49 **ABSTRACT**

50 **Background:** Polyhexamethylene biguanide (PHMB)-based antiseptic solutions can  
51 reduce bacterial loads in different clinical settings and are believed to lower risk of  
52 infections.

53 **Objective:** To assess the efficacy of a PHMB-based solution in lowering bacterial  
54 loads of full-thickness skin grafting (FTSG) wounds and the risk of SSIs.

55 **Methods:** In this double-blinded clinical trial, 40 patients planned for facial FTSG  
56 were randomized 1:1 to receive tie-over dressings soaked with either PHMB-based  
57 solution or sterile water. Quantitative and qualitative bacterial analysis was performed  
58 on all wounds before surgery, at the end of surgery, and 7 days postoperatively. In  
59 addition, all patients were screened for nasal colonization of *S. aureus*.

60 **Results:** Analysis of wounds showed no statistically significant difference in bacterial  
61 reductions between the groups. The SSI rates were significantly higher in the  
62 intervention group (8/20) than in the control group (2/20) ( $P=.028$ ). Higher  
63 postoperative bacterial loads were a common finding in SSIs ( $P=.011$ ). This was more  
64 frequent when *S. aureus* was present postoperatively ( $P=.034$ ), intraoperatively  
65 ( $P=.03$ ), and in patients with intranasal *S. aureus* colonization ( $P=.007$ ).

66 **Limitations:** Assessment of SSIs is largely subjective. In addition, this was a single-  
67 center study and the total number of participants was 40.

68 **Conclusion:** Soaking tie-over dressings with PHMB-solution in FTSG had no effect  
69 on postoperative bacterial loads and increased the risk of SSI development. The  
70 presence of *S. aureus* intranasally and in wounds preoperatively and postoperatively  
71 increased postoperative bacterial loads, which in turn resulted in significantly more  
72 SSIs.

99 Capsule summary:

- 100       • PHMB as an antiseptic has gained popularity in different clinical settings but  
101       hasn't yet been studied in full-thickness skin grafting (FTSG).
- 102       • This trial showed that adding PHMB to tie-over dressings had no effect on  
103       reducing bacterial loads in wounds and resulted in more surgical site  
104       infections.
- 105       • Use of PHMB in FTSG as a method to prevent SSIs is questionable, and  
106       further clinical studies are warranted.

## 124 INTRODUCTION

125 Polyhexamethylene biguanide (PHMB) is a polymer used as a disinfectant and  
126 antiseptic.<sup>1-6</sup> In recent years, it has gained popularity and has been used safely in  
127 different clinical settings such as in intraoperative irrigation during nail surgery<sup>1</sup>,  
128 treatment of burns<sup>5</sup>, orthopedic surgery antiseptics<sup>6</sup>, wound dressings<sup>3</sup>, prevention of  
129 infections in peritoneal catheters<sup>4</sup>, and in combination with negative-pressure wound  
130 therapy (NPWT) where it has been shown to be better than NPWT alone in treating  
131 infected wounds.<sup>7</sup>

132

133 The advantages of PHMB include broad antibacterial activity, good cell and tissue  
134 tolerability, low risk of contact sensitization, promotion of wound healing, and no  
135 development of bacterial resistance.<sup>2</sup> In addition to having an effect on Gram-  
136 negative bacteria<sup>8</sup>, it also has effects against methicillin-resistant *Staphylococcus*  
137 *aureus* (MRSA).<sup>9</sup> The microbicidal effect of PHMB is comparable to that of  
138 chlorhexidine<sup>10</sup>, but does not contain the toxic substituents found in chlorhexidine.<sup>11</sup>

139

140 In this study we investigated whether a PHMB-based antiseptic solution added to tie-  
141 over dressings used in full-thickness skin grafting (FTSG) could reduce bacterial load  
142 of wounds. This is a factor believed to have a role in the development of surgical site  
143 infections (SSIs) as previously published by our group.<sup>12</sup> We hypothesized that a  
144 reduction in the bacterial load would lower the risk of SSIs. We were also interested  
145 in examining the presence of *S. aureus* intranasally and wanted to study its relevance  
146 for SSIs. Recent studies have indicated that nasal colonization with *S. aureus* is an  
147 important risk factor for development of SSIs.<sup>13-15</sup> By analyzing bacterial quantities

148 and species at different stages of surgery, we sought to improve our understanding of  
149 the development of SSIs and its complex pathogenesis.

150

## 151 **METHODS**

### 152 **Study Design**

153 We conducted this prospective, double-blinded, randomized, placebo-controlled trial  
154 between September 2014 and September 2015 at Lund University Hospital, Sweden.  
155 This single-center study was approved by the ethical committee in Malmö/Lund,  
156 registration number (2013/762) and registered with ClinicalTrials.gov  
157 (NCT02253069). All patients over age 18 planned for facial FTSG were allowed to  
158 participate in the trial. We limited inclusion to surgery localized to the face because  
159 bacterial loads are known to vary from one anatomical site to another.<sup>16</sup> All grafts  
160 were harvested from the neck region. Exclusion criteria were diabetes, treatment with  
161 antibiotics within the last four weeks prior to surgery, and planned antibiotic therapy.  
162 Written informed consent was obtained from all patients before enrollment. The same  
163 nurse prepared all patients for surgery, which included using a 0.5% chlorhexidine  
164 solution for preoperative skin preparation. Four dermatologists performed surgery  
165 under routine sterile conditions. One principal investigator was in charge of collecting  
166 bacterial samples and assessing wounds postoperatively.

167

### 168 **Power analysis and randomization**

169 In a previous *in vitro* study, a reduction of  $>5 \log_{10}$  was achieved with a concentration  
170 of 0.02% PHMB against *S. aureus*.<sup>10</sup> We hypothesized that application of 0.1%  
171 PHMB as found in the commercially available Prontosan<sup>®</sup> Wound irrigation solution  
172 (B. Braun Medical, Switzerland) would at least reduce bacterial load in wounds by

173 half versus placebo. To get 80% power with an  $\alpha$ -value of 0.05, it was calculated  
174 that 16 patients were required in each group. By including 20 patients in each group  
175 in this trial to allow for dropouts, noticeable differences in bacterial reduction would  
176 be detected. Patients were randomized according to a list generated using QuickCalcs  
177 ([www.graphpad.com/quickcalcs](http://www.graphpad.com/quickcalcs)).

178

### 179 ***In vitro* antibacterial assay**

180 Prior to this trial, *in vitro* experiments were performed to assess antibacterial activity  
181 of PHMB. See Supplementary Methods.

182

### 183 **Intervention**

184 At the end of each surgery, once the skin graft had been sutured to the wound, a tie-  
185 over dressing was cut from Mepilex<sup>®</sup>. It was then soaked with either Prontosan<sup>®</sup>  
186 solution or sterile water (see Supplementary Methods for details) according to the  
187 randomization protocol.

188

### 189 **Follow up**

190 All patients were planned for a single follow up 7 days after surgery. Skin grafts were  
191 assessed in terms of redness, edema, discharge, graft take, and pain resulting in an  
192 overall assessment by the blinded principal investigator classifying a wound as  
193 "infected" or "non-infected". No scoring system was used for this purpose. Digital  
194 photographs were taken of all wounds pre- and postoperatively.

195

### 196 **Bacterial load analysis**

197 Bacterial samples were blindly collected from each patient using Eswabs (Copan,  
198 Brescia, Italy). Swabs were taken in a controlled manner by swabbing in a circular  
199 motion for 10 seconds. This was done at 3 different phases. Before surgery (BS) prior  
200 to antisepsis, the skin area containing the suspected neoplasm planned for excision  
201 was swabbed to establish the starting bacterial load level. Next, at the end of surgery  
202 (ES), the skin graft sutured to the wound was swabbed to establish a second starting  
203 load level. A final swab was taken from the wound one week after surgery (1W) after  
204 removal of the tie-over dressing.

205 Each swab was analyzed quantitatively by counting CFU per cm<sup>2</sup> of area swabbed as  
206 well as the type of bacteria present. Bacterial quantification was done by serially  
207 diluting each swab to 3 different concentrations plating each concentrate onto a Todd-  
208 Hewitt agar plate using sterile glass beads and incubating all plates in 5% CO<sub>2</sub> at  
209 37°C for 24 h. The CFU were then counted and were usually between 30 and 300  
210 CFUs. The CFU was divided with the swab area to measure bacterial loads in  
211 CFU/cm<sup>2</sup>. Bacterial species were determined via matrix-assisted laser  
212 desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry.

213

#### 214 **Intranasal swabs**

215 Before surgery, an Eswab was rotated in the patient's naris that was closest to the  
216 neoplasm planned for excision. Typing was performed using MALDI-TOF to detect  
217 presence of *S. aureus*. No quantification was done on these swabs.

218

#### 219 **Statistics**

220 Statistical analyses were performed with SPSS v.22 software (SPSS Inc., Chicago,  
221 IL). Bacterial load reduction was determined by using the following formulas:

222 CFU(1W)-CFU(BS), CFU(1W)-CFU(ES), CFU(1W)/CFU(BS), and  
223 CFU(1W)/CFU(ES). All median values obtained were compared using a Mann-  
224 Whitney U test to examine if differences existed between the groups. Differences in  
225 categorical variables were determined using the chi-square test. Differences in  
226 continuous variables were estimated using Student's *t* test. Statistical significance was  
227 set at  $P < .05$ .

228

### 229 **Outcome measures**

230 Our primary measure was to compare bacterial load reductions in both groups. The  
231 development of SSIs was a secondary outcome in this trial, and the tertiary outcome  
232 was the intranasal presence of *S. aureus* and examining its relevance for the bacterial  
233 dynamics of surgical wounds.

234

### 235 **RESULTS**

236 Our *in vitro* trials showed that only dressings soaked with PHMB inhibited growth of  
237 both *S. aureus* and *S. epidermidis* (Supplementary Figure 1). This was in accordance  
238 with previously published studies demonstrating antibacterial properties of PHMB  
239 against various skin bacteria.<sup>17-20</sup> As for this trial, there were no significant differences  
240 in patient characteristics in each group in terms of age, sex, wound location, and  
241 tumor excised (Supplementary table 1). Most wounds were located on the nose, which  
242 is known to be the most common site of skin malignancies.<sup>21</sup> No significant  
243 differences were noted among the groups in bacterial load levels measured before  
244 surgery, at end of surgery, and after one week. (Supplementary Table 2). No  
245 significant differences were detected between the groups in terms of bacterial  
246 reduction via the four calculations described in Methods (Supplementary Table 2).

247

248 A total of 10 wounds were assessed as infected to give an overall SSI rate of 25% in  
249 this study. Eight of these wounds belonged to the intervention group, which had a  
250 statistically higher rate of infection (chi-square 4.8,  $P=.028$ ). Statistical analyses  
251 showed that patient characteristics such as gender, age, and wound location did not  
252 correlate to SSI rates in this study. All patients with SSIs had a significantly higher  
253 bacterial load measured postoperatively after one week as illustrated in Figure 1A.  
254 When *S. aureus* was isolated from wounds postoperatively after one week, patients  
255 had a significantly higher bacterial load (Figure 1B). The presence of *S. aureus*  
256 intranasally before surgery was also associated with a higher postoperative bacterial  
257 load (Figure 1C). Whether coagulase-negative staphylococci (CoNS) were isolated  
258 from wounds postoperatively or not had no effect on postoperative bacterial loads,  
259 although a higher spread in the total CFUs was observed (Figure 2A). The presence of  
260 *S. aureus* at the end of surgery in patients resulted in significantly higher  
261 postoperative bacterial loads (Figure 2B).

262

263 Typing of all strains isolated from swabs revealed that CoNS and *S. aureus* were the  
264 predominant species (Table 1). The number of species successfully isolated from all  
265 patients was highest in in the swabs before surgery (27 different species) and lowest  
266 one week after surgery (8 species). Four out of 10 infected wounds contained *S.*  
267 *aureus*.

268

## 269 **DISCUSSION**

270 SSIs in dermatologic surgery result in unnecessary health costs as well as added pain,  
271 discomfort, and dissatisfactory cosmetic outcomes for patients.<sup>22,23</sup> Furthermore, the

272 use of preventative measures such as antibiotic prophylaxis, although sometimes  
273 warranted, can contribute to the emergence of resistant bacterial strains and give  
274 unwanted side effects, such as allergic reactions in patients.<sup>24</sup> Effective evidence-  
275 based measures are therefore highly needed—especially in FTSG surgery, which is  
276 normally associated with a higher rate of SSI.<sup>25</sup>

277

278 In this randomized controlled trial, we tested the efficacy of PHMB in preventing  
279 SSIs. Our results show that PHMB had no effect on reducing postoperative bacterial  
280 loads. Surprisingly, adding PHMB to tie-over dressings resulted in a significantly  
281 higher risk of SSI. Previous studies have shown that applying a certain antibacterial  
282 agent locally to wounds can suppress the growth of certain bacterial species, which  
283 can cause an overgrowth of other species that might be harmful.<sup>26</sup> Although  
284 speculative, it is possible that PHMB, by reducing the commensal flora, *i.e.* the  
285 microbiome, could give rise to an increased colonization of *S. aureus* or other  
286 pathogens. Indeed, there appeared to be a higher spread in the bacterial levels when *S.*  
287 *epidermidis* was absent postoperatively (Fig. 2A), and Gram-negative bacterial  
288 species were particularly detected in the PHMB-treated group one week after surgery  
289 (Table 1), findings suggestive of possible microbiome changes induced by PHMB.  
290 Clearly, the limited number of patients enrolled in this study makes it impossible to  
291 draw any firm conclusions on the protective role of commensals and the role of  
292 PHMB. However, it is worth noting that the microbiome has recently been attributed  
293 with important roles in protection against infections. For example, *Staphylococcus*  
294 *epidermidis* can produce antimicrobials, which can keep potential pathogens at bay.<sup>27</sup>  
295 *S. epidermidis* can also activate toll-like-receptor-2 (TLR2) signaling and induce

296 antimicrobial peptide expression, thus enabling the skin to mount an enhanced  
297 response to pathogens.<sup>28,29</sup>

298

299 We found 27 different bacterial species before surgery making it impossible to  
300 analyze which particular species could be responsible for increasing the risk of SSIs  
301 from a statistical point of view. A quantification of each particular species would be  
302 necessary to investigate this further. Here, only the total quantity of all bacteria in a  
303 swab was measured. Nevertheless, it was interesting to note that the variation of  
304 bacterial species was highest prior to surgery and lowest postoperatively in both  
305 groups. Yet in 24 out of 40 patients, bacterial loads were higher postoperatively than  
306 preoperatively. It appears that certain species exhibits a stronger tendency to grow  
307 directly after surgery. Further studies in larger patient groups are needed to verify this  
308 observation. Another result was that the bacterial species observed here agreed well  
309 with previously published studies showing that most frequently isolated species from  
310 wounds are *S. aureus* and CoNS.<sup>30</sup>

311

312 In this trial, we established two different starting bacterial loads due to the nature of  
313 FTSG surgery where skin is moved from one anatomical site to another. Comparing  
314 postoperative bacterial loads present on a graft to the presurgical swab taken on  
315 anatomically different skin would be unfair. We therefore compared the postoperative  
316 bacterial loads levels with the levels observed before and at end of surgery. Our  
317 analyses showed that the PHMB-based dressing had no effect on reducing  
318 postoperative bacterial loads. Indeed, there was actually a tendency towards higher  
319 loads one week after surgery in the intervention group compared to the control group.  
320 The extensive variety of bacterial species found preoperatively (27 different species)

321 is yet another interesting finding. We could only compare these data to the variety  
322 present postoperatively (8 different species). Thus, this difference could again be  
323 attributed to the anatomical skin flora variations *per se* at the donor sites or to the  
324 microbiome and host defense changes as mentioned above. Another theory in line  
325 with a recent publication<sup>31</sup> is that the presence of a neoplasm in the swab taken  
326 preoperatively is somehow related to a high bacterial variety.

327

328 We validated our previously published findings<sup>12</sup> and showed that a total  
329 postoperative bacterial load correlates positively to wound infection. Furthermore,  
330 postoperative bacterial loads were shown to be significantly higher when *S. aureus*  
331 was present in wounds intra- and postoperatively as well as in patients who had a  
332 nasal colonization with *S. aureus* detected prior to surgery. However, there was no  
333 direct relationship between presence of *S. aureus* in wounds, or intranasally, and SSIs.  
334 Still, *S. aureus* appears to continue to be one of the key pathogens involved in the  
335 development of SSIs. The presence of CoNS in wounds on the other hand seems to  
336 reduce the tendency towards developing an SSI by a reduced postoperative bacterial  
337 load. However, this observation was not statistically significant ( $P=.08$ ) as shown in  
338 Figure 2a. Although speculative, it is thus possible that an expanded preoperative  
339 screening of bacteria present preoperatively—not only in the nares, but also at the  
340 surgical site—could aid in the prediction of SSIs. It is also possible that boosting of  
341 the "healthy" microbiome—including *S. epidermidis*—could be beneficial for wound  
342 healing outcomes and in ongoing *in vitro* based experiments. Thus, we therefore are  
343 currently evaluating the effects of both commensal and pathogenic bacteria in skin  
344 models.

345

346 A limitation of our study is that one of our outcomes (diagnosis of SSIs) was  
347 dependent on a subjective assessment of a single investigator. Studies have shown  
348 both inter- and intra-observer variations when diagnosing SSIs <sup>32</sup>. These show the  
349 importance of finding a more objective method of diagnosing SSIs in the future.  
350 Nevertheless, the SSI scoring was performed in a blinded fashion to avoid potential  
351 bias between the groups. Other limitations were that this was a single-center study  
352 and that the total number of participants in the study was 40.

353

#### 354 **CONCLUSION**

355 We used PHMB as a novel disinfectant to prevent SSIs in FTSG. PHMB appeared to  
356 increase the risk of SSIs at least in the experimental setting used here. In light of the  
357 emergence of new resistant bacterial strains that cause SSIs, there is a need for further  
358 research that can define preventative methods to improve outcomes. Measures that  
359 lower bacterial loads, prevent *S. aureus* regrowth in wounds and abolish intranasal  
360 colonization are important and ongoing.

361

#### 362 **Acknowledgments**

363 We are greatly indebted to Mina Davoudi, Emma Matsson, Ann-Charlotte Strömdahl,  
364 and Dr. Ingrid Siemund for their efforts in conducting the study. We also wish to  
365 thank the nursing staff (Eva Jacobsson, Helene Palmqvist, Susanne Erdmann) and Åse  
366 Jönsson at our clinic for valuable assistance making this trial possible.

534 **Figure 2.** Bacterial loads at one week after surgery measured in all patients  
 535 whether (A) CoNS were isolated postoperatively and whether (B) *S. aureus*  
 536 was isolated at end of surgery. The outliers were expressed with an asterisk  
 537 (\*). Solid bars depict interquartile range and the hash marks show the total  
 538 range. Calculations of median CFU/cm<sup>2</sup> values using a Mann-Whitney test  
 539 with a *P* value of <.05 were regarded as statistically significant.

540

577 SUPPLEMENTARY DATA

578

579 METHODS

580

581 ***In vitro* antibacterial assay**

582 Todd-Hewitt (TH) agar plates were streaked with *S. aureus* ATCC 29213 and *S.*

583 *epidermidis* ATCC 14909. Each plate contained  $1 \times 10^5$  colony-forming units (CFU).

584 Eight mm polyurethane dressings (Mepilex<sup>®</sup>, Mölnlycke Healthcare, Göteborg,

585 Sweden) soaked with Prontosan<sup>®</sup> solution or sterile water were applied on top to

586 simulate an *in vivo* situation where the dressing is applied onto a wound.

587 The dressings were soaked with 70% of the solution, where 100% was considered as

588 the maximum wetting capacity of the dressing. 70% wetting was also to be used in

589 this patient trial. The zone of inhibition around the discs was measured.

590

591 **Preparation of Mepilex<sup>®</sup> dressings**

592 Prior to surgery, seven circular dressing templates with varying diameters ranging

593 from 10 mm to 34 mm were cut from Mepilex<sup>®</sup>. Necessary liquid volume to achieve

594 70% wetting was calculated by subtracting each template's fully saturated weight

595 from its dry weight and multiplying the result by 0.7. For each dressing template, 20

596 test tubes were prepared containing sterile water and 20 test tubes contained

597 Prontosan<sup>®</sup> solution. These were marked with either A or B by an external

598 investigator not involved in this trial and blinded to the nurse, surgeon, and principal

599 investigator. Prontosan<sup>®</sup> solution is like water both colorless and odor-free. The

600 dressing templates were used for proper determination of the volume of Prontosan<sup>®</sup> or

601 sterile water required for wetting tie-over dressings used during surgery.
