFU-F marker candidates. However, in contrast to what has been reported previously, we did not observe expression of SSEA-4 and GD2 on primary BM-MSCs, which might have been due to differences in staining and analysis protocols.

In bone marrow sections, both CD271/H11001/CD146/H11002 and CD271/H11001/CD146/H11002 cells were associated with CD34/H11001 hematopoietic cells, and to our knowledge this is the first report demonstrating the association of distinct BM-MSC subsets with different potential HSC niche cell types in the human system. These observations agree with recently published landmark findings showing that nestin-positive mesenchymal stem cells form a niche for HSCs in murine bone marrow. In that study, murine nestin/H11001/CD45/H11002 cells were identified as a small population of quiescent, perivascular BM-MNCs, which could differentiate into multiple skeletal lineages, possessed self-renewal capacity, and were required for HSC homing and maintenance of HSC. Interestingly, the genome-wide expression profile of these cells was closest to that of human CD146/H11001 BM-MSCs. In comparison, the human multipotent CD271/H11001/CD146/H11002 BM-MSCs described herein also showed nestin expression and exhibited hematopoietic stroma characteristics in...
vitro and in vivo. The total population of CD271+/CD45− cells in human BM-MNCs identified in our study was somewhat smaller (0.03%) than the reported nonhematopoietic nestin-positive population (0.08%) in mouse bone marrow; however, CFU-F frequency in the human CD271+/CD45− population was higher (approximately 10-fold) compared with the murine cells.

It has been suggested that different endosteal and periarterial HSC niche cell types exist, and that different hematopoietic subsets reside in distinct localizations of the murine bone marrow. For example, murine long-term HSCs reside in close proximity to the endosteal surface of trabecular bone. Whether distinct human CD34+ hematopoietic stem- and progenitor-cell populations colocalize with different localizations and the different BM-MSC populations as identified herein is certainly of great interest and will therefore be addressed in future experiments.

The concept that separate endosteal and periarterial stem cell niches exist in the bone marrow has been debated. Areas of trabecular bone are highly vascularized, and therefore endosteally located HSCs are most likely not only influenced by osteoblastic signaling, but also by vascular cells. According to the findings in murine marrow, we observed a dense vasculature network in the human bone marrow biopsies studied, with vessels also located near the surface of trabecular bone. Nevertheless, it has been clearly demonstrated that an oxygen gradient exists in the bone marrow and that HSCs are localized at the lowest end of the gradient in hypoxic niches such as the bone surface area. We also observed that in vitro CD146 expression was dependent on oxygen levels and that in situ CD146 expression near the bone surface was absent or very weak. These observations might partly be explained by lower oxygen levels at the endosteum; however, additional mechanisms such as calcium-induced CD146 shedding might be operative as well, because calcium levels are high near activated osteoclasts at the endosteal surface.

In summary, we have defined the phenotype of human primary nonhematopoietic BM-MSCs based on the expression of CD271, CD45, and CD146. We demonstrate that CD146 expression in lineage-negative, NGFR-positive, common leukocyte antigen-negative stroma stem cells is correlated with in situ localization, and that different BM-MSC subpopulations colocalize with different putative HSC niche cell types. This is an important finding that is likely to be the first step toward a better characterization of the human HME, hopefully leading to a better understanding of niche anatomy and function in normal and diseased marrow.

Acknowledgments

We thank Håkan Axelson and Olle Lindvall for their help and support with the hypoxic chamber experiments and confocal microscopy, respectively, and Marja Ekbom for critical discussions and helpful suggestions.
