Rare Events in Remote Dark-Field Spectroscopy: An Ecological Case Study of Insects

Anna Runemark, Maren Wellenreuther, Hiran H. E. Jayaweera, Sune Svanberg, and Mikkel Brydegaard, Member, IEEE

(Invited Paper)

Abstract—In this paper, a novel detection scheme for the monitoring of insect ecosystems is presented. Our method is based on the remote acquisition of passive sunlight scattering by two insect species. Procedures to identify rare events in remote dark-field spectroscopy are explained. We further demonstrate how to reduce the spectral representation, and how to discriminate between sexes, using a hierarchical clustering analysis. One-day cycle showing the temporal activities of the two sexes as well as data on activity patterns in relation to temperature and wind is presented. We also give a few examples of the potential use of the technique for studying interactions between sexes on a time scale of milliseconds.

Index Terms—Calopteryx, dark-field spectroscopy, ecosystems, entomology, insects, passive scattering spectroscopy, remote sensing.

I. INTRODUCTION

The application of modern spectroscopic methods to monitor several larger constituents of the atmosphere, such as birds and insects, has previously been demonstrated by our group. In earlier papers, we mainly focused on the use of Light Detection And Ranging (LIDAR) [1]–[5], and presented several approaches to insect marking experiments using laser-induced fluorescence. We are currently exploring several more compact and less expensive approaches. Here, we present dark-field spectroscopy, a monitoring method that does not require the marking of organisms. This enables the study of species that cannot be easily handled, or are difficult to capture. In addition, natural densities of organisms can be more accurately estimated with the current approach, because no population subsets need to be measured, but instead, whole population samples within designated areas can be investigated. Traditionally, manual counts have been used to quantify the numbers of individuals of different species of damselflies and to study the temporal activity patterns and interactions between species. However, manual observations are time consuming, and simultaneous monitoring of long river stretches over long time periods is laborious. In addition, interactions between damselflies on short time scales are easily missed during manual counts. The presented inexpensive method may, therefore, enable biologists to address new questions regarding temporal activity patterns in relation to weather conditions, like in this study, or other ecological variables.

II. BACKGROUND

A. Model Organism

The river Klingavålsån in southern Sweden is occupied by two closely related, ecologically similar [6] and coexisting populations of damselfly species: Calopteryx splendens and C. virgo. For this reason, this location provides an excellent place to test new methods that can detect and identify both different species and the sexes of these damselflies by making use of their slightly different scattering spectra. Damselflies are excellent biomarkers, since they have both an aquatic larval phase and a terrestrial adult phase, and thus can be used as indicators of both water and terrestrial habitat quality. Calopteryx damselflies are particularly suited as biomarkers because they inhabit flowing rivers with clean water and are sensitive to low oxygen conditions [6], [7]. In addition to being suitable biomarkers for habitat quality, damselflies are also sensitive to temperature changes [8], and C. splendens and C. virgo are predicted to shift their ranges northward in response to the global warming [9]. Simple quantitative monitoring of damselflies can, therefore, be useful both for investigations of freshwater and terrestrial ecosystem quality, and for the study of the effects of changing climatic conditions. In this study, we monitor flying damselflies in their adult, terrestrial phase, which lasts for a few weeks during the summer months.

B. Spectral Appearance

C. spp. are diurnal and have striking blue and green–brown colored bodies. These colors are created by a combination of structural metallic colors arising from coherent scattering from...
prevalent spatial frequencies in a nanoarrangement of organelles and chromophores [10]; see Fig. 1. Although the phenomenon is structural, the spectral features show no iridescence due to the spherical symmetry of the nanoarrays [10]. Females of *C. splendens* are greenish, whereas *C. virgo* females are more brownish. Females of both species have wing colors similar to their body [3], see Fig. 1. In contrast, males of both species have a blue body, and conspicuously melanised wings. *C. virgo* males have melanised wing-spots covering most of the wing (∼90%), whereas *C. splendens* males have wing-spots, which cover around half of the wing [3], see Fig. 1. The differences in coloration between the sexes and species could be the result of sexual selection, and since males have higher variance in reproductive success, they are expected to be under stronger sexual selection [11]. The conspicuous dark body and wing color of males can be more easily spotted than the color of females (against the vegetation background), and the melanised wing patches of the males have also proven important for species recognition in coexisting populations [12]. Newly emerged and not fully hardened specimens [6] show increased specular reflectance, and can be distinguished by their glittering appearance from more mature individuals that have a hardened exoskeleton [13]. The habitat area studied in this study is the air volume above the river surface, and this area is generally not utilized by newly emerged individuals but typically exclusively by adult sexually mature damselfly individuals.

**C. Visual System**

Several dragonfly species have been found to have up to six spectral classes of photoreceptors (spectral bands) covering the range 330–650 nm [14]. Although no such studies have been performed on damselflies so far, dragonflies and damselflies are sister taxa and hence likely to have similar visual systems. Damselflies have compound eyes and have a rather poor spatial resolution compared to humans, but an extremely wide field of view, and a fast temporal response. Another interesting aspect of the damselfly visual system is the ability to detect polarized light, a feature which is common in insects, and in particular in species living over the water surface. The ability to detect polarized light has several implications both for the perception of structural colors and for horizon estimation during flight navigation.

### III. Material and Methods

#### A. River System With Two Coexisting Damselfly Species

The river site in the Klingavågsan nature reserve (latitude 55.63°, longitude 13.54°) harbors a population consisting of both *C. splendens* and *C. virgo* damselflies. These damselfly populations have been extensively studied as model organisms for sexual selection, species recognition, and predation [15]–[17]. Studies of damselfly distribution and activity patterns have also been performed with fluorescence LIDAR in this population [4].

In order to compare the developed method to traditionally employed methods, manual counts of damselflies along the same stretch as used in the dark-field spectroscopy study were performed. These counts were performed every 30 min. Species and sex of all damselflies above the river surface was estimated and recorded. A synchronized digital still camera was used to take photographs for cross validation, and additional observations were recorded manually in a log book.

#### B. Equipment and Optical Setup

The one-day experiment was carried out using instruments placed in an astronomical tent-dome observatory (Omegon, approximately ø 3 m). The dome was placed under the shade of an oak tree to minimize variation in instrument temperature. Further, the dome provided protection from the resident cattle. Power was provided by a 2-kW portable gasoline generator which had to be refueled three times during the day of the experiment. A weather station was installed on a 3-m pole 40 m from the dome, clear of the oak canopy. Light received from a 95-m-long observational path was collected by a ø 203 mm Newtonian telescope (Bresser, Location T, Fig. 2), focal length 800 mm, installed on a motorized equatorial GoTo mount (LXD75 Meade; the position was kept fixed during this experiment). The telescope’s field of view (FOV, see details in Table I) was directed toward a 1 m cubic box of black anodized aluminum 95 m straight north from the dome (see Fig. 2, location B). We refer to this as the black termination; in the ideal case, the termination is entirely dark in which the only contribution to the light intensity received by the telescope would be the scattering from atmospheric constituent in the stretch T–B (see Fig. 2). The first 55 m of the FOV was over grassland and the remaining 40 m was over the river Klingavågsan. The FOV descended roughly from 4 m to less than 0.5 m over the river surface. Most of the FOV was illuminated throughout the day. The focusing and overlap of the FOV with the black termination was performed with an imager in the focal plane, after which the telescope was locked in position and alignment. The imager was removed and a 1-mm UV fiber (Edmunds Optics) was instead installed at the same place as the image of the black box in the focal plane of

The experiment was carried out on the July 3, with clear sky during the whole day. Recording started at 6:31 A.M. and finished at 5:25 P.M. All times stated throughout this paper are true sun times (TST), corrected for summer time settings, and the longitude between the study site and Greenwich. In order to estimate the intensity and spectral profile of the illumination impinging on the FOV, standardized $\varnothing$ 30 mm pieces of white polystyrene foam were dropped through the FOV every hour. Precaution was taken so that the shadow of the operator did not disturb the white calibration. The calibration was performed at location C shown in Fig. 2.

IV. DATA PROCESSING AND ANALYSIS

A. Temporal Detection of Rare Events

Initially, the intensity counts from each spectrum were averaged within the visible range 400–680 nm. The NIR region was omitted in order to avoid vegetation-induced bias. The intensity vector $I_{vis}$ over time was filtered with a median filter with a time window of 2 s (101 samples); see Fig. 3. The filtered vector represents the static intensity counts $I_{stat}$ that arise due to three factors: from the dark-current (instrument temperature dependent), from the nonperfect black termination, and from atmospheric scattering in the FOV, which can change during the day. The static background vector is subtracted from the intensity vector, so that a background corrected intensity vector is obtained, $I_{BG}$.

A threshold is then used to detect all rare events that are caused by insects intersecting the FOV. Since the intensity impinging $I_0$ on the FOV changes during the day, the threshold is weighted
Fig. 3. Total scattered intensity over time, in the visible range, sampled at 50 Hz and with a 2-s broad median filter applied to the same signal, which is used to estimate the static signal. The positive fast spikes are caused by insects. Typically, the specimen passes the FOV in less than 50 ms. For comparison, the slow increase of scattering between 11:24 and 11:25 arose from a wide dust plume that was caused by a tractor driving upwind.

by $I_0$. We describe the time-dependent $I_0$ as follows:

$$I_0(TST) = A \left(1 - \cos\left(\frac{\pi}{12}TST\right)\right)^W + D.$$  (1)

The parameters $A$, $W$, and $D$, were fitted to $I_{BC}$ for white reference events carried out throughout the day. $A$ represents the light intensity and instrument sensitivity, $D$ represents a bias, and $W$ changes the waveform of the daily cycle. By plotting the skewness of $I_{BC}$ on a histogram (see Fig. 4), the noise level can be estimated from the negative values of $I_{BC}$, and a level where the positive spikes can be identified with a negligible risk of including a false positive. The time-dependent threshold was scaled by this level. 1526 000 spectra were recorded during the day; and 3613 of these spectra were identified to belong to scattering events caused by insects given the specified threshold. When merging consecutive scattered spectra, the number of insect events passing the FOV was 1285. The average chance of detecting an insect for each acquisition was thus $2.4 \times 10^{-3}$, and if we assume no interactions between insects, then the risk for pile-ups would be $5.6 \times 10^{-6}$ which is negligible; however, such an assumption is arguable. As can be seen in Fig. 4, a large number of events were also caused by insects below the threshold. These can also be identified when observing $I_{BC}$ over time. They could be caused by smaller insects, which could potentially be prey species upon which the damselflies are feeding [6]. These events are omitted from this study, since their signal-to-noise ratio (SNR) would be too low for spectral analyses.

B. Spectral Processing

The full spectra from the triggered events were extracted from the data files, and the neighboring static spectra were subtracted in such a way that dark current, imperfect dark termination, and slow atmospheric scattering were rejected so that only the scattering contribution was considered. In order to compensate for the spectral profile of the sun’s emission, the spectral throughput of the atmosphere, the telescope, the fiber, and the sensitivity of the spectrometer, all scattering spectra were divided by the scattering spectrum from standardized white polystyrene foam pieces. The part of the spectra with reasonably good intensity (380–900 nm) was decomposed linearly using singular value decomposition (SVD) [18]–[21]. The singular values showed unambiguously that all scattering events during the entire day could be explained as a linear combination of six base spectra (see Fig. 5); thus, we are able to represent each spectra with six variables rather than one for each for the original 2664 spectral bands. A 6-D color space was expanded by this set of orthogonal base spectra and the scores were weighted by the singular values to maintain equal SNR on each axis. Because the absolute scattered intensity is likely to vary with the FOV-specimen-overlap and the cross section with the orientation and wing beat phase, the six scores were divided by the first principal component score. This kind of autonormalization leaves us with a spectral shape for improved spectral classification [22]. Further, since the first axis always becomes 1, we can reduce the dimensionality of our representation by 1, and thus we can now describe the spectral shape of each event in a 5-D color space.

C. Unsupervised Clustering and Classification

After redundant information was removed with SVD, the Euclidean distances, in the 5-D color space, between each event and all other events were calculated, and the distances were fed into a hierarchical cluster analysis considering the furthest distance (see Fig. 6) [23]. The number of clusters should be at least as many as the spectral truncation number; otherwise, the spectral components would not be independent. However, the
Fig. 5. When decomposing the spectra of the 2664 spectral bands of the 3613 events, the singular values suggest a remarkably clear truncation point after six spectral components. The red dashed line indicates the noise floor. Projection of data onto the first component gives an SNR of 30:1, whereas projection onto the sixth component only yields an SNR of 2:1.

Fig. 6. Euclidean distance between each event represented in the 5-D color space is fed into a hierarchical cluster analysis. This dendrogram shows how similar the 3613 events are to each other. The first six branches were interpreted.

Fig. 7. Mean scattering spectra of each cluster. A scattering coefficient of 1 corresponds to the scatter from a white calibration polystyrene foam piece. M: male, F: female, V: vegetation imprint, U: uncertain. The spectra were interpreted as follows: 1F: female, 2FV: female with vegetation imprint, 3MV: male with vegetation imprint, 4M: male, 5M: male, 6U: uncertain.

40 m of FOV). Since this component reflects in any event, the effect would be a multiplication by two of any original discrete clusters, i.e., each cluster with and without a vegetation imprint.

We interpreted the first six branches of the hierarchical tree by plotting the cluster centroid spectra. The centroid spectra were calculated as the mean of all spectra assigned to a particular cluster (see Fig. 7). Clusters 3–5 show characteristic blue features, which are unlikely to arise from anything else natural other than the nanoarrays of damselfly males. The blue feature has close resemblance to the laboratory reference measurements in [3]. We are uncertain, however, whether the several peak positions (see clusters 3–5 in Fig. 7) relate to natural variance, the age of the individual, or perhaps the fact that two species are present at the site. Cluster 3 shows a significant imprint of vegetation, whereas clusters 4 and 5 can be assumed to be associated with males flying over the river surface. Clusters 1 and 2 can be associated with damselfly females. The green spectral feature at 550 nm could potentially be of importance for crypsis when the damselflies sit in the vegetation. This feature is less intense and broader than for males, as previously shown in laboratory measurement [3]. Cluster 2 carries a significantly larger vegetation imprint than cluster 1; and for this reason cluster 1 is associated with females flying over the river and cluster 2 is associated with females flying over the grassland. To further strengthen the statements made earlier, we can attend to a small detail in the centroid spectra presented in Fig. 7. The oxygen absorption band at 760 nm is a Fraunhofer line from the earth’s atmosphere. The oxygen path length from the detector to the insect compared to several kilometers’ path length prior to the incidence on the FOV is basically insignificant; however, the steady-state fluorescence of vegetation fills up this Fraunhofer line [25]. The white calibration was performed over grassland; thus, the oxygen line is not present in the two clusters that carry vegetation imprint, namely clusters 2 and 3. In cluster 1, which contains events over the river, the lack of vegetation number of clusters can be larger than the number of spectral components. This would be the case if several clusters share the same chromophores, but in different discrete concentrations [1], [2]. The four groups of damselflies (males and females of *C. splendens* and *C. virgo*) share the same melanin pigment, but are differently melanised in discrete quantities [3], [24]. The most prominent signature, however, arises from the structural phenomenon and this does not decompose linearly because the center wavelength and feature width relate to the size and ordering of the nanostructures, respectively, rather than to specific spectral transition energy. Another spectral component, which is unrelated to the damselflies, arises from light reflected off the surrounding vegetation and carries the imprint of the chlorophyll absorption. This feature is mainly characterized by the steep slope at 700 nm. This component can be expected to be much stronger in events detected over grassland (the first 55 m of the FOV) in comparison to events detected over the river (the last
V. BIOLOGICAL RESULTS

A. Interactions Between Sexes

A common idea is that males chase females when they arrive at the river for reproduction [6]. If we interpret “chasing” as two insects sharing the same trajectory in space, where the second insect is somewhat delayed behind the first, then there should be an increased chance of spotting a male when a female is detected if this hypothesis is true. To test this, we estimated the time-dependent correlation [26], [27] between the females classed to cluster 1F and the males classed to clusters 4M and 5M (see Fig. 8). The symmetric female autocorrelation is plotted with a green line for reference. This autocorrelation shows the duration of the scattering events arising when the female damselflies intersect the FOV. The male autocorrelation is plotted with a red line. From the width of the male autocorrelation, it can be seen that males stay longer in the FOV. In addition, the shapes of the female autocorrelation and male autocorrelation differ. While the autocorrelation at 0.5 is 54 ms for females and 70 ms for males, at 0.1 the difference in width of the auto-correlations has increased considerably to 120 and 248 ms for females and males, respectively. This could potentially be due to the territorial behavior of the males, which causes them to patrol and/or engage in territorial male–male interactions with con- and heterospecifics [28]. Alternatively, their flight patterns could differ with respect to the monitored path, e.g., the case of males mainly flying along the river. To our surprise, we find a female–male cross correlation, where females appear in the FOV approximately 100 ms after males have passed. This is likely the result of precopulatory tandems between males and females, rather than females chasing males. In such tandems, males grab females by the thorax with their clasping organs. When flying, clasped females are then connected to the males in such a way that they have to fly behind the males and hence pass the FOV after the males. We also find a much weaker, but still significant, correlation where males follow females, however. This less-well-defined increase in males that enter the FOV approximately 1 s after females have passed supports the prediction that females flying over the river are chased by males. The dashed confidence line at the bottom of the plot shows the 99% confidence limits of the female–male long-term cross correlations for the entire day. This type of analysis, with inspiration from digital signal processing [29] and system identification in robotics [30], is not possible with manual observations because of the poor time resolution, large uncertainty, and short observation duration. Clearly, a longer recording time would improve the accuracy of these types of correlations.

B. Activity Patterns in Relation to Time, Temperature, and Wind Speed

The activity (in terms of number of damselflies in the FOV per hour per cubic meter) is similar to that estimated by manual censuses (see Fig. 9). The relative proportions of male and female damselflies are also consistent (see Fig. 9), which supports that the clusters have been correctly classified. The damselfly densities are also suitable for analyses of patterns on a much slower time scale than shown in Fig. 8. The activity of the two sexes can, for example, be analyzed with respect to the TST, wind and temperature (see Fig. 10).
In general, the activity of organisms with respect to temperature can be described by the shape

$$\text{Act}(T) = \text{Act}_0 \sqrt{T_{\text{max}} - T} e^{-T_{\text{th}}/T - T_{\text{act}}}$$

(2)

where Act is the activity in counts per hour cubic meter, $T$ is the environmental temperature, $\text{Act}_0$ is the general activity related to other circumstances than temperature, $T_{\text{max}}$ is the maximum temperature at which the organism can be active, $T_{\text{act}}$ is the minimal temperature at which the organism can be active, and $T_{\text{th}}$ is the thermal sensitivity. This model is, however, hard to excite outside a laboratory environment where the temperatures cannot be manipulated over the entire range. Instead, we apply a simple and more robust second-order polynomial thermal relation with one less degree of freedom (DOF). We also include a term allowing the flight preferences to depend on wind speed. Because the gradient of such a relation must necessarily be continuous and zero at zero wind speed, only even polynomial terms of the Taylor expansion of the wind parameter can be included

$$\text{Act}(T, v) = k_0 + k_1 v + k_2 T + k_3 T^2 + k_4 v^2,$$

(3)

Here, $v$ is wind speed in meters per second and $k$s are model parameters found by multidimensional regression with the QR factorization. Clearly, the accuracy, model excitation, details, and DOFs of the model can be increased if longer recordings are performed. We have not included an analysis of wind direction with respect to the orientation of the FOV in this study, even if this could have implications for the observations.

VI. DISCUSSION AND OUTLOOK

The idea of this study is not to provide highly accurate data on the focal species, but rather to explore new opportunities for using automated and modern electro-optics and spectral classification in ecological monitoring. We have successfully demonstrated remote insect classification using an inexpensive, portable, and passive setup. One clear advantage of spectral identification in comparison to spatial image identification is that spectra do not become blurred when the sample is not in the focal plane of the telescope, and it does not produce a fast moving induce motion blur as is does in the spatial domain [31]. Clearly, the accuracy and reliability of the analysis of ecological events would benefit from longer recording times to improve statistical power.

The setup enabled us to successfully identify the two damselfly species to sex from their dark-field scattering differences. Since the classification presented in this study is unsupervised and we only had reference scattering spectra for the two sexes of $C. splendens$ [3], we choose not to interpret more than the first six branches in the dendrogram in Fig. 6. For this reason, we cannot exclude the possibility that a refined analysis of the lower branches would enable us to discriminate between the two species. Although the coloration of the abdomen is fairly similar in the two species, the melanization of wings differs considerably (see Fig. 1). The proportions of males and females as well as the damselfly densities that were measured with our setup were generally consistent with the manual counts (see Fig. 9). This suggests that the setup used in this study does obtain reliable counts and activity patterns that can be used instead of the more laborious and time-consuming manual techniques. In addition to this, our measurements clearly showed a vegetation signature in the spectra of the categories 2FV and 3MV (see Fig. 7). These groups are probably made up of damselflies that were flying above vegetation rather than over the river. Obtaining these habitat measures (e.g., river versus grassland habitats) simultaneously with the damselfly counts is a particularly promising part of this method, because it allows, in addition to population monitoring, ecological insights into the lifestyle, activity patterns, and possible interactions between individuals.

Another biologically interesting result is the correlation between males and females (see Fig. 8). Females are more likely to be found at a well-defined and very short time behind males. This phenomenon is most likely caused by precopulatory tandems, in which the male has clasped the female. We also see a lower and less-well-defined signal of males following behind females at approximately ten body length times longer lag time. This implies that males chasing females typically appear at ten body length distance after the females. In the courtship interactions, males are commonly observed chasing the females during manual counts, and our results suggest that a common chasing distance is approximately ten damselfly body lengths. More information on the flight distances, directions of the chase in relation to the telescope, and flight speed would be needed to draw any further conclusions from these data. Nevertheless, although more fine-tuning is needed, we have shown that it is possible to study the interactions between insects over very short time scales. This technique can be applied to study both interactions within and between sexes of the same species, such as territorial behaviors and chasing of potential mates, and to study interactions between species, for example predator–prey interactions. Finally, both males and females were more active at higher temperatures...
(e.g., activity increased from 292 to 302 K which was the highest temperature during the experimental period) and in lower wind speeds (activity was highest at 2 m/s, which was the lowest wind speed during the experimental period, and activities clearly decreased toward wind speeds of 5 m/s). Interestingly, there was a slight difference in the temperature dependence of different sexes where females were more active at slightly lower temperatures whereas males remained more active at slightly higher wind speeds (see Fig. 10).

Although the measurements with this experimental setup were rather successful, a number of improvements could be carried out: first, the analysis would benefit from an improved SNR. The components used in this experiment were simply the ones available in our laboratories and were not necessarily the optimal choice for the experiment. Given the SNR, the broad spectral features, and the necessity for a fast sampling, a slit width should be chosen that allows an increase of light. The SNR could further be improved by choosing a detector and grating blazing angle for optimal sensitivity around 400 nm. This would allow exploitation of the 300–400 nm region, where several interesting features could be expected (for example, absorption of chitin below 330 nm and UV features visible to the focal species and their bird predators). In the present experiment, the blaze was optimized for NIR, and the obtained signal was too weak for the UV region, even if plenty of sunlight can be found in this region. Thermoelectrically cooled compact spectrometers would further improve the SNR. Even compact multichannel photo multiplying tube (PMT) spectrometers could be considered [32]; however, the costs are considerable, the channels are few, and they typically do not include higher order rejection filters, which is necessary for such experiments. An improved SNR would also allow the detection and monitoring of smaller insects, and, for example, the interaction between predator and prey insects could also be studied. While the damselflies in this study have rather slow and chaotic wing beats, detection of other species might benefit from even faster sampling rates toward kilohertz [33], [34]. For studies of this kind, PMTs or avalanche photo diodes (APDs) should be used.

An improved black termination with improved shielding from the sunlight incident from all angles throughout the day would further make the interpretation easier and cancel out some uncertainty. Also, the white calibration could be made more consistent; one way would be to use a white sphere on a motorized swinging axis, so that the timing and intersection with the FOV are identical during each calibration event. Reference measurements of several groups of species and sexes could also be performed for improved interpretation of the centroid spectra.

For long-term unsupervised recordings, several issues should be addressed. A more robust telescope mount is necessary; also the entire setup would need a box or shed for weather protection. A CMOS RGB all-sky-imager should be included to monitor the sky in relation to the illumination of the FOV, which might be uneven on a partially clouded day. The USB storage device should preferably be powered by laptops, so that the recordings are not interrupted by power cuts. The generator should preferably be exchanged with a solar panel.

A number of problems and questions still remain unsolved. Those are the estimation of the sample-FOV overlap, estimations of range to the events, and direction of flight with respect to the wind direction. Also, discrimination between the two species would be desirable to allow the more detailed investigation of the interactions and general ecology of them. One of the most interesting techniques involves the marking of individuals without recapture, such as those previously carried out with active fluorescence LIDAR [4], [5]. These studies allow the estimation of insect dispersal and lifetimes. This was not pursued in this study, but is likely to work well in the passive mode.

Although we describe purely passive sensing in this paper, there might be several benefits of intermittently employing an inexpensive continuous wave laser diode (LD), available from 405–980 nm up to 1 W power [35]. The method could still be noninvasive and nonperturbing if an NIR LD is used. Potential benefits could include the possibility to estimate the distance by $1/r^2$ attenuation, and to estimate the sample-FOV overlap. The latter could be solved by painting the termination with a special fluorophore responding to that laser line with a given signature. Then, any obstruction of the beam would cause a decrease in that spectral component. Rare earths would produce very specific signatures, and could be used for various encoding strategies. Even fluorescent marking experiments, without range resolution, could be performed.

VII. CONCLUSION

We have presented a simple, compact, inexpensive, and portable setup for remote insect classification. In contrast to earlier LIDAR-based studies [1]–[5], this setup can easily be employed by biologists. In this study, we have also provided an outline of how data from such a setup can be analyzed, and have given some tentative ideas that could be addressed with such data. We presented quantitative measures of temporal variations in damselfly activities during a day cycle, and related activities to temperature and wind speed. Moreover, phenomena were presented on a fast (millisecond) time scale, which has not been possible to estimate previously. Finally, we have discussed possible improvements and perspectives for future studies.

Anna Runemark was born in 1982 in Karlshamn, Sweden. She received the M.Sc. degree in biology from Upssala University, Upssala, Sweden, in 2006. The master’s thesis was a minor field study, which was financially supported by a grant from the Swedish International Development cooperation Agency, and supervised by Prof. M. Bjorklund. Since 2007, she has been working toward the Ph.D. degree in evolutionary ecology at Lund University, Lund, Sweden, under the supervision of Prof. E. Svensson.

Her major research interests include evolutionary processes in fragmented populations, e.g., “Island biology and morphological divergence of the Skyros wall lizard Podarcis gaigeae: A combined role for local selection and genetic drift on color morph frequency divergence?” (BMC Evolutionary Biology, 2011) and “Simulating range expansion: Male species recognition and loss of premating isolation in damselflies” (Podarcis gaigeae) (Journal of Evolutionary Biology, 2011) and “A role for learning in population divergence of male preferences” (Evolution, 2010). She has also been involved in an interdisciplinary collaboration with Prof. S. Svanberg’s research group, which has resulted in three publications on ecological monitoring applications of LIDAR published in Applied Optics. Ms. Runemark is a member of the European Society for Evolutionary Biology and has been reviewing for Evolution, American Naturalist, Biological Journal of the Linnean Society, Animal Behavior, Journal of Avian Biology, and BMC Biology Notes.

Maren Wellenreuther was born in 1976 in Göttingen, Germany. She undertook undergraduate studies from the University of Göttingen, Göttingen. She received the M.Sc. degree in 2001 from the University of Hamburg, Hamburg, Germany, within the field of marine science. In 1998, she received a one-year research grant from the German Academic Exchange Service (DAAD) to conduct postgraduate research at the University of Adelaide, Australia, on predator-prey relationships. She started the Ph.D. degree with K. Clements, in 2001, on ecological speciation in a sympatric group of marine fish at the University of Auckland, Auckland, New Zealand, which was completed in 2007. The Ph.D. research was funded by a Top Achiever Doctoral Scholarship.

In 2007, she started a postdoctoral fellowship, funded by the Swedish Research Council, with Prof. E. Svensson at Lund University, Lund, Sweden, to study “the interplay between interspecific interactions, sexual isolation and gene flow in the dynamics of species ranges: the evolution of wing coloration in calopterygid damselflies.” She is currently a Marie-Curie Postdoctoral Fellow at Lund University and is involved in “Mapping genotypes to phenotypes: development of a linkage map and mapping of colour polymorphisms in Ischnura elegans (Odonata)” with Prof. B. Hansson and Prof. E. Svensson. Her previous and current research interests involve the study of speciation using ecological and molecular tools, and include investigations of species distribution patterns, mate choice, sexual and natural selection, gene flow, and the interplay between phenotypes and genotypes in species formation. Three representative and recent publications are given as follows: “The role of ecology on the molecular diversity and population structure in a coenogamid damselfly” (PLoS ONE, 2011), “Simulating range expansion: Male species recognition and loss of premating isolation in damselflies” (Evolution, 2010), and “The role of ecology in male mate discrimination of immigrant females” (Biological Journal of the Linnean Society, 2010).
Hiran H. E. Jayaweera was born in 1980 in Matara, Sri Lanka. He received the B.S. degree in physics from the University of Colombo, Colombo, Sri Lanka, in 2004 with the specialty in microcontrollers and embedded systems. He is currently working toward the Ph.D. degree at the Centre for Instrument Development, University of Colombo. The work here is related to monitoring agricultural products with nondestructive tests.

In 2006 and 2009, he received fellowships from the International Science Programs of Uppsala University to visit Prof. S. Svanberg’s research group to work in gas in scattering media absorption spectroscopy (GASMAS) and LED-induced fluorescence and reflection spectroscopy with application to biological materials. He was a Teaching Assistant and Assistant Lecturer at the University of Colombo. He teaches mathematics and physics to school kids who are the victims of the war in Sri Lanka. He has been teaching development of low-cost embedded systems for the undergraduates of the University of Colombo and general public in Sri Lanka.

Mr. Jayaweera is a member of the Institute of Physics, Sri Lanka; the Young Scientist Federation, Sri Lanka; and the Sri Lanka Association for Advancement of Science.

Sune Svanberg was born in 1943 in Trollhättan, Sweden. He received the Ph.D. degree in physics from Gothenburg University, Gothenburg, Sweden, in 1972.

He has been a Professor of physics at Lund University, Lund, Sweden, since 1980. During 1980–2009, he was the Head of the Atomic Physics Division and during 1996–2010, he was the Director of the Lund Laser Center. He is also the Coordinator of a long-term Linnaeus grant from the Swedish Research Council to the Lund Laser Center. He is an Honorary Doctor/Professor at Lund, Liège, Lima, Riga, Chanchuen, Harbin, Hangzhou, and the Chinese Academy of Sciences. His research interests include atomic physics, high-power laser matter interaction, combustion diagnostics, environmental monitoring, and biophotonics.

Dr. Svanberg is a Fellow of the American Physical Society, the Optical Society of America, and the European Optical Society.

Dr. Svanberg is a Fellow of the American Physical Society, the Optical Society of America, and the European Optical Society.

Mikkel Brydegaard (M’11) was born in 1980 in Copenhagen, Denmark. He studied in a number of countries ranging from Venezuela to Romania. He received the Master of Electrical Engineering in 2007 from Lund University, Lund, Sweden, with specialty in measurements and control theory. He is currently working toward the Ph.D. degree in Lund University in Prof. S. Svanberg’s group Applied molecular spectroscopy and remote sensing. Here, he is involved in broadband elastic and inelastic spectroscopy with applications in medicine, food science, and ecology.

He was a Teacher of Electronics in technical formation in Peru. He teaches ultrasound physics during internship in an Indian university. He filed more than five patent applications on instrumentation. He is teaching optical spectroscopy and imaging on request of the Swedish Government Program for Capacity Building (ISP-SIDA) in Ghana, Senegal, and Mali, for ICTP, Trieste, Italy, and for the Puya Raimondi Foundation, Lima, Peru. His special interests include realistic LED-based instrumentation, e.g., “Versatile multispectral microscope based on light emitting diodes” (Review of Scientific Instrument, 2011) and also novel applications of LIDAR, e.g., “Remote nocturnal bird classification by spectroscopy in extended wavelength ranges” (Applied Optics, 2011).

Mr. Brydegaard was appointed to a Board Member of the Interdivisional Group of Physics for Development (IGPD-EPS) 2010. He is a reviewer of the Journal of Applied Optics and Journal of Physics.
