Sexual behaviour among Ugandan university students: A gender perspective

Devika Mehra
Abstract

Feminisation of the HIV/AIDS epidemic in sub-Saharan Africa is an important public health concern. Therefore, it is crucial that we understand the various risk factors that shape unsafe sexual behaviours among young people in Uganda. The overall aim of this thesis was to gain a deeper understanding of the various factors that have an association with risky sexual behaviours among Ugandan university students, focusing on a gender perspective. This knowledge can contribute to effective policy formulation and implementation of programs. In 2010, 1,954 students participated in a cross-sectional study and the data was collected using a self-administered questionnaire. Logistic regression was used as the main analytical tool for the analysis and effect modification analysis was conducted for some of the associations. Study I found that there was an association between non-use of contraception and socio-demographic factors, relationship status, and alcohol consumption. The socio-demographic determinants that affected this association were different for males and females. Early sexual debut was found to modify the effect of this association. Study II concluded that there was an association between alcohol consumption and the experience of sexual coercion among Ugandan university students. Frequent consumption of alcohol on the occasion of sexual intercourse and poor mental health were found to have a synergistic effect with recent experience of sexual coercion. Study III demonstrated an association between self-reported poor academic performance and inconsistent condom use with a new sex partner. Females who were poor academic performers were found to be at a higher risk of inconsistent condom use compared to their male counterparts. Study IV showed that there is an association between low condom efficacy and inconsistent condom use with a new sex partner. Gender differences were observed: females with low condom efficacy were at a higher risk of inconsistent condom use, in comparison to males. Our studies concluded that the key factors that contribute towards risky sexual behaviours among Ugandan university students were socio-demographic factors, relationship status, alcohol consumption, academic performance, and condom efficacy. Unequal gender power relations in this region further aggravates the sexual risk behaviours. Therefore, we need to create a policy action environment (not merely policies) in which sexual and reproductive health rights is addressed by raising awareness among males and females. In universities this could be achieved through skill building programs such as sex education, peer counseling, and partner communication, with a special focus on women by providing them skills for negotiating condom and contraceptive use. These programs need to address the socio-cultural and gender perspectives in addition to focusing on safe sex and sexual rights.

Introduction

Today, we have a larger population of young people of ages 10 to 24 than ever before in history: an estimated 1.8 billion representing a quarter of the world’s population [1]. Nearly 90% of them live in low- or middle-income countries [2]. Structural determinants such as national wealth, income inequality, access to education, and gender inequality constitute the social determinants of health and cause much of the health inequity within and between countries [3-5]. Social determinants affect the health of young people who are crucial for the economic development of nations [4]. There has been a lot of international discussion about the demographic dividend and the power of young people’s contribution to global development [6]. However, the demographic transition has not been realized in low- and middle-income countries, which is why we need to invest in young people’s health and their well-being [7].

In spite of the commitments made in the program for action of the 1994 International Conference on Population and Development (ICPD), sexual and reproductive health needs of young people still remain poorly understood and inadequately served [8]. This neglect has far-reaching consequences for the lives of this population, which is evident from the global burden of disease. In 2004, 2.6 million deaths occurred in 1.8 billion young people ages 10 to 24 years, out of which 97% of the deaths occurred in low and middle-income countries [9]. Some of the prominent causes of this were HIV/AIDS and tuberculosis, which contributed to 11% of the deaths; another 15% of the mortality occurred due to maternal conditions [9].

The bio-social gap between the early onset of puberty and the increasing age of marriage has widened in most low-to middle-income countries [10, 11]. This increases window for pre-marital sexual activity, which has stigma attached to it in Asia and Africa, their young age further exposes them to the risk of unwanted pregnancies, unsafe abortions, and sexually-transmitted infections (STIs) [12-15].

Young people ages 15 to 24 comprise more than twenty percent of the sub-Saharan African population [16]. There is a wide range of empirical evidence that has highlighted the prevalence of risky sexual behaviours among this population, such as early sexual debut, having multiple sex partners, and non-use of condoms and contraception [11, 17-19]. These risky sexual behaviours have been the prime driver of the HIV epidemic in sub-Saharan Africa [20, 21].
Feminization of the HIV/AIDS epidemic has also been a prominent phenomenon in sub-Saharan Africa [22]. Young people between the ages of 15 to 24 are particularly affected with 75% of all HIV infections occurring in women in this region [23], where the epidemic has been exacerbated due to existing socio-cultural factors, gender inequalities in particular [24]. But today understanding of how the HIV pandemic moves and develops should be understood in a broader perspective addressing gender, health system challenges, education, poverty, sexual and reproductive health needs of young people, and that of all individuals irrespective of their sexual orientation [25].

**Gender health inequality**

Gender inequality is prominent on the global agenda for social change, as evident in the United Nations Third Millennium Development Goal (MDG 3), that addresses ‘gender equality and empowering women’ [26]. According to the report on the social determinants of health, reducing the health gap in a generation is possible only if we address the existing gender inequalities, and women’s empowerment is the key to achieving fair distribution of health [5]. This report further states that gender inequalities are pervasive in all societies but the magnitude varies in different contexts, something which influences women’s health in terms of discriminatory feeding patterns, violence against women, lack of decision-making power, and limited possibilities of improving one’s health. Therefore, gender equity must stand for absence of bias at various levels in a society within households, societal norms regarding male and female sexuality, reproduction and rights, health systems, policies, and research [27, 28].

**Theoretical framework of gender**

Gender is a concept used as a social and cultural construct, as opposed to the biological distinction between the sexes [25]. Gender and sexuality have been explained in the literature by various feminist theorists. According to Connell, the theory of gender and power (social structural theory) is based on sexual inequality and gender power imbalance [29]. According to this theory, there are three major social structures that characterize gendered relations: the sexual division of labor, the sexual division of power, and the structure of cathexis explained as the social norms and affective attachments regarding how men and women relate to each other in a society [29]. The extended versions of this theory propose that these structures exist at societal and institutional levels through social mechanisms [30]. Such mechanisms produce gender-based inequalities and disparities, which create power imbalances.
Traditional gender roles are based on the unequal distribution of power between men and women, which further aggravates these gender inequalities [30]. It can be argued that these traditional gender role-based attitudes reflect individual endorsement and internalization of giving social norms, more power to men than women, and women to risky sexual situations [31]. Also, men who internalize such social norms may feel the pressure to behave in a stereotypical masculine manner that may include having multiple and casual sexual partners, and women may leave the important sexual decisions to men [31]. Power relations around sex, reproduction, and the complex intersections of gender profoundly affect women’s health-seeking behaviour and health outcomes [27]. These gender power imbalances in sub-Saharan Africa have been identified as one of the major reasons for unwanted pregnancies, STIs, and feminization of the epidemic HIV/AIDS.

Therefore, there is a crucial need to understand gender and sexuality closely, not only with a narrow focus on addressing sexual reproductive health outcomes regarding pregnancies and diseases, although that is certainly crucial in this era of HIV/AIDS. But we also need to widen our understanding about the sexual and reproductive health needs of young people, by using different analytical frameworks to weigh the various factors that shape their behaviour. It is imperative that we move towards a society with more balanced gender relations that are equally fair to men and women. Hence, there is a need to approach sexuality in more positive terms, emphasizing on pleasure, desire intimacy, and respecting the sexual rights of each individual and being sensitive towards all sexual orientations.

Uganda

Uganda is one of the 49 poorest countries in the world, and its population growth is 3.3% which is one of the highest in the world [32]. According to the Uganda Bureau of Statistics, the estimated population in 2012 was 34.1 million [33]. Uganda has a young population, nearly half of which is below the age of 15, and another 20% are between 15 and 25 [34]. With the introduction of universal primary and secondary education, there is an increasing number of students going to schools and universities [35]. The national prevalence of HIV is 7.3% [36]. Its prevalence for those ages 15 to 24 differs for males (2.1%) and females (4.9%) [36]. Furthermore, there is a higher prevalence of HIV in females (7.1%) than males (2.8%) between the ages of 20 to 24. Amid the high HIV prevalence there is a high frequency of risky sexual behaviours, with glaring differences between males and females in this region, as described below.

¹Uganda Demographic and Health Survey 2011  ²Ugandan Aids Indicator Survey 2011

According to the table given above a greater percentage of females have had an early sexual debut. This may be due to the large number of girls entering into early marriage, which puts them at a higher risk for unwanted pregnancies and STIs. A higher percentage of males reported having had multiple sexual and concurrent partners, which could be a risk factor for spreading HIV, especially considering that the prevalence of condom use on last occasion of sex is low. It is evident from the statistics above that there is a prevalence of risky sexual behaviours among the general population, with striking gender differences. Therefore, there is a need for interventions that consider gender issues which will help us in improving the reproductive health indicators of the country.

**Policy environment and health system challenges**

There are favorable youth policies that do exist in Uganda, including the National Youth Policy [37], sexual and reproductive health policy, sexual and reproductive health minimum package, national adolescent health policy [38], and a gender policy [39]. Despite these well-meaning policies, meeting the sexual and reproductive health needs of young people continues to be a challenge. Uganda’s health sector strategic plan for 2010 to 2015 includes procurement and distribution of contraception for all males and females, with a special focus on adolescents [40]. By contrast, there is evidence from a prior study conducted in Uganda that young people face refusal or restrictions when they demand contraceptives from providers [41]. It was found that nearly one-third of the providers said that they will not provide contraceptives to
individuals who are younger than 18, unmarried, still in school, or are without children, although the policy guidelines of Uganda have no such requirements. Therefore, resistance from providers due to individual and cultural biases demonstrates an unwillingness to prioritize young people’s unmet need of contraceptives. The existing gap between sexual and reproductive health policy and the availability of contraception restricts actual contraceptive use.

Factors for risky sexual behaviours among Ugandan university students

The wide range of factors that can lead to risky sexual behaviour among young people include socio-demographic ones like area of origin, educational level of head of the household, and religion. Gender differences have been observed regarding this association in a sub-Saharan African setting [42, 43]. According to a survey conducted among students from six Ugandan universities, there is a high prevalence of risky sexual behaviours in this population: 51% used a condom during their last sexual intercourse (higher than the national average), 9% currently use contraception other than male contraceptives, 24% have had more than one sexual partner in the last 12 months, 79% have had a non-regular partner, and 10% had an STI-related symptom [44]. The study further reported that 6% of all sexually active girls ages 15 to 19, and 13% ages of those 20 to 24 have at some time been pregnant, and 4.2% have had an induced abortion. Unwanted pregnancies are an important public health concern as they can have long-term psychosocial and economic implications, which in turn can also lead to students dropping out of university.

There is evidence from prior research conducted among adolescents in Uganda, Malawi, Ghana, and Burkina Faso that a large number of unintended pregnancies result from lack of awareness of contraceptive methods, their source of availability, and from an array of social and structural inequalities that compromise sexual decision making [45]. Some of the prominent factors that lead to a risk of unintended pregnancies are multiple concurrent relationships, cross-generational sex, transactional sex, and sexual violence [46, 47], all of which are prevalent in Ugandan universities [44].

Alcohol consumption is widely known to be one of the risk factors that may lead to risky sexual behaviours and the threat of sexual coercion [48-52]. There is evidence from a previous study conducted among university students in the US showing that, despite being a high income country, nearly 50% of all cases of sexual coercion there involves the use of alcohol or other drugs by the victim or the perpetrator [50]. Alcohol consumption in Ugandan universities is considered to contribute to cases of sexual coercion, including rape, both on and off campus [53].
In the Ugandan context, alcohol consumption may be a part of the control mechanism that is used to obtain sex without the consent of the other person [54]. Sexual coercion may not allow the victim to negotiate safer sex, thus leading to risky sexual behaviours. There are various theories that have been discussed in relation to alcohol and sex such as alcohol disinhibition [55]. Another is alcohol myopia theory, [56] which is explained as the restriction of cognitive capacity where the person focuses on the salient situational cues of sexual initiation and ignores the peripheral ones. This suggests that alcohol consumption in an initiate situation, when the arousal is high it may limit a person’s ability to identify potential dangers, including the risk of STI, unwanted pregnancy, or sexual coercion.

Another potential risk factor that may lead to risky sexual practices among this population may be academic performance. University students undergo great deal of psychological pressure. As a result they may resort to coping mechanisms like risky sexual behaviours, alcohol consumption, and drug use to release their stress [57-59]. There is evidence from studies conducted on adolescents in the US that show that students with a low grade point average (GPA) have a higher likelihood of teenage pregnancy than those with a high GPA who tend to postpone their pregnancies until their 20s [60]. Another study conducted among high school students found a low GPA associated with a high number of sexual partners and lower condom use [61]. It could also be argued that poor academic performance may lead to risky sexual behaviour because, due to the psychological stress such individuals may not be able to do a good risk assessment of interpersonal situations [61]. This may also be due to reduced motivation to pursue one’s academic career and therefore more time spent on social activities.

Low condom efficacy is known to be another potential risk factor that could lead to non-use of condoms. There are various studies in sub-Saharan Africa that have documented this association [62, 63], but the gender differences in this regard have not been well investigated. There are certain individual and social factors (peer norms) that can affect this association among young people. Perceived self-efficacy is one of the individual determinants that can influence condom use. This concept is derived from social cognitive theory and is one of the components that could potentially lead to health-related behavioural change [64]. Perceived self-efficacy has been described as the confidence in one’s ability to demonstrate motivation and capability to achieve a given goal [65]. Condom efficacy is therefore one’s ability to successfully use a condom during sexual intercourse [66]. However, it requires risk reduction strategies and self-regulation skills to transform condom efficacy into behaviour, which in difficult circumstances can be a challenge for young university students [67].

In the Ugandan context, where gendered cultural norms and inequitable power relations prevail, women have less control in a sexual relationship [11]. Interpersonal
communication along with behavioural skills between partners is an integral part of a relationship that determines behaviour [68, 69]. There is evidence from prior research that demonstrates having a positive attitude towards condoms and a greater confidence in one’s ability to use them consistently in various circumstances corresponds to higher levels of condom use [70, 71].

‘Intention to use a condom’ is another predictor that can affect condom use [72, 73]. According to planned behaviour theory [74] and its extended versions [75], any behaviour is more likely to occur if there is a strong intention to carry it out, in the absence of environmental barriers. Uganda has inequitable gender power relations: women possess less control so just having the intention to use a condom might not translate into behaviour [11].

Along with individual factors many social factors affect condom use. Evidence from previous studies conducted in the US among university students, demonstrates that peer norms towards alcohol consumption, romantic relationships, and sexual behaviours can put pressure on young people, affecting their sexual decisions [76-78]. Young people who feel this is normative behaviour among their peers might engage in having multiple sexual partners, using condoms inconsistently, and consuming alcohol in conjunction with having sex [78]. This is further supported by studies of adolescents in Ethiopia, Cambodia, and Laos, where peer influences have been shown to affect risky sexual practices [79, 80].

Therefore, it is important that we take into account these risk factors in addressing the socio-cultural factors particularly gender inequalities in Uganda, which will help in reducing the negative reproductive health outcomes such as unintended pregnancies, STIs and abortions, including feminization of the HIV epidemic in this region.

**Conceptual Framework : The social-ecological model**

The model presented in Figure 1 is an adaptation of Bronfenbrenner’s ecological model [81], previously used to understand factors for risky sexual behaviour among young people [82]. It depicts four levels that correspond to our analysis. These factors interact with one another on the individual, relationship, community and societal levels. The first level, the individual, includes psychological characteristics and various high risk behaviours that affect health. The second level, relationships, comprises an individual’s proximal relations such as family, intimate partners, and peers, which among vulnerable young people can influence a person’s behaviour positively or negatively. The third level is community, encompassing a person’s social capital in which he/she develops social networks in various settings like a university, workplace, and neighbourhood. The outermost layer covers the broad societal factors including
religion, politics, policies, social norms, gender norms, and media, all of which have a potent effect on young people’s sexual behaviours. Gender norms seem to be pervasive across all levels. The multiplicity of these factors shape young people’s sexual behaviours.

The sexual behaviour of young people has largely been viewed as an individual level phenomenon [82]. Consequently, many intervention efforts have been made to understand factors that influence sexual decision making, but they have not addressed the pervasive contextual influences like gender and social norms which directly or indirectly affect individual behaviours [82]. Therefore, individual level interventions over longer periods of time or in the presence of these countervailing forces might not change into behaviour. Therefore, it is crucial to understand sexual risk behaviours of young people in a broader perspective.

A conceptual framework that addresses the complexity of factors that affect risky sexual behaviours, including sexual coercion, among Ugandan university students in our thesis is given below.
Figure 1. An adaptation of the social-ecological model: individual, relationship, community, and society (Bronfenbrenner 1977)
Figure 2. Effect modification analysis in studies I-IV.
Previous studies have described risk factors for unsafe sexual behaviour among young people in Uganda, but gender differences in a university population have not been very well investigated. Moreover, to the best of our knowledge there is no previous research on issues like academic performance and how this affects risky sexual behaviour in a university population in this region. This thesis examines socio-demographic factors, alcohol consumption, academic performance, and condom efficacy and analyzes how they are associated with risky sexual behaviours, including the risk of sexual coercion, from a gender perspective. Understanding these dynamics will enable culturally sensitive recommendations to be made regarding strategies that can meet the sexual and reproductive health needs of young people.
Aims

General Aim

The overall aim of this thesis was to gain a deeper understanding of the various factors that have an association with risky sexual behaviours among Ugandan university students, focusing on a gender perspective. This knowledge can contribute to effective policy formulation and implementation of programs.

Specific Aims

1. To determine the relationship between non-use of contraception and socio-demographic factors, alcohol consumption, and types of partner(s) among Ugandan university students (Study I)

2. To study the association between alcohol consumption and the experience of sexual coercion among Ugandan university students (Study II)

3. To investigate the association between self-reported academic performance and risky sexual behaviours, and whether gender affects this relationship among Ugandan university students (Study III)

4. To investigate whether gender differences regarding individual and social factors determine the association between condom efficacy and inconsistent condom use with a new sex partner among Ugandan university students (Study IV)
Material and Methods

The four studies in this thesis are based on data collected through a self-administered questionnaire distributed among all the undergraduate students at Mbarara university of Science and Technology (MUST) in 2010.

Study design and setting

The study adopted a cross-sectional study design. The survey was conducted at MUST, the second largest university in Uganda, a public institution that was founded in 1989. It is located in the centre of Mbarara, approximately 350 kms to the southwest of the capital city, Kampala. In 2010, the number of universities in Uganda expanded, resulting in 29 new institutions of higher learning. Many more students are now being enrolled in universities than in the past. Those receiving government scholarships remain in campus during their course of study, while others live on campus during their first and second years and then move on to privately run hostels.

Our target population consisted of undergraduate students from the university’s four faculties: Science, Medicine, Computer Science, and Development Studies. The total sample was comprised of 2706 individuals, of whom 1954 participated in the study (72% of all registered undergraduates). The respondents included 1087 males (55.6%) and 867 females (44.4%). Ethics approval for the project was granted by the Institutional Review Committee at MUST.

Data collection and analysis

The data was collected by means of an 11 page self-administered questionnaire with 132 questions based on socio-demographic factors, academic progress, social capital, mental health, sexual behaviour, alcohol consumption, and other lifestyle variables. The questionnaire was developed on the basis of a pilot study conducted among young people at the university which was in turn based on prior focused group discussions among students. The approximate time used for filling in the questionnaire was 45 minutes. The language used in this survey was English. The same questionnaire has also been used in previous studies of university students in this setting [19, 83, 84].
The entire undergraduate student body at MUST was invited to take part in the survey. Prior to the questionnaire distribution, a consent form was circulated describing the purpose of the study, and students were asked to sign if they agreed to participate. The research team informed the students that participation in the survey was voluntary and anonymity would be assured. The contact details of the project’s principal investigator and the research assistant were provided in case students had any personal questions. The signed consent forms and completed questionnaires were deposited by each student in a sealed box.

Measures

Background variables

Sex was classified into male or female (Studies I to IV).

Age was a continuous variable that was dichotomized into ≤ 22 (‘younger’) and > 22 (‘older’) using mode as the cutoff point in Study I and median in Study II (which used the entire sample). In Studies III and IV we used 23 as the cut-off point, since only students who had sexually debuted were analyzed.

Area of growing up was dichotomized into rural or urban, the latter combining peri-urban and small towns (Studies I to IV).

Educational level of head of the household during childhood was categorized as ‘did not complete primary school’ and ‘completed primary school’, which were coded as ≤ Primary education and > Primary education (Studies I to IV).

Religious affiliation during childhood was categorized as Catholic, Protestant, Moslem, Pentecostal, Seventh-Day Adventist, Orthodox, and Other. The variable was then trichotomized as Catholic, Protestant, and Other since the first two were the major religions in our study sample and the remaining denominations were too small to be analyzed separately (Study I).

The role of religion in family life while growing up was dichotomized into major (‘religion played a big role or was relatively important’) and minor (‘religion was not so important or was not important at all’) (Studies I to IV).

‘Number of boyfriends/girlfriends you have had’ was dichotomized into 0–1 and ≥ 2 partners while ‘Boyfriend/girlfriend at the moment’ was categorized as ‘Yes’ or ‘No’, as in the questionnaire, and referred in the study as ‘currently in a relationship’ (Study I).

‘Length of the current relationship’ was dichotomized into ≤ 1 year or > 1 year. (Study I).
Type of partner was a dummy variable combining, ‘number of boyfriend/girlfriends you have had’ and ‘number of lifetime sexual partners’. It was then categorized as ‘irregular partners’, ‘regular partners’ and ‘mixed partners’ (Study I).

The definition of irregular partners was used for individuals who reported having had no girlfriends/boyfriends and one or more sexual partners or individuals reporting two or more sexual partners in excess of the number of girlfriends/boyfriends they reported.

The definition of regular partners was based on an individual reporting having had one girlfriend/boyfriend and one sexual partner, or who had more girlfriends/boyfriends than sexual partners.

The definition of mixed partners was based on an individual reporting having had two or more sexual partners and an equal number of girlfriends/boyfriends, or one more sexual partner than girlfriends/boyfriends.

Age at sexual debut was dichotomized into ≥ 16 years and < 16 years. (Studies I and III).

‘Number of sexual partners in the past 12 months’ was determined by the response to the question: ‘How many sexual partners have you had in the past 12 months?’ The variable was dichotomized into 0 to 1 or ≥ 2 partners (Studies I, III and IV).

Alcohol consumption variables

Alcohol consumption in the past 12 months was assessed by asking ‘How often have you consumed alcohol in the last 12 months?’ There were five alternative responses: four times per week or more, two to three times per week, three to four times per month, once a month or less, or never. The variable was then dichotomized into ‘risk’ for the first three alternatives and ‘no risk’ for the last two (Study I). This was a dichotomous variable, used only as a confounder in this study and not our main exposure. The variable was then trichotomized into ‘abstainers’ (never), ‘infrequent users’ (three to four times per month, once a month or less) and ‘frequent users’ (four times per week or more often; two to three times per week) (Study II). Since it was the main exposure of our study, we trichotomized this variable. Therefore, it did not affect the outcome for a better estimation of results.
Consumption of alcohol on your latest occasion of sexual intercourse was categorized as ‘Yes’ and ‘No’, as in the questionnaire (Studies I and II).

Alcohol consumption on the occasion of sexual intercourse had the following response alternatives: always, or almost always, more often than on half of the occasions; about half of the occasions; more seldom than on a quarter of the occasions; almost never; or never. The first three options were coded as ‘frequent consumers of alcohol on the occasion of sexual intercourse’ and the last two as ‘infrequent users of alcohol on the occasion of sexual intercourse’ (Studies II, III and IV).

Heavy episodic drinking (HED) was based on the question “How often do you drink six glasses or more on the same occasion?” The following alternative answers could be selected: daily or almost daily; every week; every month; more seldom than once a month; or never. The variable was then trichotomized into ‘abstainers’ (never), ‘frequent HED’ (daily or almost daily; every week; every month) and ‘infrequent HED’ (more seldom than once a month; never). We used alcohol consumption over the past 12 months as the main exposure instead of HED, as the trends were quite similar (Study II).

Mental health

The Hopkins Symptom Check List (HSCL-25) was used to assess the mental health status of participants in the survey. This scale consists of 15 items analysing symptoms of depression and 10 items assessing symptoms of anxiety during the week prior to the survey [85]. An additional, 10 items from the Symptom Checklist-90 (SCL 90) were included to measure symptoms of psychoticism during the past week prior to the survey. Each item was graded on a four point Likert scale [86]. Both instruments mentioned have been validated and applied in different African cultural contexts [52, 87, 88].

The total mean mental health scores as well as the mean scores of depression, anxiety and psychoticism were calculated from each student’s total score for each measure. Scores were divided by the number of items for all the responses and dichotomized into ‘high score’ and ‘low score’, based on the median split between the total scores for each measure. These variables are referred to in the manuscript as ‘poor mental health’ and ‘good mental health’, respectively (Studies II and III).
Experience of sexual coercion was measured by means of a validated instrument that had been used in previous studies of sexual behaviour [89, 90]. Experience of sexual coercion was based on responses to the following statements: ‘You have been forced to show your sexual organ’, ‘Someone forced you to let them touch your sexual organ’, ‘Someone forced you to let them suck or lick your sexual organ’, ‘Someone forced you to let them show you their sexual organ’, ‘You have been forced to watch someone masturbate’, ‘You have been forced to masturbate someone’, ‘You have been forced to take part in oral sex or to lick someone’s sexual organ’, ‘You have been forced to take part in sexual intercourse with the penis in the vagina or someone has inserted an object into your vagina’, or ‘You have been forced to pose for a sex photo or sex film’. If the respondent answered affirmatively to any of these alternatives, they were classified as being exposed to sexual coercion and coded as ‘Yes’, otherwise they were coded as ‘No’ (Study II).

Early experience of sexual coercion was assessed by combining the variables ‘Age at first time of sexual coercion’ and ‘Current experience of sexual coercion’. We coded all those who reported being coerced before age 18 but were not currently being exposed to coercion as ‘early experience of sexual coercion’ (Study II).

Academic achievement variables

Academic performance was based on the question ‘How well are your studies going?’ A response could be chosen from the following: ‘My studies are going well’; ‘My studies are going reasonably well’; ‘My studies are not going as well as I wish’. The variable was then dichotomized so that the first two options were coded as ‘good academic performance’ and the last as ‘poor academic performance’ (Study III).

Academic year was determined by the question: ‘In what year of your studies are you currently?’ The variable was dichotomized into ‘1st year’ and ‘> 1st year’ for those in years 2 to 5 (Study III).

Social capital variables

Trust in others was measured on the basis of answers to questions that are widely used in empirical studies [91]: ‘Most people would take advantage of you if they had an opportunity;’ ‘Most people try to be fair;’ ‘You can trust most people;’ and ‘You
cannot be careful enough when dealing with other people.’ The response alternatives were ‘I do not agree at all,’ ‘I do not agree,’ ‘I agree,’ or ‘I agree completely’. They were assigned values from 1 to 4, with a maximum total score of 16. On the basis of the median score, the variable was categorized into ‘high’ (above the median) and ‘low’ (below the median) (Study III).

Social participation was defined on the basis of 12 different social activities in which students may have participated over the previous few months. A validated measure used for this had previously been employed in Sweden [92]. The variable was dichotomized on the median value: the total scores of those who answered ‘yes’ (maximum total score 12) were coded into ‘high’ (above the median) and ‘low’ (below the median) (Study III).

Condom efficacy was assessed by combining two statements: ‘I am satisfied with my ability to use a condom correctly’ and ‘I believe I can persuade a new sex partner to use a condom’. The respondents who indicated ‘Yes’ to both statements were coded as ‘high efficacy’ and other responses were categorized as ‘low efficacy’ (Study IV).

Pleasure of using a condom was based on the question ‘How would you compare the degree of pleasure in using a condom during intercourse with not using one? The responses ‘no difference’ and ‘more pleasure with a condom’ were coded as ‘same or more pleasure’; ‘less pleasure’ remained coded as ‘less pleasure’ (Study IV).

Intention to use a condom was based on the statement ‘I intend to use a condom whenever I have intercourse with a new sex partner’. Those who responded positively were coded as ‘Yes’ and others were classified as ‘No’ (Study IV).

Peer norms

Peers use a condom with a new sex partner was based on the statement ‘My friends at the university always use a condom with a new partner’. The response alternatives were ‘Yes’ or ‘No’ (Study IV).

Peers having difficulty demanding condom use was based on the statement ‘My friends at the university have difficulty demanding condom use with a new partner’. The response alternatives were ‘Yes’ or ‘No’ (Study IV).
Dependent variables

Prevention of unwanted pregnancy was assessed through responses to the question: ‘Did you use any method for avoiding pregnancy on your latest occasion of sexual intercourse?’ There were four alternative answers: no; yes, a condom; yes, a contraceptive pill; or yes, another method. The variable was then dichotomized so that all of the ‘Yes’ answers were considered as ‘Yes’ (Study I).

Recent experience of sexual coercion was based on the response to two questions: ‘How old were you when the coercive experience happened for the first time’ and ‘Is it still going on?’ We classified all those who reported that their first experience of sexual coercion happened at age 18 or above, or below 18 years but is still going on, as exposed to a recent experience of sexual coercion (Study II).

Multiple sexual partners was ascertained by the response to the question ‘How many sexual partners have you had during the last 12 months?’ and was dichotomized into ‘0 to 1’ and ≤ 2. Students who responded ≤ 2 partners were classified as having multiple sexual partners (Study III).

Inconsistent condom use was ascertained by asking ‘How often do you use a condom with a new sexual partner?’ The response option ‘always’ was coded as ‘consistent condom use’ and the other alternatives (‘often’, ‘sometimes’, ‘never’, ‘does not apply to me’) were coded as ‘inconsistent condom use’ (Study III and IV).

Statistical methods

Statistical analysis was conducted using PASW (SPSS) statistical package Version 21.0. We first measured the prevalence of the variables we used within our sample population. Logistic regression analysis then calculated the crude odds ratio (OR) with 95% confidence intervals (CI) for investigating the associations between the potential determinants and non-use of contraception (Study I); to investigate the associations between alcohol consumption patterns and recent experience of sexual coercion (Study II); to study the association between self-reported academic performance regarding multiple sexual partners and inconsistent condom use (Study III); and to determine the association between condom efficacy and inconsistent condom use with a new sexual partner (Study IV).

Multivariate logistic regression was used step-wise to adjust for potential confounders in our studies. These were age, sexual debut, area of origin, and educational level of
head of household (Study I); sex, age, area of origin, educational level of head of the household and mental health (Study II); sex, age, area of origin, social participation, mental health, alcohol use on the occasion of sexual intercourse, and sexual debut (Study III); and age, area of origin, pleasure of using a condom, intention to use a condom, multiple sex partners, alcohol in relation to sexual intercourse, and peer norms (Study IV). The analysis in Study I was performed separately for males and females, whereas in Studies II, III, and IV were adjusted for sex. The significance level was accepted at $p < 0.05$, two tailed.

To further investigate the associations we analyzed the estimates of effect modification (synergy) ‘departure from additivity of effects on the chosen outcome scale’ and calculated the synergy index (SI) to disclose effect modification between the chosen variables (Studies I to IV), as proposed by Rothman and Greenland [93].

The following algorithm was used in which SI $> 1$ signifies a synergistic effect (representing a positive effect modification) and SI $< 1$ an antagonistic effect (representing a negative effect modification):

$$\text{SI} = \frac{(\text{OR}_{1+1} - 1)}{\text{OR}_{1+0} - 1 + \text{OR}_{0+1} - 1}$$

where:

$\text{OR}_{1+1}$ = odds ratio for dummy variable exposed to both factors

$\text{OR}_{1+0}$ = odds ratio for dummy variable exposed to one factor

$\text{OR}_{0+1}$ = odds ratio for dummy variable exposed to other factor

$\text{OR}_{0+0}$ = odds ratio for dummy variable unexposed to both factors

Significant effect moderation between two variables indicates that when both are present there is an amplified effect, i.e., the combination of the two indicators has a stronger effect, which is higher than added effect of the variables in question.
Results

The total sample comprised 2706 individuals, of whom 1954 participated in the study (72% of all registered undergraduates). The respondents included 1087 males (55.6%) and 867 females (44.4%).

Table 3 describes the socio-demographic factors, sexual behaviour variables, alcohol consumption, mental health, and outcome variables of risky sexual behaviours (contraceptive method used on latest occasion of sexual intercourse, recent experience of sexual coercion, inconsistent condom use, and number of sexual partners in the last 12 months).

A majority of females (63.1%) in our sample were younger than age 22. Fewer, males (49.6%) were under 22. Nearly 40% of the females grew up in a rural environment, whereas the corresponding percentage for males was 49%. A larger proportion of females (77.5%) came from a background in which the educational level of the head of household was above primary education. This was only true of 68.9% of the males. Sixty-three percent of those in our sample stated that religion played a major role in their family of origin. Nearly 31% of the males reported that they had debuted sexually at age 16 or before, whereas only 14.2% of the females stated the same. A considerable percentage of males (22.5%) and females (33.9%) reported an experience of sexual coercion.

More females (21%) than males (17%) did not use contraception on their most recent experience of sexual intercourse. Inconsistent condom use with a new sex partner was higher in females (49.2%) than in males (37.4%). The prevalence of multiple sex partners over the last 12 months among males (41.3%) was almost double that of females (22.5%). More males (66.2%) had previously had sex compared to females (60%). Almost, 23% of the males said they frequently consumed alcohol in relation to sex; the prevalence was lower in females (17%). Frequent consumption of alcohol over the last 12 months was again higher in males (11%) than in females (6.2%).

¹Only analyzed for those individuals who had sexual intercourse
²Only analyzed for those individuals who consumed alcohol
Study I

The aim of this study was to determine the relationship between socio-demographic factors, alcohol consumption, and types of partner(s) with non-use of contraception among Ugandan university students.

A total of 1,179 students (60.3% of the study population) reported that they had debuted sexually. Of these, 199 (18.6%) had not used contraception in their last sexual encounter. In the bivariate analysis we found an association between who were not currently in a relationship and non-use of contraception. This association continued to be statistically significant in the multivariate analysis among both males and females, even after adjusting for age, sexual debut, area of growing up, and educational level of head of household (Table 4). The socio-demographic determinants of age (22 or younger), early sexual debut (16 years or younger), and rural background were significant for males, but not for females. To further investigate the association, sexual debut was analyzed as an effect modifier. A synergistic effect was found between those not currently in a relationship and early sexual debut in its bearing on non-use of contraception among males and females (Table 5).

**Conclusion**

We found an association between those who were not in a relationship and non-use of contraception. The socio-demographic factors that affected this association differed for males and females. Early sexual debut modified the effect of this association.
Study II

The aim was to study the association between alcohol consumption and the experience of sexual coercion among Ugandan university students.

Of the 1954 students, we surveyed, 27.6% reported having experienced sexual coercion and 16.4% stated that they had had such an experience recently. Alcohol consumption over the past 12 months had a significant association with recent experience of sexual coercion for males (OR crude 2.14, 95% CI 1.38–3.32) and females (OR adjusted 2.29, 95% CI 1.40–3.72). The multivariate analysis indicated that there was possible confounding between alcohol consumption and poor mental health. It was also found that females older than 23 years were at a greater risk for being sexually coerced (Table 6).

The association between alcohol consumption on the occasion of sexual intercourse and recent experiences of sexual coercion showed considerable gender differences. Females had a higher risk (OR crude 5.65, 95% CI 2.24–14.22) compared to males (OR crude 2.53, 95% CI 1.27–5.05). This association remained significant even after adjusting for confounders (OR adjusted 1.79, 95% CI 1.05–.04) (Table 7).

To further investigate the association between alcohol consumption and recent experience of sexual coercion, we sought to determine whether mental health was an effect modifier and found that frequent alcohol use on the occasion of sexual intercourse in combination of poor mental health had a synergistic effect on recent experience of sexual coercion (Table 8).

Conclusion
From our findings we conclude that there was an association between alcohol consumption and a recent experience of sexual coercion. Frequent consumption of alcohol on the occasion of sexual intercourse and poor mental health were found to have a synergistic effect on recent experience of sexual coercion in our sample.

Study III

The aim of was to investigate the association between self-reported academic performance and risky sexual behaviours, and determine whether gender affects this relationship among Ugandan university students.

A total of 1,179 (60.3%) students reported having debuted sexually. Of these, 440 (42.2%) used condoms inconsistently with new sexual partners, and 344 (33.6%) had had multiple sexual partners. Table 9 shows an association between self-reported poor academic performance and inconsistent condom use, which was found to be significant in the fully-adjusted model (Model 7, OR adjusted 1.76, 95% CI 1.19–2.62). By contrast, the association between poor academic performance and multiple sexual partners was significant in the unadjusted model (Model 1). However, when adjusted for poor mental health, consuming alcohol on the latest occasion of sexual intercourse, and early sexual debut, the association became insignificant (OR adjusted 1.20, 95% CI .79–1.82) (Table 10).

To further investigate the association we used gender as an effect modifier. The analysis showed that the association between poor academic performance and inconsistent condom use was, modified by gender, resulting in an association that was stronger among females (Table 11). However, gender did not seem to modify the association between poor academic performance and having multiple sexual partners.

Conclusion

The results of this study suggest an association between self-reported poor academic performance and inconsistent condom use with a new sex partner, but no association was found with multiple sex partners. Females who were poor academic performers were at a higher risk of inconsistent condom use as compared to their male counterparts.
Study IV

The aim was to investigate whether gender differences in individual and social factors determine the association between condom efficacy and inconsistent condom use with a new sex partner, among Ugandan university students.

A total of 1,179 (60.3%) students reported having debuted sexually. Of these, 231 (37.4%) males and 209 (49.2%) females reported inconsistent condom use with a new sex partner. Table 12 presents the association between condom efficacy and inconsistent condom use (adjusted for the confounding factors of sex, age, rural origin, friends who always use a condom with a new partner, friends who have difficulty demanding a condom, less pleasure using a condom, multiple sex partners, and alcohol consumption in conjunction with sexual intercourse). In the fully-adjusted model, a statistically significant association persisted between low condom efficacy and inconsistent condom use (OR adjusted 3.94, 95% CI 2.20–7.05).

In Table 13, we tested gender as an effect modifier regarding the association between condom efficacy and inconsistent condom use. The result confirmed the possible synergistic effect of gender, i.e., female gender aggravated the impact of low condom efficacy on inconsistent condom use.

**Conclusion**

Study IV showed an association between low condom efficacy and inconsistent condom use with a new sex partner. Females with low condom efficacy were found to be at a higher risk of inconsistent condom use in comparison to males.
Discussion

The results of this thesis indicated various factors that can determine risky sexual behaviours. Inequitable gender power relations play a crucial role in this area, even among an educated Ugandan university population.

Our findings showed an association between socio-demographic factors, relationship status, alcohol consumption, academic performance, condom efficacy, and risky sexual behaviours, including sexual coercion, among those in our sample. However, there were considerable gender differences observed and some of the factors modified the effect of these associations. The socio-ecological model we used as a conceptual framework pointed to a number of individual, relationship, community, and societal factors that affect young people’s sexual behaviours. On an individual level, a person’s age, sex, mental health, condom efficacy, academic performance, alcohol consumption patterns, intention to use a condom, early sexual debut, and taking less pleasure in using a condom played a vital role in their behaviour. Proximal relationships with peers and sexual partners have a crucial influence on young people, and may affect their sexual decisions. As young university students, they might not have a good risk assessment of certain situations. On a community level, area of origin and social capital can contribute to their experiences, and may affect their behaviours. Societal factors such as religion, socio-economic status, and gender norms play a vital role in behaviours. Combined with existing gender inequalities these can also affect the sexual behaviours of young people. Gender norms are a societal construct but their impact cuts across all levels of society.

Gender norms have been explained by Connell’s theory of gender and power. It describes social structures such as the sexual division of labor, sexual division of power and the structure of cathexis (social norms and affective attachments by which men and women relate to each other in a society) as based on sexual inequality and a gender power imbalance between males and females [29]. Connell describes these structures on the institutional and societal level. An institutional level has discrepancies such as stereotypical or degrading pictures of women in the media, access to health care, and men controlling the family income [30]. The presence of these disparities, together with other social mechanisms, creates gender inequalities.

On a societal level social norms are maintained through mechanisms which limit men and women in the expression of their sexuality [30]. Social norms enforce strict gender roles and stereotypical beliefs that a women’s sexuality is for procreation only. They restrain a woman for example, from having multiple sexual partners, which is an accepted norm for men. Women who must live under such norms such as having
older partners, living in a family environment that is not supportive of HIV prevention, mistrusting the medical system, and forbidden access to contraception, are at increased risk of poor reproductive health outcomes [30].

Since Uganda has a young population, one must understand the effect these issues of gender and sexuality have on behaviour. Due to rapid globalization and mass media awareness, young people today have different exposures. University students in particular are suddenly exposed to a liberal environment and are away from parental control. Also, as they are in a phase where they are more prone to taking risks and exploring their sexuality, it may put them at risk of unwanted pregnancies and sexually transmitted diseases (STIs). Therefore, it is crucial that their concerns are addressed through appropriate channels.

University students have internalised gender norms, as is evident from a study conducted among Ugandan university students that revealed 32.5% of the males and 30%, of the females thought force is justified for obtaining sex in a relationship [44]. Moreover, 37% of the males thought that force is justified when you have spent money on your partner, and 28.8%, females were of a similar opinion. Gender power relations seem to play an integral role in a Ugandan society, and this may lead to poorer reproductive health outcomes for women.

There is a need to provide university students with sex education that addresses gender and sexuality. This may be a way forward towards having equal gender relations between males and females. We sought to determine the potential risk factors associated with certain sexual behaviours in this population, and especially the role gender plays in shaping its sexual behaviours.

In Study I, we found that the determinants for non-use of contraception differed between men and women. Students who were not in a relationship had a higher risk of not using contraception. Students, who were not in a steady relationship, were engaging in unplanned sexual activity. The non-use of contraceptive at that time could be due to lack of communication between partners or the non-availability of contraception. There is evidence from previous research that higher levels of intimacy and partner communication increases the probability of condom and contraceptive use [94].

Our findings for ‘type of partner’ and ‘length of relationship’ did not show any association with non-use of contraception. This was in contrast to previous literature which showed that individuals in steady relationships have a higher prevalence of contraceptive use due to better communication between partners [95-97].
In our study, females were found to be at higher risk for non-use of contraception when not in a relationship, as compared to males. A possible explanation might be that the socio-cultural factors and gender norms in Uganda, where men are the decisions makers (even regarding contraceptive use) which places women in a vulnerable position for negotiating safe sex [11]. We did not have information regarding the age of partners, but there is evidence from previous research in Uganda that there is a prevalence of transactional and cross-generational sex (i.e a considerably older man with whom women are in a sexual relationship for money or material goods, also known as ‘sugar daddies’) [90, 98]. These relationships create inequalities and power imbalances that may lead to sexual coercion and non-use of contraception. Such issues should be addressed when planning interventions.

The high rate of fertility rate (6.2) and teenage pregnancies (24%) [99] suggests that many sexually active young people in Uganda are not prepared to protect themselves from pregnancy. They may be unaware of how or where to obtain contraceptives. They may also lack knowledge about STIs due to barriers in accessing health care services [100]. This is supported by the results of Study I, where early sexual debut was found to have an independent association with non-use of contraception. Previous research in China and Uganda on young people shows that those who experience sex early in life are less likely to use contraception compared to those who begin at a later stage [101, 102]. Sex education at an early stage may be of prime importance, in Uganda, considering that nearly 12% of the males and 13% of the females there have sexually debuted by 15 years of age [99]. Early sex education might help combat unwanted pregnancies, STIs, and unsafe abortions later in life.

Alcohol consumption was found to be a risk factor for unsafe sexual behaviours in Studies I, III and IV (including sexual coercion as found in Study II). In a university environment where students socialize at bars and parties, excessive alcohol consumption may lead to risky sex or sexual coercion. As previous research on sexual coercion, has shown, it might be difficult to disentangle the direct effect of the alcohol consumed by the victim, from the effect of the setting or environment, in which perpetrators were also present [103].

Our specific findings regarding alcohol in relation to sex and its association with recent experience of sexual coercion could be due to various mechanisms. On a psychological and behavioural level, alcohol may decrease the risk perception and the ability to communicate assertively, making an individual more vulnerable to sexual coercion [50, 103, 104]. There are various theories about alcohol and risky sex, such as alcohol disinhibition [105] and alcohol myopia theory [56] suggesting a person might not be able to identify the potential dangers, including the risk of being sexually coerced.
We found some gender differences regarding this association, females who consumed alcohol were found to be at a higher risk of being sexually coerced compared to their male counterparts. The reason for this may be the gender norms prevalent in Uganda, where consuming alcohol by males is considered masculine, while alcohol consumption among females is perceived as a signal that they are available for sex [106]. These stereotypes become exacerbated by the gender inequalities in Ugandan society.

Little is known about self-reported poor academic performance as being a factor for risky sexual behaviours. Academic performance put a great deal of psychological pressure on young university students. Perhaps risky sexual behaviours are affected by poor academic performance. We did find an association between poor academic performance and inconsistent condom use in agreement with previous study conducted among undergraduate students in China among undergraduate students that found poor academic performance to be a risk factor for inconsistent condom use and having multiple sex partners [107].

Our association of poor academic performance with inconsistent condom use corroborates prior studies, although they were conducted in high income countries. In the (US) on adolescents with a high GPA score were prone to risky sexual behaviours, early pregnancies and substance abuse [108-110]. We feel these findings are even more appropriate in a university population, as students undergo considerable stress and may not be able to apply cognitive skills such as risk assessment to sexual behaviours, one result of which might be inconsistent condom use.

We did not find an association between poor academic performance and having multiple sexual partners. A possible explanation could be that poor mental health and alcohol consumption were acting as mediating factors. It may be that, due poor academic performance, students become depressed or visa-versa, and to compensate for their low self-esteem they might engage in risky sexual practices, alcohol, and substance abuse. There is prior research conducted in Uganda and South Africa which shows that these factors have a strong association with multiple sexual partners [111, 112].

Regarding the effect of gender, our findings were different for men and women, particularly for inconsistent condom use. Poor academic performance was found to be a higher risk factor for women than men. A possible reason for this could be that women lack self-esteem and feel that their value as a future partner or spouse has been lowered. As a result they are unable to negotiate condom use compared to females who are doing well academically, which strengthens their self-confidence and makes them feel more empowered to negotiate safe sex.
Condom efficacy is also another crucial factor that is known to increase in condom use among young people. Based on our findings there was an association between low condom efficacy and inconsistent condom use. The effect was considerably higher among women than men. There is evidence from previous research conducted in Tanzania, that shows that gender differences regarding predictors of condom use in relation to condom efficacy [113]. This could be due to the gender power relations in this region, as similar findings were found in previous studies conducted in South Africa, Botswana, and Angola [114, 115]. An explanation for this could be that condom use is equated with lack of trust by men, leading to fear of rejection by some women, who feel intimidated. The result may be non-use on condoms.

Among other individual factors ‘less pleasure when using a condom’ was associated with non-use of condoms, agreeing with evidence from a meta-analysis study where the prevalence of non-use was higher among males than females [116]. Contrary to previous research our findings regarding ‘intention to use a condom’ did not show any association with inconsistent condom use. This can be explained by the theory of planned behaviour, which shows that behavioural intentions are determined by attitudes, subjective norms, and perceived behavioural control. These may lead to substantial variation in actual behaviour, in different situations [74, 75]. Therefore, just having the intention to use a condom might not translate to behaviour in Uganda, where the traditional socio-cultural norms of non-condom use are so pervasive. Amid the feminization of the HIV epidemic in this region it is important to focus on improving condom efficacy to improve reproductive health indicators.

**Strengths and limitations**

One of the limitations of our study was that only 10% of all Ugandan young people attend tertiary education. Therefore, our findings might not be generalizable to the national population of Uganda. However, we do feel that our results may reflect the situation of other Ugandan university students. According to our calculations the statistical power of the studies was adequate for the main analysis, but was somewhat small for the effect modification analysis. As a result, no test of statistical significance was done on that analysis. We feel that we may have lost some information due to dicotomization of the variables. To reduce the response bias in our study, anonymity of the respondents was maintained, which may have increased truthful reporting and in turn, might have given more accurate results. Another potential limitation was that our questionnaire did not have information on the drinking patterns of sex partners or for the perpetrators of sexual coercion. We also lacked data to access the types of contraceptive methods used at first sexual intercourse or lifetime use, which could
have given us a better representation of the consistency of contraceptive prevalence in our sample.

One of the strengths of our study was examining the drinking patterns of the victims of sexual coercion and the effect these had on sexual coercion, whereas most previous research has investigated the opposite causal direction. We speculate that sexual coercion might be higher among non-responders, who may underreport in a survey, because of stigma attached to sexual coercion that may make them apprehensive in disclosing such details. Another limitation of our study was our assessment of condom efficacy. Since it was limited to two questions, it is possible that more information could have resulted in greater disclosure on the efficacy of the participants.

**Methodological considerations**

**Study design**

Our studies adopted a cross-sectional design, due to which we were unable to judge the causal direction for some of the associations analyzed in our studies. In studies I-IV it is more plausible that relationship status, alcohol consumption, poor academic performance, and condom efficacy might have led to risky sexual behaviour than vice-versa, since one needs to have a partner either to use or not use a contraceptive (Study I). In Study III, alcohol consumption might have led to sexual coercion. This can be supported by the mechanisms as discussed above on alcohol myopia [56] and alcohol disinhibition theory [55]. In Study IV, condom efficacy may have been necessary to determine the use or non-use of a condom.

**Selection and recall bias**

Our survey was directed towards all students at MUST. The response rate of 72% may leave some room for a selection bias. However, the reasons for non-participation do not appear to be linked to the exposure or the outcome, but were mainly due to logistical circumstances and could therefore be considered random. The internal missing data was represented as it was either stated in the dataset or could be random, possibly leading to some selection bias in an unknown direction. However, the probability of that drastically affecting our results is unlikely. The information for some of the sexual behaviour variables in our studies was retrospective, which may have led to a recall bias. Some of our findings may, therefore, have been underestimated due to the issue of social desirability.
Misclassification
Misclassification is one of the most common measurement errors in epidemiological research. It occurs when the exposure or the disease is wrongly classified, i.e., when an exposed individual is classified as unexposed or visa-versa [117]. Non-differential misclassification refers to errors in the classification of the exposure that are unrelated to the outcome or visa-versa. As a result, misclassification influences the effect towards the null, which leads to an underestimation of the effect. On the other hand, differential misclassification of the exposure occurs if the classification of exposure is influenced by outcome status (i.e. as a case or a non-case). The outcome in all our studies was risky sexual behaviours. As these are sensitive issues, we feel the prevalence of these behaviours might have been underreported due to the social desirability. Therefore, if this were the case of non-differential misclassification, it would have biased our findings towards the null.

Confounding
Confounding occurs when the effect of an exposure is mixed with the effect of another variable, possibly leading to underestimation or overestimation of the effect measured [118]. A variable is considered a confounder only under three conditions: it should have a) an association with the exposure, b) a causal association with the outcome, and c) not be a part of the causal pathway [119]. We adjusted for the confounding factors by adopting a step-wise multivariate analysis. As we adjusted for most of the obvious confounding factors, we feel that residual confounding would be of minor importance.
Conclusions and recommendations

Our studies reinforce the international awareness that the key issues affecting young peoples’ sexual and reproductive health outcomes are largely similar, but the mechanisms for addressing them need to be country specific.

The key factors that contribute towards risky sexual behaviours among Ugandan university students were socio-demographic factors, relationship status, alcohol consumption, academic performance, and condom efficacy. Unequal gender power relations between males and females played a crucial role in sexual relations, due to which women lacked the power to negotiate condom or contraceptive use. Therefore, they are at a higher risk for poor reproductive health outcomes such as STIs and unwanted pregnancies. Males, who are currently not the focus of programs in low- or middle-income countries, were also found to be at risk for unsafe sexual behaviours.

We need to create a policy action environment (not merely policies) in which sexual and reproductive health rights is addressed by raising awareness among males and females. In universities this could be achieved through skill building programs such as sex education, peer counseling, and partner communication, with a special focus on women by teaching them skills for negotiating condom and contraceptive use. These programs need to address the socio-cultural and gender perspectives in addition to focusing on safe sex and sexual rights. Improving access to health care services, fostering gender equality, encouraging safer sexual initiation will have a positive impact on the reduction of HIV transmission and unwanted pregnancies. Such empowering programs will help us achieve MDG 3 (Promote gender equity and empower women), MDG 5 (Improve maternal health), MDG 5b (Universal access to reproductive health), and MDG 6 (Combat HIV, malaria, and other diseases) on the country level.
Summary in Swedish

Det finns idag 1,8 miljarder ungdomar i världen och de utgör ungefär 25 % av jordens befolkning. De flesta av dem bor i låg- och mellaninkomstländer. Trots de åtaganden som världssamfundet tagit på sig i samband med FN:s befolkningskonferens 1994 och arbetet med att uppfylla milleniemålen, har dessa ungdomars behov av sexuell och reproduktiv hälsa inte tillgodosetts, vilket innebär allvarliga konsekvenser för ungdomars sexuella och reproduktiva hälsa.

I det andra delarbetet *Does drinking alcohol expose Ugandan university students to sexual coercion? A cross sectional study* utvidgas analysen avseende avhandlingens övergripande frågeställning till att specifikt analysera sambanden mellan alkoholvänor och erfarenheter av att ha varit utsatt för sexuellt tvång, vilket är vanlig bland unga personer i Uganda, särskilt kvinnor. Ett samband kunde konstateras mellan alkoholkonsumtion och nyligen upplevt sexuellt tvång, vilket potentiades i närvaro av symptom på psykisk ohälsa. Även dessa fynd sätts in i ett genusperspektiv och möjligheten att förebygga sexuellt tvång och hög alkoholkonsumtion i universitetsmiljön diskuteras.

I det tredje delarbetet med titeln *Association between self-reported academic performance and risky sexual behavior among Ugandan university students - a cross sectional study* analyseras hur en viktig stressfaktor i universitetsmiljön, bristande framgång i studierna, påverkar sexuellt risktagande och hur detta samspelet med andra bestämningsfaktorer för sådant beteende. Ett statistiskt signifikant samband mellan bristande framgång i studierna och låg kondomanvändning kunde konstateras för hela studerandegruppen. Detta samband var emellertid mer framträdande bland kvinnorna än bland mannen, och olika genusrelaterade förklaringsmodeller till detta diskuteras.

I det fjärde delarbetet med titeln *Inconsistent condom use with a new sexual partner among Ugandan university students in a gender perspective- a cross sectional study* fördjupas analysen av bestämningsfaktorer för kondomanvändning i den studerade gruppen. Syftet med studien var att ur ett genusperspektiv undersöka hur individuella och sociala faktorer påverkar sambandet mellan så kallad “condom efficacy” (den egna bedömningen hur väl man anser sig kunna föreslå och använda kondom i samlagssituationen) och inkonsekvent användning av kondomer. Den beteendefaktor som framstod tydligast för både män och kvinnor, var just “condom efficacy”. Även detta samband var tydligare för kvinnorna i undersökningen, jämfört med männen. Detta diskuteras i förhållande till hur traditionella genuserelationer påverkar effekten av “condom efficacy”.

Slutsatsen från studierna är att de viktigaste faktorerna som bidrog till sexuella riskbeteenden bland ugandiska universitetsstudenter var sociodemografiska faktorer, civilstånd, alkoholkonsumtion, studieresultat samt kondomanvändning. Ojämlika maktrelationer mellan könen i regionen utgjorde också en bidragande faktor till sexuella riskbeteenden. Det är således viktigt att skapa en policymiljö (inte bara politisk) i vilken sexuell och reproduktiv hälsa och rättigheter adresseras genom att öka medvetenheten bland män och kvinnor. Bland universiteten kan detta uppnås.
genom kapacitetsutvecklande program såsom sexualundervisning, kamratrådgivning och partnerkommunikation- med särskilt fokus på att stärka unga kvinnors inflytande i förhandlings situatio nen kring användandet av kondom och andra preventiv medel. Förutom att fokusera på säker sex och sexuella rättigheter måste sådana program även ta itu medrädande genusnormativa och sociokulturella aspekter.
Acknowledgements

I would like to extend my warmest gratitude to all those people who have guided and supported me in the completion of my thesis work, and in particular to following:

Per-Olof Östergren, my supervisor, for your impeccable scientific knowledge and sharp constructive criticism which pushed me to think and perform better. This has been a great foundation of learning that has made me aspire to higher goals and will go a long way in my professional career. I also enjoyed our stimulating discussions and the hilarious stories from your past experiences.

Anette Agardh, my co-supervisor, for your guidance, critical comments and insightful questions that challenged me to improve my work and for your help during crisis. I appreciate your permission for letting me have access to your Ugandan dataset. A special heartfelt thank you for being there, even for personal matters when my parents were not around.

Karen Odberg Pettersson, co-author, for immense support, dedication, wise comments, and encouragement during my journey.

Martin Stafström, co-author, for your sharpness and contributions that always added a new dimension to my thought process.

Bjorn Ekman, co-author, for your valuable insights and generous contributions to my work.

Emmanuel Kyagaba, co-author, for sharing your knowledge and a much needed Ugandan perspective to this thesis.

Maria Emmelin, for your warmth, support and encouragement. I appreciate the courage you possess to express your opinions and for all the positive energy you bring to the work environment. Also, special thanks for introducing me to the Swedish Research School for Global Health and for agreeing to be the chair at my PhD defense.

Anders Emmelin, for being a wonderful colleague and for accepting to be the opponent for my pre-PhD defense.
Elizabeth Cantor-Grace, for sharing your knowledge and experience answering my questions in the middle of your work, and for your interest and love for my native country.

Charlotte A Larsson, for being a helpful colleague and for teaching me epidemiology.

Mahnaz Moghaddassi, for your kindness and all the statistical support you have provided over the years.

Kontie Moussa, for always being so cheerful and telling me to ‘work hard for that one day when you graduate and all this hard work seem worth it’. Every time I felt low, I thought of this and took a step further.

Vikas Choudhry, for being such an integral part of my professional life. This thesis would not have been what it is if it were not for the endless discussions we have had in the past few years. Heartfelt thanks for being like my family in Sweden. You truly filled the void of all the relations I missed back at home.

Benedict Oppong Asamoah, for being friendly, modest, humble and for the immense support you provided whenever it was needed. Your dedication and work ethic is admirable.

Mats Sundbeck, for your friendship and for all the humor you bought to our PhD room.

Markus Larsson, for always being so caring and supportive, professionally and personally. I enjoyed all the fun times we had together.

Faisal Hazza Al-Emrani, for your support and always being around when we were sharing similar situations from the start of this journey to the finish line.

Susanne Sundell-Lecerof, a great friend and colleague. I truly admire your strength for handling tough situations and also for being a great support

Georgios Gavriilidis for your friendly and helpful presence during my journey.

Jenny Arfwedson, for your warmth and concern, especially times of crisis, as when I fractured my hand.

Cecilia Fernbrant, for being so warm, supportive, a patient listener and whose sensitive eye could see when I was feeling low.
Becky Nelson, for contributing towards my work and for always being there when I needed a friend. Thank you so much for helping me make new friends in Sweden.

Ditte Mårtensson, for all the support, warmth, and love that is beyond words, and for always going that extra mile in helping out in every little thing professionally and personally.

Maria Scherling, for being so lovely and sweet to me throughout my journey.

Sanna Melin Schyllert, for being such a warm and loving friend. I truly admire the clarity of your vision towards life and the perfectionism you try to bring in everything you do.

Linda Palmqvist, for always being so warm, fun, and present whenever I needed a friend. You made up for all the girlfriends I left at home.

Elena Lirakis, for being so helpful and kind, for being the first friend I made in Sweden, and for introducing me to salsa.

Teddy Primark, for working so efficiently in proof reading my thesis. It has been a great learning experience which will go a long way in my academic writing.

A special thanks to the research team and all the students at MUST who participated in the survey, without which these studies would not have been possible.

Sunil Mehra and Beenu Mehra, my parents, for whom words will never suffice to thank you for your boundless love, warmth, encouragement and believing in me when I myself did not. I hold all the values you have given very me close to my heart. I cherish you as the best parents in the world.

Ruchika Jain, my sister, for all the love and concern you show, in the sweet gestures and the little things you do for me. I have truly missed you around in these years.

Kushal Jain, my brother-in-law, for your love, support and guidance whenever it was needed.
