11   **Abstract**
12
13   People who suffer from swallowing disorders, commonly referred to as dysphagia, are often
14   restricted to a texture-modified diet. In such a diet, the texture of the fluid is modified mainly
15   by the addition of gum or starch-based thickeners. For optimal modification of the texture,
16   tunable rheological parameters are shear viscosity, yield stress, and elasticity. In this work,
17   the flow properties of commercial thickeners obtained from major commercial suppliers were
18   measured both in shear and extensional flow using a laboratory viscometer and a newly
19   developed tube viscometry technique, termed Pulsed Ultrasound Velocimetry plus Pressure
20   Drop (PUV+PD). The two methods gave similar results, demonstrating that the PUV+PD
21   technique can be applied to study flow during the swallowing process in geometry similar to
22   that of the swallowing tract. The thickeners were characterized in relation to extensional
23   viscosity using the Hyperbolic Contraction Flow (HCF) method, with microscopy used as a
24   complementary method for visualization of the fluid structure. The gum-based thickeners had
25   significantly higher extensional viscosities than the starch-based thickeners. The rheological
26   behavior was manifested in the microstructure as a hydrocolloid network with dimensions in
27   the nanometer range for the gum-based thickeners. The starch-based thickeners displayed a
28   granular structure in the micrometer range. In addition, the commercial thickeners were
29   compared to model fluids (Boger, Newtonian and Shear-thinning) set to equal shear viscosity
30   at $50s^{-1}$ and it was demonstrated that their rheological behavior could be tuned between highly
31   elastic, extension-thickening to Newtonian.

32   **Practical applications**
33   Thickeners available for dysphagia management were characterized for extensional viscosity
34   to improve the understanding of these thickeners in large scale deformation. Extensional
35   deformation behavior was further explained by using microcopy as corresponding technique
36   for better understanding of structure/rheology relationship. Moreover the major challenge in
37   capturing human swallowing process is the short transit times of the bolus flow (<1 second).
38   Therefore the ultrasound based rheometry method; PUV-PD which measures the real-time
39   flow curve in ~50ms was used in addition to classical shear rheometry. The two methods
40   complimented each other indicating that the PUV-PD method can be applied to study the
41   transient swallowing process which is part of our future research, where we are studying the
42   flow properties of fluids in an *in-vitro* swallowing tract.

1. Introduction

Dysphagia, which refers to swallowing disorders in general, has various causes, such as brain damage, post-stroke complications, Parkinson´s disease, and trauma (Clavé *et al.*, 2006). Approximately 8% of the global population suffers from dysphagia(Steele, 2015). Dysphagia is a growing concern in the developed world due to the aging population. Currently in Europe, about 17% of the population is ≥65 years of age. This segment of society has increased by 28% during the past 10 years, as compared to the remainder of the population, which has increased only 0.8%. It is estimated that in general, 30% of individuals who are ≥65 years of age and 40% of persons who are registered at care facilities suffer from dysphagia (Ekberg *et al.* (2002). Thus, there is an urgent need for research into new therapies for swallowing disorders.

During normal swallowing, rapid transfer of food or drink from the mouth to the stomach takes place without misdirection into the airways (Bülow, 2003). Dysphagics are challenged by the fast and turbulent flow of liquids through their oropharynx (Cichero, 2013), and they have been reported to aspirate when the velocity of water in the pharynx increases to 0.5 m/s (Tashiro *et al.*, 2010). This makes texture modification an important consideration for reducing the fast flow of fluid through the pharynx. A thickened diet is a common food-based strategy to manage dysphagia. The underlying idea is that a viscous food bolus travels with lower velocity, thereby providing more time for the oropharyngeal apparatus to close (Moret-Tatay *et al.*, 2015; Steele, 2015; Tashiro *et al.*, 2010). However, highly viscous liquids require the exertion of more force by the tongue to push the bolus through which may increase the chances of post-swallow residues (Clavé *et al.*, 2006; Steele, 2015). A recent White Paper published by the European Society for Swallowing Disorders suggests that more rheological parameters should be investigated as part of the bolus modification strategy, such as extensional viscosity and yield stress (Newman *et al.*, 2016). Thickener-based powders, which can be either gum or starch-based, are available in the market (Mackley *et al.*, 2013). These thickeners are added to liquids to thicken the texture and promote ease of swallowing (Tatay *et al.*, 2015). Gum-based and starch-based thickeners differ in the way that they absorb water. Starch-based thickener swells, while a gum-based thickener creates a network that entraps water upon hydration. Gum-based thickeners are less susceptible to viscosity modification during oral processing, whereas starch-based thickeners are modified by the amylase enzyme in the saliva resulting in reduced viscosity (Leonard *et al.*, 2014).

Thickeners need to be classified to provide guidelines to healthcare professionals for the preparation of foodstuffs with different consistencies. Different countries have developed their scales for the consistency ranges of thickened products for treating dysphagia. The protocol is set in the US by the National Dysphagia Diet (NDD), in Australia by the Dietitians and Speech Pathology Associations, and in the UK by the British Dietetic Association (Popa Nita *et al.*, 2013). The NDD guidelines, which are the most widely used, consider the shear rate of 50 s^{-1} (as being relevant for swallowing) and a temperature of 25°C as reference. Moreover, the NDD guidelines categorize the food products on the basis of apparent shear viscosity at 50 s^{-1} on the range from as thin as water (1-50 cP) to the consistency of pudding

86   (>1750 cP). Alternative scales rely on subjective terms, such as nectar-like and pudding-like
87   and are not so popular (Quinchia *et al.*, 2011). The NDD scale has been criticized for not
88   considering the shear rate-dependence and the extensional properties of the food (Zargaraan *et*
89   *al.*, 2013), the latter referring to the ability of a material to resist extensional flow. Studies
90   have shown that a food bolus is subject to both shear and extensional flow during swallowing,
91   and also when the bolus is compressed between the tongue and the soft palate (Chen *et al.*,
92   2011; Hasegawa *et al.*, 2005; Salinas-Vázquez *et al.*, 2014). The swallowing literature refer to
93   this as cohesiveness of the bolus, and there is some confusion whether the mechanism is fluid
94   elasticity as expressed by the extensional viscosity or if there could also be an effect of the
95   yield stress. A cohesive food fluid has been concluded to resist disintegration during
96   swallowing reflux, thereby reducing the risk of post-swallowing residues (Chen *et al.*, 2011;
97   Ishihara *et al.*, 2011). However, unlike the shear response , the extensional rheology of the
98   food has been largely neglected (Chen, 2009). The main reason being the lack of appropriate
99   experimental techniques (Chen, 2009). A general challenge in extensional flow is to achieve a
100   steady state (Petrie, 2006), and the measured extensional viscosity is in reality always
101   transient. A measurement system such as the Hyperbolic Contraction Flow (HCF) technique,
102   has been developed which is suitable for medium-viscosity fluids (Stading *et al.*, 2001;
103   Wikström *et al.*, 1999a). This technique has been applied to various food systems such as
104   dough/dairy products (Andersson *et al.*, 2011), bread (Oom *et al.*, 2008) and ketchup (Berta *et*
105   *al.*, 2016) as well as to polymer melts (Köpplmayr *et al.*, 2016).
106
107   The technique utilizes a flow through a hyperbolic nozzle designed to have constant extension
108   rate. The calculation of the extensional viscosity from the measured force on the nozzle and
109   the given extension rate assumes a Power-law fluid (Debbaut & Crochet, 1988). The
110   contribution of shear is small for a shear-thinning fluid and is subtracted from the total
111   measured stress (Wikström *et al.*, 1999a). The HCF method gives the transient extensional
112   viscosity for a given extension rate at fixed Hencky strain. A precise determination of the
113   extensional flow in the hyperbolic nozzle requires comparative simulations, but the simplified
114   determination using the assumption of a Power-law fluid has proven to be good (Nyström *et*
115   *al.*, 2012). The method has also recently been validated against other methods for polymer
116   melt samples (Köpplmayr *et al.*, 2016).
117   The human pharynx has a complex geometry that ranges in shape from tubular to elliptical,
118   with dimensions 5–6 cm and 2.8–3.0 cm (Walsh *et al.*, 2008). Since swallowing is a dynamic
119   process, it is imperative to study it in real-time and in the context of a relevant geometry. In-
120   line Pulsed Ultrasound Velocimetry (PUV) combined with Pressure Drop (PD) is an advanced
121   version of tube viscometry. Originally developed to study human blood flow, this technique
122   has subsequently been applied successfully in many food applications (Reinhardt Kotzé *et al.*,
123   2013; Wiklund *et al.*, 2008). Examples of applications include: chocolate tempering (Dufour
124   *et al.*, 2007), dairy products/xanthan gum (Wiklund *et al.*, 2008); and improving the flow of
125   tomato ketchup (Dogan, 2002). An advantage as compared to rotational viscometers is the
126   real time determination of the flow curve which is measured approximately every 50 ms. In
127   the present study, we apply the technique for the first time towards characterizing the
128   thickeners used in dysphagia management, as well as the model fluids.

The main aim of this study was to characterize commercial thickeners for dysphagia management for clinically relevant rheological parameters, such as shear viscosity, extensional viscosity and yield stress. We further compared existing laboratory rheometry to advanced tube PUV+PD viscometry, which mimics the nearly tubular geometry present in the swallowing tract. The thickeners were also characterized for microstructural properties. The results from the rheological analyses of the commercial thickeners were compared with model fluids serving as a reference in the current study since they were standardized for elasticity and viscosity. The present study is the first in a series aimed at the construction of a laboratory-based human swallowing tract that could be used to study the flow properties of model fluids, dysphagia products, and general foodstuffs in a pharyngeal swallowing geometry using the PUV+PD method.

2. Materials and Methods

2.1 Materials

Five commercially available thickener products designed for patients with dysphagia were kindly provided by the suppliers: Nutilis powder from Nutricia Nordic AB, Stockholm, Sweden (denoted herein as Nutilis); Fresubin® Clear thickener from Fresenius Kabi GmbH, Bad Homburg, Germany (Fresubin Clear); Findus thickener from Findus Sweden AB (Findus); Nestlé Resource® Thicken-up™ (Nestlé Thicken-up); and Nestlé Resource® Thicken-up™ Clear (Nestlé Clear) from Nestlé Health Science Center, Stockholm, Sweden. The syrup used in the study was Lys Syrup (84% sugar) from Dan Sukker, Malmö, Sweden, the xanthan gum (Grinsted Xanthan CLEAR 80) was supplied by Danisco France SAS (Melle, France), and the poly(acrylamide) (PAA) was supplied by ACROS Organics.

2.2 Sample preparation

A large volume of the thickener solution (~2 liter) was prepared by mixing the sample with tap water following the manufacturer's guidelines to achieve a honey-like consistency (according to the NDD scale) using a magnetic stirrer until complete homogenization was achieved (about 1 hour). The thickeners are used in elderly care centers to thicken fluid food and therefore are expected to be highly soluble. Shear viscosity was adjusted within the honey consistency range (0.35-1.75 Pa.s) specifically to 0.55±0.03 Pa.s (Table 1) at a shear rate of 50 s^{-1}. The amounts of powder that were used to achieve the desired shear viscosities (Pa.s) are listed in Table 1. The model Newtonian, Boger, and shear-thinning fluids were made by diluting the syrup with water to achieve the targeted viscosity of 0.55 Pa.s at a shear rate of 50 s^{-1}, with subsequent mixing (in the case of the Boger and shear-thinning fluid) with a concentrated solution of either the xanthan gum or PAA polymer (Table 1). Finally all the samples mixed were degassed before mixing using a vacuum pump, D-82178 from ASF-THOMAS: Munich, Germany.

[Table 1 here]

Separate sample preparation was performed for microscopy. The given thickeners were dispersed in deionized water on % w/w basis in different concentrations depending upon the thickener structure visualization (table 1) and stirred constantly for 4 to 8 hours until they were dissolved completely. All the samples were mixed at room temperature (~25°C) except for Findus where higher temperature (~65°C) was used since it was not easily soluble at room temperature.

3. <u>Rheological measurements</u>

3.1 *Shear rheology measurement (Flow curves and yield stress)*

The shear rheology of the samples was measured for shear rates ranging between 1 to 1000s^{-1} to cover the entire shear rate range mentioned in the literature, using an ARES-G2 (TA Instruments, New Castle, DE, USA) equipped with a cone and plate geometry with a diameter of 40 mm and cone angle of 0.04 rad. The yield stress was measured using the Reologica Stresstech HR (Reologica AB, Lund, Sweden) stress-controlled rheometer. Flow measurements were performed by the continuous increase of the shear stress. The stress value at which the two tangents crossed was considered as the yield stress value (Moller *et al.*, 2006). The yield stress was also determined from the flow curve by curve fitting of the Hershel-Bulkley model

$$\tau = \tau_0 + K(\dot{\gamma})^n \qquad (1)$$

where τ denotes the shear stress, τ_0 the yield stress, $\dot{\gamma}$ the shear stress while 'K' and 'n' are constants. Stresstech instrument was equipped with concentric cylinders (bob and cup geometry) with the cup radius,R_c=13.5 mm and bob radius, R_b=12.5 mm. All the rheological measurements were performed at 25°C as recommended by the NDD standards.

3.2 *Advanced tube viscometry, PUV+PD (Flow curves and yield stress)*

The real-time velocity profile was monitored with advanced tube viscometry using PUV+PD measurement to acquire the flow curve (Flow-Viz, Gothenburg, Sweden). The method and the system are described in detail elsewhere (R Kotzé *et al.*, 2015; Wiklund *et al.*, 2007; Wiklund *et al.*, 2008). In the present study, the sample was mixed in the product tank with an agitator (Fig. 1).

[figure 1 here]

Flowing of the sample was initiated by the positive displacement pump through a stainless steel pipe. The shear stress (τ) at the wall and the radial shear distribution inside the tube are determined from the pressure drop (Δp) across a fixed length (l =0.6m) and radius (r=0.011 m) of the tube (Fig. 1) using the relationship:

212
$$\tau = \frac{r\Delta p}{2l} \qquad (2)$$

213 Two ultrasound sensors were used to capture the velocity profile. The shear rate was
214 calculated from the gradient of the measured velocity profile. The PUV+PD software
215 measures the complete inline viscosity profile. Moreover, the software can post-process the
216 data and measure the yield stress from the pressure drop and plug radius data as

217

218
$$R = 2I\tau_0/\Delta P \qquad (3)$$

219 where R is the radius of the plug, and l is length of the pipe in which the fluid is flowing.
220 Thus, real time estimation of the yield stress can be performed with PUV+PD.

221 3.3 *Extensional rheology measurement using Hyperbolic Contraction Flow*
222

223 The transient extensional viscosity of the thickened solutions was determined by the HCF
224 method using an Instron 5542 (Instron Corp., Canton, USA). The method used is thoroughly
225 described elsewhere (Nyström *et al.*, 2012; Stading *et al.*, 2001; Wikström *et al.*, 1999a).
226 The hyperbolic nozzle used for the measurement had an inlet radius of 10 mm and outlet
227 radius of 0.78 mm. The maximum Hencky strain was in the range of 3.6–8.7 depending on the
228 fluid tested. The power law parameters (K and n) from equation 4
229

230
$$\sigma = K\dot{\gamma}^n \qquad (4)$$

231 Required to subtract the contribution of shear stress σ to the total measured stress were
232 determined from the flow curves measured in the ARES-G2 by fitting the data to the Power
233 law model. Each measurement was performed in triplicate and the relative standard deviation
234 was <3.7% between measurements for all samples tested.

235

236 3.4 Microstructural characterization
237

238 3.4.1 *Mica sandwich technique and transmission electron microscopy (TEM)*
239

240 The microstructure of a diluted thickener (Table 1) was determined using the Mica Sandwich
241 Technique described in detail by Barreto et al. 2013 (Barreto *et al.*, 2013). TEM was used to
242 analyze the replicas under the LEO 706E microscope (LEO Electron Microscopy Ltd.,
243 Cambridge, England).

244 3.4.2 *Light microscopy (LM)*

245 The starch-based thickeners, Nestlé Thicken-up and Findus, were analyzed using light
246 microscopy, revealing that they had structure at micro-meter scale compared to nano-meter
247 scale for the xanthan-based thickeners. Two staining methods were used: Lugol's iodine
248 solution for starch; and a mixture of Lugol's iodine and Light Green solution (1:1) for both
249 starch and protein. Lugol's iodine stains amylopectin a pink-to-brownish color and amylose

250 purple, whereas Light Green stains proteins green. The light microscope used was a Nikon
251 Microphot-FXA (Nikon, Tokyo, Japan), together with an Olympus Altra 20 color camera
252 connected to a computer and operated using the Olympus cellSens Dimension software
253 (Olympus Soft Imaging Solutions GmbH, Münster, Germany).
254

255 **4.   Results and Discussion**

256 4.1   Microstructure

257 TEM and LM were used to visualize the fine structures of the xanthan gum and starch in the
258 commercial thickeners (Fig. 2). The xanthan gum-based thickeners, Fresubin (Fig. 2A and D),
259 Nestlé Clear (Fig. 2B and E) and Nutilis (Fig. 2C and F), formed transparent solutions which
260 meant that no microstructure could by observed by LM due to the limiting resolution of about
261 1 µm. With TEM at high magnification, a main mesh-like network structure was observed
262 (Fig. 2A, B and C). At even higher magnification thin filaments were observed as shown in
263 the micrographs (Fig. 2D, E and F). The main component of the gum based thickeners is
264 xanthan gum, while the manufacturers do not specify other biopolymers present. The thin
265 filaments correspond well with the structure of xanthan helices previously visualized with the
266 same microscopy technique (Lundin *et al.*, 1995).   The starch-based thickeners were
267 analyzed at a lower magnification using LM to accommodate the starch-based microstructure.
268 They were not visualized by TEM because the microstructure is too heterogeneous. In Nestlé
269 Thicken-Up (Fig. 2G), only slightly swollen starch granules were noticed. Most of the
270 granules stained light-brown, indicating that they contain amylopectin, and a few starch
271 granules stained purple, which indicates that amylose had leached out. The granule structure
272 was at largely retained indicating a low degree of gelatinization. The Findus sample showed
273 some starch granules that stained purple and a protein network that stained green (Fig. 2H).
274 Moreover, unstained fat droplets were observed in the sample. The Findus thickener is not a
275 single thickener-based product, in addition to the starch, protein and fats contribute to the
276 microstructure and fluid consistency.

277 [Figure 2 here]

278 4.2   Shear rheology by viscometry and PUV+PD

279 The thickeners and the model fluids were characterized using laboratory-based viscometry as
280 well as advanced tube viscometry (PUV+PD) with tube dimensions that resemble those of the
281 pharynx. The latter was mainly included in the study to demonstrate to the clinical dysphagia
282 community that a flow in a tube, such as the pharynx can be evaluated with both methods, as
283 well as a basis for our future studies of flow in the pharynx using the ultrasonic techniques
284 where we want to utilize the real time ability to determine flow curves in transient flows.

285 4.2.1   Flow curves in shear rheology (Lab-based and PUV+PD)

286 Thickeners used for dysphagia management and model fluids were characterized using
287 laboratory-based viscometry as well as advanced tube viscometry (PUV+PD) with tube
288 dimensions that resemble those of the pharynx. Figure 3(A–C) and Table 2 show that the flow

289 curves derived from the two methods overlapped well with similar power-law K and n values
290 for all the thickener-based and model fluids. The gum-based thickeners were the most shear-
291 thinning (Fig. 3A), with the lowest shear thinning indices noted for Nestlé Clear (n=0.19) and
292 Fresubin Clear (n=0.19), followed by Nutilis (n=0.33). The starch-based thickeners (Fig. 3C),
293 Nestlé Thicken-up and Findus, were the least shear-thinning, showing higher n values of 0.39
294 and 0.61, respectively. The shear thinning index for the Newtonian and Boger fluids was as
295 expected 1 for both the methods. The model fluids (shear thinning with either PAA or xanthan
296 gum) were not measured using the PUV+PD method due to the limited capacity of the pump
297 used in the current study to propel such highly viscoelastic fluids.

298 [Figure 3 here]

299 [Table 2 here]

300 The results show that the PUV+PD method in a clinically relevant geometry gives the same
301 results as classical viscometry. Furthermore, the PUV+PD method gives a complete flow
302 curve in 0.19-1.35 ms and can thus be used in fast transient flows such as for a bolus passing
303 the pharynx in about a second. The main limitation of the method is that air may be
304 introduced during pumping thus transforming a surface active fluid to foam.

305 The flow behavior index for the model shear-thinning xanthan gum polymer was n=0.22 and
306 for the shear-thinning PAA was n=0.79, as assessed by the laboratory viscometry. The model
307 fluids used in the study serve as a reference, since they are based on a single elastic polymer
308 (PAA or xanthan gum) and a Newtonian fluid (either syrup or water) system, thereby
309 eliminating the interference effects of other polymers used in the commercial powders. In
310 addition to the food-grade elastic polymer xanthan gum, PAA was also used in the model
311 fluids (PAA). The PAA is not a food grade polymer but is much more elastic than xanthan
312 gum (Jones *et al.*, 1989). The use of PAA allows the study of high-level elastic effects. These
313 model fluids are also planned to be used in the future to study the influence of high
314 extensional viscosity in relation to swallowing.

315 All the fluids used in the present study were thickened to syrup consistency (range, 0.35−1.75
316 Pa.s), as recommended by the NDD, and more precisely to a viscosity of 0.55±0.03 Pa.s at a
317 shear rate of 50 s^{-1} for the reason mentioned earlier. Gum-based xanthan solutions are strongly
318 shear-thinning owing to their rigid-rod polymer conformation in solution. This means that a
319 xanthan-based thickener is perceived as being less thick as the shear rate increases during oral
320 processing. It should also be noted that starch-thickened foods are susceptible to reductions in
321 thickness during oral processing through the action of the amylase in saliva, thus reducing the
322 effective viscosity during swallowing. Moreover, less xanthan gum than starch was needed to
323 acquire the set viscosity of 0.55 Pa.s in the current study.

324 It should be noted that shear-thinning is less pronounced in PAA-based model fluids. This is
325 because PAA is a highly compact molecule with very strong intramolecular bonding, and the
326 shear flow, which is considered to be a "weak flow", is not sufficient to stretch the polymer.
327 Hence large extensional deformation, as applied in the present study, is needed to study the
328 flow properties of PAA in detail.

329   4.2.2 Yield stress in shear rheology (Viscometry and PUV+PD)

330   Yield stress for the thickeners and model fluids was considered during measurements since
331   previous publications (Marcotte, 2001; Steele, 2014) have proposed yield stress as a
332   contributing factor to bolus cohesiveness and therefore yield stress has to be considered in
333   addition to other parameters to alleviate aspiration. The yield stress values were determined
334   by viscometry and the PUV+PD method and are presented in Table 2. Figure 4 presents an
335   example of determination of yield stress with laboratory rheometer for the sample having the
336   highest yield stress value; Fresubin Clear. The value is taken at the stress value when two
337   tangent lines intersect each other at the point of sudden drop in shear viscosity and the
338   consequential increase in shear rate. The two methods gave similar values and the small
339   differences were not statistically significant ($P>0.05$).

340   [Figure 4 here]

341   Generally the samples composed of xanthan gum had higher values for the yield stresses in
342   the order Fresubin Clear>Nestlé Clear>Nutilis and no or negligible yield stress was detected
343   in the starch-based thickeners (Nestlé Thicken-up and Findus). The yield stress depends on
344   the structure of the thickener fluid and the exact composition of the commercial fluids is not
345   known. However, from the microscopy images in Fig. 2 it is clear that the gum-based
346   thickeners have a well-developed network structure at rest.

347   The model xanthan gum fluid had a yield stress of 13 Pa which is similar to the reported value
348   of 10 Pa by Marcotte and coworkers (Marcotte, 2001). Furthermore the yield stress noticed in
349   model xanthan-gum system confirms observed yield stresses noticed in the gum-based
350   thickeners. The yield stresses of the PAA based model fluids (Boger and shear thinning) were
351   negligible and similar results were reported by Yang (Yang, 2001). Yield stress has been
352   proposed to be responsible for the "binding properties" of xanthan gum in dysphagia
353   management (Marcotte, 2001). In the swallowing context, this binding property is expected to
354   promote a cohesive bolus structure, thereby reducing the risk of premature disintegration of
355   the bolus during swallowing. The pressure gradient created as the bolus is squeezed between
356   the tongue and palate is essential for causing the bolus to flow across the oropharynx (Steele,
357   2014). Therefore, the higher the yield stress, the greater the force needed to initiate the flow.
358   This means individuals with weak swallowing reflux may suffer from post-swallow residues
359   in case they swallow food of very high yield stress or they have reduced capacity to generate
360   appropriate tongue pressure as mentioned by the group of Becker (Becker *et al.*, 2015).
361   However, during oral processing and swallowing, the bolus is never static and therefore the
362   overall stress required exceeds the yield stress at the levels measured by Steele and coworkers
363   (Steele, 2014). While it has been shown by Alsanei and Chen (Alsanei *et al.*, 2014) that the
364   average maximum tongue pressure generation capacity decreases with growing age, the study
365   conducted by Steele (Steele, 2014) noted that the senior citizens (aged 70 years) still can
366   generate enough tongue pressure to handle a honey-thick consistency bolus at the shear rate of
367   50 s^{-1} studied herein. Therefore we believe the yield stresses noticed in the present work is
368   less likely to influence the swallowing process overall. While the yield stresses measured with
369   two different methods gives relatively identical values, the PUV-PD method has the

370 advantage of being independent of any possible wall slip, since the yield stress is determined
371 from the radius of the plug not in direct contact with the wall. Moreover PUV-PD mimics the
372 flow geometry of the pharynx.

373 Yield stress is an important characteristic in many food systems such as in ketchup and
374 mayonnaise, (Berta *et al.*, 2016) however the measurement of yield stress is not straight
375 forward. Many difficulties such as wall slippage arise during measurement and a detailed
376 discussion on these difficulties has been discussed elsewhere. (Barnes, 1995; Walls *et al.*,
377 2003). In the current work, bob and cup geometry was used since the results matches better
378 with the ones from PUV-PD method and we believe the PUV-PD method addresses the wall
379 slip condition in a better way.

380 4.3   Extensional flow

381 The HCF method was applied to measure the extensional viscosity of the given products.
382 Extension rates were varied from 1–$100\ s^{-1}$ (Fig. 5) for all the fluids. The extensional
383 viscosity of the thickeners (Fig. 5A) was measurable even at an extension rate $<10\ s^{-1}$, which
384 was not the case for the model fluids. The thickener-based and model fluids behaved
385 differently in extensional flow. The xanthan-based thickeners were more elastic than the
386 starch-based thickeners, while the model fluids (Fig. 5 b) made with PAA (Boger and shear-
387 thinning) showed extension-thickening, whereas 2% xanthan gum exhibited extension-
388 thinning behavior. The extensional viscosity corresponds well with the presence of the
389 xanthan dominated network structure shown in Figure 2A-F.
390
391 [Figure 5 here]
392
393 We have previously shown that the extensional viscosity of xanthan gum fluids promotes safe
394 swallowing, which means that extensional viscosity is an important parameter to consider
395 while designing fluid foods for persons with dysphagia (Nyström *et al.*, 2015). In the labeling
396 information for the thickeners, the precise amount of xanthan gum is not given, although it is
397 reasonable to assume that with a higher level of xanthan gum, greater elasticity is achieved, as
398 previously observed (Choi *et al.*, 2014). The extension-thinning behavior noticed for the
399 xanthan-based model fluids is consistent with a xanthan gum based commercial fluid. This is
400 likely due to the semi-rigid rod-like conformation of the xanthan gum. The extension-
401 thickening behavior of PAA is due to its coiled structure and the polymer uncoils and aligns
402 in the stretching direction (Ferguson *et al.*, 1990).
403
404 The fact that xanthan gum solutions both in the commercial thickeners and in water behaves
405 extension-thinning at higher extension rates possibly suggests that they are perceived less
406 slimy in the context of swallowing than PAA. While assigning a fixed shear rate during
407 swallowing of $50\ s^{-1}$ is an over-simplification, extension rates during swallowing have not
408 been described to date in the literature to the best of our knowledge. This makes predictions
409 about extensional viscosity with respect to swallowing even more complicated, and therefore
410 prompts further research. As noticed in TEM, the structure of network is more pronounced in
411 Fresubin and Nutilis than in Nestlé clear. It is however not possible to relate the nature of the
412 network to the individual components since the exact thickener composition is not known.

In the current study, we have characterized commercial thickeners and model fluids to understand flow properties. However, further studies are required to determine the appropriate level of elasticity and type of polymer to promote safe and easy swallowing, as well as to define the most dominant shear and extension rates. Trouton ratio $Tr = \frac{\eta_{\dot{\varepsilon}}}{\eta_{\dot{\gamma}}}$ estimates the departure of ratio of extensional to shear viscosity from its Newtonian counterpart, which is estimated around 3 (Sochi, 2010) for the Newtonian equivalent. Trouton ratios for the gum-based thickeners were: Fresubin =~40, Nestlé Clear=~45 and Nutilis =~68 and for starch-based thickeners: Nestle thicken-up=41.9 and Findus=~152. The ratio is higher than three for all the fluids which confirms the elastic nature of the samples.

5. Conclusions

This study shows that the xanthan-based commercial thickeners used for dysphagia management are slightly more shear-thinning and have considerably higher extensional viscosities than starch-based thickeners. Moreover, with microstructural characterization using light and electron microscopy, we further elucidated how the network structure of xanthan gum influences the rheology in a different way than starch does. Model fluids can be designed to mimic commercial thickeners as well as to set the upper limit for maximum elasticity that will be tested in clinical studies in the future. The shear viscosity measured using laboratory viscometry and the newly developed PUV+PD method gave similar results, which means by using the PUV+PD method the flow curve and yield stress can be acquired in less than 1.4 ms which is important for the short time scales involved in human swallowing. Only low yield stresses were detected, considerably lower than expected to occur during swallowing.
