Embryonic stem cells (ESCs) represent a promising source of midbrain dopaminergic (DA) neurons for applications in Parkinson disease. However, ESC-based transplantation paradigms carry a risk of introducing inappropriate or tumorigenic cells. Cell purification before transplantation may alleviate these concerns and enable identification of the specific DA neuron stage most suitable for cell therapy. Here, we used 3 transgenic mouse ESC reporter lines to mark DA neurons at 3 stages of differentiation (early, middle, and late) following induction of differentiation using *Hes5::GFP*, *Nurr1::GFP*, and *Pitx3::YFP* transgenes, respectively. Transplantation of FACS-purified cells from each line resulted in DA neuron engraftment, with the mid-stage and late-stage neuron grafts being composed almost exclusively of midbrain DA neurons. Mid-stage neuron cell grafts had the greatest amount of DA neuron survival and robustly induced recovery of motor deficits in hemiparkinsonian mice. Our data suggest that the *Nurr1*⁺ stage (middle stage) of neuronal differentiation is particularly suitable for grafting ESC-derived DA neurons. Moreover, global transcriptome analysis of progeny from each of the ESC reporter lines revealed expression of known midbrain DA neuron genes and also uncovered previously uncharacterized midbrain genes. These data demonstrate remarkable fate specificity of ESC-derived DA neurons and outline a sequential stage-specific ESC reporter line paradigm for in vivo gene discovery.

Introduction

Embryonic stem cells (ESCs) represent a potentially unlimited source of cells for applications in regenerative medicine. One promising strategy is the derivation of midbrain dopaminergic (DA) neurons for cell replacement therapy in Parkinson disease (PD). Several protocols have been developed to obtain ESC-derived midbrain DA neurons in vitro, though current technologies are far from perfect and cell preparations often contain contaminating non-DA cell populations and potentially tumorigenic cell types (1, 2). Furthermore, despite more than 40 years of research on developing DA cell replacement paradigms, many fundamental questions critical for effective clinical translation have remained unanswered, such as the stage of DA neuron development most appropriate for transplantation; whether other non-dopamine cell types within the graft, such as glia, are necessary for in vivo DA neuron survival and function; and how closely in vitro-generated cells match the properties of authentic midbrain DA neurons generated in vivo. The use of ESC technology has the potential to address all these questions and presents a virtually unlimited source of fully defined DA neurons.

One strategy to obtain highly enriched populations of midbrain DA neurons is the purification of ESC-derived progeny prior to transplantation through the use of fluorescence-activated cell

sorting (FACS) (3, 4). BAC transgenesis has been developed as an efficient platform to produce cell-type specific GFP reporter mice (5) and has been adapted to engineer fluorescent ESC reporter lines in vitro (6). BACs carry more genetic information than conventional transgenes, which often results in more faithful expression and less susceptibility to positional effects. However, misexpression of BACs can occur, for example, due to fragmentation or due to the lack of important very distant regulatory elements. Gene targeting represents an alternative approach for generating mouse ESC (mESC) or human ESC (hESC) reporter lines with potentially even higher fidelity of expression. However, knockin reporter lines may show lower expression levels (single copy integration) and can potentially disrupt gene function (haploinsufficiency), both of which are less of a concern in BAC transgenesis. Here, we used 3 distinct BAC transgenic mESC reporter lines that mark the neural precursor stage (*Hes5::GFP*) (6), DA neurons at the stage of cell cycle exit (*Nurr1::GFP*), or fully differentiated DA neurons (*Pitx3::YFP*) (for review of markers, see ref. 7). Sequential expression of the 3 markers is thought to mimic the developmental progression of midbrain DA neurons in vivo. BAC transgenic reporter ESC lines were subjected to directed differentiation in vitro followed by FACS purification of reporter⁺ cells at differentiation day 14–15. GFP⁺ cells from the *Hes5::GFP* line showed an enrichment of neurons and glia, while reporter⁺ cells from the *Nurr1::GFP* and *Pitx3::YFP* lines yielded nearly pure populations of neurons, with marker expression and functional properties consistent with the midbrain DA neuron identity.

Authorship note: Elizabeth L. Calder and Sonja Kriks contributed equally to this work.

Conflict of interest: The authors have declared that no conflict of interest exists.

**Figure 1**

Characterization of reporter expression in the 3 BAC lines. (A–C) Live reporter expression on day 14 of differentiation. (D–F) Overlay of reporter expression and phase-contrast images. (G–I) FACS analysis for reporter expression at day 14 of differentiation plotted against PE and FITC channels. Numbers represent the percentage of positive cells. Scale bar: 50 μm .

Reporter⁺ progeny of all 3 lines were transplanted into 6-hydroxydopamine-lesioned (6-OHDA-lesioned) immunocompromised mice, and each population reliably induced functional recovery, while sham-grafted control animals did not show any behavioral improvement. Among the 3 reporter lines, both *Pitx3::YFP* and *Nurr1::GFP* yielded robust survival of nearly pure neuronal grafts, indicating that graft-derived glial cells are not essential for *in vivo* DA neuron survival. Transplantation of *Nurr1::GFP*⁺ cells resulted in the largest number of surviving DA neurons, thus defining the *Nurr1* stage as particularly suitable for *in vivo* DA neuron replacement therapies.

Comparative global transcriptome analysis revealed that *in vitro*-generated FACS-purified DA neurons express nearly all known markers of *in vivo* midbrain DA neurons. This remarkable authenticity further enabled the identification of what we believe are hereto unknown markers of midbrain DA neurons in the developing brains of both humans and mice. Our study is first to our knowledge to perform sequential stage-specific reporter line analysis (SSRLA) toward the identification of the stage most suitable for cell therapeutic intervention and establishes what we believe to be a novel paradigm for ESC-based gene discovery.

Results

Characterization and *in vitro* differentiation of BAC ESC reporter lines. In order to generate the *Nurr1::GFP* and *Pitx3::YFP* lines, RP23-236113 (GENSAT) and RP11-946K20 (CHORI) BACs, respectively, were retrofitted for mammalian selection and nucleofected into J1 mESCs, as previously reported for the *Hes5::GFP* BAC (6). G418-resistant colonies were expanded and differentiated toward the DA neuron lineage according to our previously pub-

lished protocol (8), with minor modifications (see Methods), and screened for GFP or YFP expression. A total of 3 (out of 50) *Nurr1::GFP* and 2 (out of 22) *Pitx3::YFP* G418-resistant clones showed specific reporter expression at the DA neuron stage, as assessed by colocalization with NURR1 and PITX3 antibodies 24 hours after sorting, respectively (Supplemental Figure 1, A–C and E–G; supplemental material available online with this article; doi:10.1172/JCI58767DS1). Quantitative analysis confirmed high levels of coexpression of GFP antibody with the respective marker protein (Supplemental Figure 1, D and H). The low percentage of properly reporting G418-resistant clones is consistent with previously characterized BAC transgenic stem cell lines in both humans (9) and mice (6), with most clones showing no GFP expression and only very rare clones showing ectopic expression. Clones for each line were analyzed for stable, single-site, genomic integration of BAC DNA via FISH (Supplemental Figure 1, I–K). The lack of incorporation of BrdU within the *Nurr1::GFP*⁺ and *Pitx3::YFP*⁺ cells confirmed a postmitotic neuron identity (data not shown). Expression of the reporter was first seen at day 6 of differentiation for the *Hes5::GFP* line, day 10 of differentiation for the *Nurr1::GFP* line, and day 12 of differentiation for the *Pitx3::YFP* line. At day 14, reporter expression was present in all 3 lines (Figure 1, A–F), and, upon FACS purification (Figure 1, G–I), cells could be plated without feeder cell support at high concentration (50–100,000 cells in 1- to 2- μl droplets) onto Matrigel-treated chamber slides. Cells isolated by FACS were analyzed by qRT-PCR to confirm enrichment for their respective transcripts in reporter⁺ cells compared with that in reporter⁻ cells (Figure 2A). The *Hes5::GFP* line has previously been characterized to enrich 19.5 fold for *Hes5* mRNA (6).

**Figure 2**

Short-term characterization of marker expression in FACS-purified cells. **(A)** qRT-PCR data showing enrichment of *Nurr1* (14.6 fold) and *Pitx3* (10.0 fold) in reporter⁺ cells compared with that in reporter⁻ cells of the respective cell lines. **(B–K)** Immunocytochemical analysis of reporter⁺ cells 24 hours after sorting. **(B)** Quantitative analysis in *Hes5*, *Nurr1*, and *Pitx3* lines for coexpression of GFP and TH (GFP⁺/TH⁺, TH⁺/GFP⁺), the percentages of GFP⁺, Tuj1⁺, and TH⁺ cells among total cells (GFP⁺/DAPI⁺, Tuj1⁺/DAPI⁺, TH⁺/DAPI⁺), and the colocalization of midbrain markers EN1, LMX1A, and FOXA2 in TH⁺ cells (EN1⁺/TH⁺, LMX1A⁺/TH⁺, FOXA2⁺/TH⁺). **(C–K)** Representative images of immunocytochemical marker analysis. Scale bar: 50 μ m.

Immunocytochemical analysis 24 hours after sorting showed that the large majority of reporter⁺ cells derived from the *Nurr1::GFP* and *Pitx3::YFP* lines, but not the *Hes5::GFP* line, were positive for DA neuron markers, such as tyrosine hydroxylase (TH; Figure 2, B–E). In contrast, unsorted cultures typically yield about 20% TH⁺ cells under identical differentiation conditions (2). TH⁺ cells from all 3 reporter lines coexpressed the midbrain transcription factors EN1 (Figure 2, B and F–H) and LMX1A (Figure 2B and Supplemental Figure 1, L–N). In contrast, FOXA2, another transcription factor essential for the midbrain DA neuron lineage, was coexpressed in nearly all TH⁺ cells derived from the *Pitx3::YFP* line but only in a subset of those derived from the *Hes5::GFP* and *Nurr1::GFP* lines (Figure 2, B and I–K). Analysis 7 days after sorting demonstrated that the *Hes5::GFP* line enriched for both neurons and glia (Figure 3A), while the *Nurr1::GFP* and *Pitx3::YFP* lines yielded nearly pure populations of neurons (Figure 3, B and C), most of which coexpressed TH (Figure 3, D–F). While most *Nurr1::GFP*- and *Pitx3::YFP*-sorted cells retained reporter expression upon further in vitro differentiation, there was variability in the levels of expression, particularly in the *Nurr1* and *Hes5* lines. This may be due to the

fact that *Nurr1*- and *Hes5*-positive cells, at the time of sorting, comprise a broader range of differentiation stages compared with those that are *Pitx3*-positive, whose onset of expression is initiated just around the time of sorting. Other potential reasons include differences between endogenous protein and BAC reporter expression and/or BAC reporter silencing. Regardless, these data demonstrate the extensive survival of FACS-purified reporter⁺ neurons, even in the absence of glial feeder support. Upon further differentiation, reporter⁺ cells isolated from the *Nurr1::GFP* and *Pitx3::YFP* lines developed long axons (Figure 3G) and exhibited electrophysiological properties compatible with the midbrain DA neuron identity (Figure 3H), including firing multiple action potentials at moderate rates (2–10 Hz) in response to sustained depolarizing current injection. Together, these in vitro data support the use of BAC transgenic reporter ESC lines to generate and purify stage-specific populations of midbrain DA neurons.

In vivo analysis of FACS-purified midbrain DA neuron populations. We next tested whether FACS-purified populations can functionally engraft in vivo and induce behavioral recovery upon transplantation into the striatum of adult unilateral 6-OHDA-lesioned mice.

Figure 3

Long-term in vitro characterization of cells after sorting. (A–C) Immunocytochemical analysis for GFP, GFAP, and DAPI in the 3 lines. (D–F) Immunocytochemical analysis for GFP, TH, and Tuj1. (G) Phase-contrast and GFP expression in *Nurr1::GFP*⁺-sorted cells 6 days after replating. (H) Whole-cell recordings in current clamp mode from *Nurr1* and *Pitx3* lines show neuronal-like excitability, with cells firing multiple action potentials at rates between 2 and 10 Hz and evidence of spike frequency adaptation (“accommodation”). Scale bar: 100 μ m (A–F); 40 mV (G).

Animals were monitored for 3 independent behavioral parameters to quantify the extent of hemiparkinsonian symptoms, including amphetamine- and apomorphine-induced rotational asymmetry (ipsilateral and contralateral, respectively) and the cylinder test for determining ipsilateral paw preference during rearing. Mice with stable amphetamine-induced ipsilateral rotation scores (>5 rotations/min) were selected for transplantation studies. Each of the 3 BAC reporter lines were each differentiated in vitro (2, 8) and sorted for their respective reporters prior to transplantation (day 14–15).

One challenge of transplanting mESC-derived DA neurons is the risk of tumor formation due to the presence of contaminating undifferentiated cells within the graft. Our laboratory has previously reported reduced frequency of tumor formation upon short-term replating of mESC-derived DA neurons prior to transplantation (2). Here, we tested whether FACS purification of neural cell populations is sufficient to prevent tumor formation, even under adverse conditions such as (a) omitting the replating step, (b) grafting large cell numbers (75,000–150,000 cells/ μ l for a total of 150,000–200,000 cells/brain), and (c) grafting into immunocompromised SCID hosts. Histological analysis 6 weeks after

transplantation revealed large tumor-like structures in roughly 50% of *Nurr1::GFP*- and *Pitx3::YFP*-grafted mice and 33.3% of *Hes5::GFP*-grafted mice (Supplemental Figure 2, A–C). Tumors were preferentially located in the cortex despite stereotactic targeting of the striatum, suggesting that the cortex may be particularly susceptible for tumor formation. Tumor-forming grafts were composed of mostly neural cells but also contained areas of cells expressing pluripotent markers and markers of mesendodermal lineages (Supplemental Figure 2, D and E). These teratoma-like components within some of the grafts suggested contamination with ESC-like populations. Using SSEA1-PE- or SSEA1-647-conjugated antibodies, we found between 0.1% and 0.8% contamination with SSEA1⁺ cells after the first round of sorting (this would equal between 175 and 1,600 cells in our grafts) (Supplemental Figure 3). To determine whether SSEA1⁺ cells are responsible for tumor formation, we grafted 1,500 ($n = 3$ mice) and 15,000 ($n = 3$ mice) SSEA1-PE⁺ cells isolated at day 14 of differentiation into the striatum of SCID mice. All 6 animals developed large tumors within 2 weeks. These data illustrate that tumor formation is likely due to rare populations of contaminating undifferentiated SSEA1⁺

research article

cells after sorting and that residual ESC-like cells at frequencies of less than 1% of total cells represent a significant tumor risk. Our sorting and grafting protocol was thus modified to include the SSEA1-647 antibody to remove these contaminants and thus reduced tumor formation by roughly 50% (4 out of 19 mice developed tumors) across the lines. Short-term replating prior to transplantation, a technique used previously (2), reduced the number

of SSEA1⁺ cells from approximately 5% to 7% (no replating) to approximately 2% to 3% (after replating; Supplemental Figure 3). To address whether further enrichment of FACS-purified reporter⁺ cells can eliminate tumor risk, we resorted the reporter⁺ cells after the first round of sorting and transplanted double-sorted reporter⁺ cells for each of the 3 reporter lines (*n* = 9). Under these conditions, tumor formation did not occur.

Figure 5

Microarray analysis of FACS-purified cell populations. (A) Venn diagram plot for significantly enriched (increased expression only) genes in intraline analysis, showing 107 genes common to both *Nurr1::GFP*⁺ and *Pitx3::YFP*⁺. (B) Venn diagram plot of significantly enriched genes in interline analysis, showing 148 genes common to both *Nurr1::GFP*⁺ and *Pitx3::YFP*⁺ cells in contrast to *Hes5::GFP*⁺ cells. (C–E) Scatter plots of significantly altered genes (≥2 fold increased/decreased; *P* ≤ 0.05). Red boxes represent genes enriched at the *Hes5* stage (H+/H–), while blue boxes represent genes that are decreased at that stage. (C) Intraline scatter plot of the 233 altered H+/H– genes (x axis) compared with the altered 232 N+/N– genes (y axis) (449 genes common to both). (D) Intraline scatter plot of the 232 altered N+/N– genes compared with the 556 altered P+/P– genes (656 genes common to both). (E) Interline scatter plot of the 586 altered N+/H+ genes compared with the 1,203 altered P+/H+ genes (1,355 genes common to both). (F) Dendrogram plot of all significantly altered genes (*P* ≤ 0.05) in all 3 reporter⁺ and reporter⁻ sorts across the 3 lines. H, *Hes5*; P, *Pitx3*; N, *Nurr1*.

A key goal of our study was to compare the efficiency of DA neuron engraftment among the 3 reporter lines in an effort to define the stage most suitable for cell replacement therapy. Analysis of the tumor-free single-sorted and all of the double-sorted grafts showed robust survival of TH⁺ neurons in all 3 lines in comparison to similarly sorted (SSEA1-negative/propidium iodide-negative) J1 cells – the parental cell line of the transgenic lines (Figure 4, A–F). Single-sorted *Hes5::GFP*⁺ cells yielded slightly lower numbers of TH⁺ cells in vivo (13,006 ± 3,734 TH⁺ cells) as compared with those of grafts derived from the *Nurr1::GFP* (37,697 ± 11,709 TH⁺ cells) and *Pitx3::YFP* (25,824 ± 4,896 TH⁺ cells) lines, but all were significantly higher than those of non-reporter-sorted J1 controls (2,840 ± 192 TH⁺ cells). Grafts from the *Hes5::GFP* line showed preferential localization of TH⁺ cells to the graft periphery and contained a large number of GFP⁺/GFAP⁺ astrocytes (Supplemental Figure 4A). In contrast, *Nurr1::GFP* and *Pitx3::YFP* grafts

were composed of nearly homogenous TH⁺ neurons that distributed evenly throughout the graft core (Supplemental Figure 4B) without any GFP⁺/GFAP⁺ cells (data not shown). To determine whether GFAP⁺ cells in the *Nurr1* grafts came exclusively from the host, we generated subclones of the *Nurr1::GFP* and *Hes5::GFP* lines modified with a vector (10) designed to express RFP constitutively (*Nurr1::GFP;UbC::RFP* and *Hes5::GFP;UbC::RFP*). These lines were differentiated as above, and, at day 14 of differentiation, GFP⁺/RFP⁺ cells were sorted and grafted into hemiparkinsonian mice. While the majority of GFAP⁺ cells came from the host, in the *Hes5::GFP;UbC::RFP* grafts, we observed many more GFAP⁺/RFP⁺ cells within the graft than in the *Nurr1::GFP;UbC::RFP* grafts (Supplemental Figure 4C), which is consistent with our in vitro results (Figure 3, A and B).

The midbrain DA neuron identity of TH⁺ cells in the grafts was confirmed by colabeling with FOXA2 (Figure 4, G–I) and *Pitx3*

mDA TF, midbrain-specific transcription factor.

(Supplemental Figure 5, A and B). Reporter⁺ cells from both the *Nurr1::GFP* and *Pitx3::YFP* grafts also colabeled with GIRK2, a marker of substantia nigra (SN, also known as A9) type DA neurons, or calbindin, a marker expressed in postmitotic DA neurons of the ventral tegmental area (VTA, also known as A10), indicating that FACS-purified populations yielded both A9- and A10-type midbrain DA neurons in vivo (Supplemental Figure 5, C and D). Consistent with our in vitro results, we did not observe any cycling cells in the *Nurr1* grafts, as evident by an absence of Ki67 staining (Supplemental Figure 5, E and F). The largest TH⁺ cell numbers and densities were observed in the *Nurr1::GFP* line followed by the *Pitx3::YFP* line for both single- and double-sorted cells (Figure 4, J and K). The significantly smaller number of TH⁺ cells in grafts from double-sorted cells compared with that in single-sorted cells is likely due to increased mechanical stress upon sequential FACS and/or the lower total cell numbers grafted (50×10^3 to 100×10^3 cells in double-sorted cell preparations compared with 150×10^3 to 200×10^3 cells in single-sorted cell preparations).

Single- and double-sorted grafts provide behavioral recovery in hemiparkinsonian mice. While sham-grafted animals did not show any recovery in the amphetamine-induced ipsilateral rotation assay, animals grafted with FACS-purified cells from all 3 lines showed robust recovery, both for single-sorted (tumor-free) and double-sorted cell preparations (Figure 4, L and M, and Supplemental Figure 6A). Similarly, both single- and double-sorted grafts from all 3 lines showed improvements in apomorphine-induced contralateral rotation behavior (Supplemental Figure 6B), a parameter of dopamine hypersensitivity in the host striatum. Results from the cylinder test showed more variable results in graft-induced recovery (Supplemental Figure 6C). These data indicate that FACS-purified midbrain DA neuron progeny are capable of in vivo survival and complete restoration of amphetamine-induced rotation behavior in the 6-OHDA lesion model. Additionally, the near lack of graft-derived glia among the transplanted cells, in the case of *Nurr1::GFP* and *Pitx3::GFP* grafts (Figure 3, B and C), suggests that ESC-derived neurons can co-opt host glia into the graft (Supplemental Figure 4, B and C).

Microarray analysis of the 3 reporter lines confirms cell identity and enables discovery of midbrain DA neuron-specific genes. The transplantation of purified postmitotic DA neurons instead of a more heterogeneous grafting population makes it imperative that the sorted cells exhibit a fully authentic midbrain DA neuron phenotype. In order to assess midbrain DA neuron identity in an unbiased manner, we performed global transcriptome analysis of FACS-purified populations for each of the 3 reporter lines at day 14 ($n = 3$ independent differentiations for each line). All raw data are available at GEO (accession no. GSE37446; <http://www.ncbi.nlm.nih.gov/geo/>). We assessed midbrain DA neuron-specific gene expression profiles using 2 separate paradigms for data analysis: (a) intraline analysis — comparing reporter⁺ with reporter⁻ cells for each line; and (b) interline analysis — comparing individual reporter⁺ fractions from each of the 3 reporter lines against each other (i.e., *Nurr1::GFP*⁺ and *Pitx3::YFP*⁺-committed DA neurons compared with the *Hes5::GFP*⁺ precursor cell population). With the intraline analysis, we found 107 genes that were commonly enriched (≥ 2 fold; $P \leq 0.05$) in the reporter⁺ fractions of both the *Nurr1* and *Pitx3* lines (Figure 5A). With the interline analysis, there were 148 commonly enriched genes in the *Nurr1*⁺ and *Pitx3*⁺ cells compared with those in the *Hes5*⁺ population (Figure 5B). More than half of all putative midbrain DA neuron genes in the intraline analysis (*Nurr1*^{+/Nurr1}⁻ [N⁺/N⁻] and *Pitx3*^{+/Pitx3}⁻ [P⁺/P⁻] only) overlapped with those of the interline analysis, for a total of 85 core transcripts, of which, 67 were upregulated and 18 were downregulated (Supplemental Table 1). Scatter plots of the significantly altered genes were established from both intraline (Figure 5, C and D) and interline (Figure 5E) analyses. Intraline analysis demonstrated that the only common gene upregulated in both *Hes5*^{+/Hes5}⁻ (H⁺/H⁻) and N^{+/N}⁻ cells was *Gfp* (Figure 5C). In contrast, there was a strong correlation of genes regulated in N^{+/N}⁻ cells compared with those in P^{+/P}⁻ cells, with *Th*, *DAT*, and *Gfp* being the most highly enriched (Figure 5D and Supplemental Table 2). Similarly, the interline analysis showed a strong correla-

Scale bar: 200 μm (**A–D**); 100 μm (**E, F, H, and I**); 25 μm (**G, J, and insets for A–D**).

tion for genes regulated in *Nurr1*⁺/*Hes5*⁺ (N+/H+) cells compared with those in *Pitx3*⁺/*Hes5*⁺ (P+/H+) cells, with *Th* and *Cck* being the most highly enriched and *Pou6f1* and *Olig1* being the most down-regulated transcripts (Figure 5E and Supplemental Table 3). The similarities between the *Nurr1*⁺ and *Pitx3*⁺ fractions were further illustrated by unsupervised clustering of all significantly changed genes in a dendrogram that grouped all of the *Nurr1*::*GFP*⁺ and *Pitx3*::*YFP*⁺ samples together, while *Hes5*::*GFP*⁺ samples clustered with the all the reporter⁻ fractions (Figure 5F).

Further analysis of the genes significantly enriched in the *Nurr1*::*GFP*⁺ and *Pitx3*::*YFP*⁺ cells (Figure 5, A and B) confirmed the expression of known midbrain DA neuron genes, including biochemical markers associated with DA synthesis and signaling, such as *Th*, *Ddc*, *Vmat2*, and *DAT*, and midbrain-specific transcription factors, such as *Pitx3*, *Nurr1* (also known as *Nr4a2*), *Foxa2*,

En1, and *Lmx1a* (Table 1). These data demonstrate the remarkable specificity of FACS-purified cell populations corresponding to the midbrain DA neuronal fate.

We next asked whether our microarray data might enable the identification of novel markers of midbrain DA neurons. In particular, we were interested in the identification of cell surface markers and novel transcriptional regulators of potential functional relevance. Based on average fold changes of P+/H+ and N+/H+ of the interline analysis ([P+;N+] vs. *Hes5*⁺), gene ontology analysis identified a total of 42 transcripts encoding genes associated with the cell membrane and 17 transcripts encoding transcription factors or transcriptional regulators that were differentially expressed at 2 fold or higher ($P < 0.05$) (Table 2 and Supplemental Table 4). To test specific expression of novel candidate midbrain DA neuron markers, we performed intraline and interline qRT-PCR analy-

research article

sis (Supplemental Figure 7A) and in vivo immunohistochemical analysis of the expression of transcription factors *Uncx4.1* and *Pbx1*. Both genes showed specific in vivo expression in the adult mouse ventral midbrain. *Uncx4.1* selectively marked TH⁺ cells in the SN and VTA, with labeling being mostly perinuclear (Figure 6, A and B). Perinuclear staining for *Uncx4.1* was surprising given the expected role of this gene as a transcription factor. However, perinuclear staining for *Uncx4.1* has been previously observed in placental tissue, and perinuclear localization has been reported for other transcription factors such as CREB (following 6-OHDA lesioning; ref. 11). In contrast, *Pbx1* showed strong nuclear localization in midbrain DA neurons but was not as exclusive to the midbrain DA neuron domain (Figure 6, C and D). Importantly, both UNCX4.1 and PBX1 were also expressed in the FOXA2⁺/TH⁺ ventral domain of the developing human midbrain (6–8 weeks after conception; Figure 6, E–J, and Supplemental Figure 8). The conserved expression pattern of these transcription factors suggests that they could play a role in human midbrain DA neuron development and/or maintenance.

Another novel marker, NECAB1, a member of a family of neuronal Ca²⁺ binding proteins (12), was also expressed in the adult mouse midbrain but was localized to only a subset (the dorsal domain) of DA neurons in both the SN and VTA (Supplemental Figure 7B). *C1ql1*, a gene that has been shown to regulate synapse formation (13), was also found to be localized to DA neurons within the adult SN (Supplemental Figure 7C). In terms of cell surface markers, we found that *Chrna6* (Table 2), a subunit of the nicotinic acetylcholine receptor (nAChR) that has previously been shown to be expressed in the adult mouse SN (14), was expressed within the developing midbrain in 3 separate mouse databases (ref. 15 and Supplemental Figure 9, A–D). This gene is interesting given the well-established link between tobacco use and decreased rates of PD and because radiolabeled ligands to this receptor have been used for visualization of the human midbrain by single-photon emission computed tomography (16). Upon further investigation (14), we found that another nAChR subunit, CHRNB3, was also expressed in the FOXA2/LMX1A domain of the developing human ventral midbrain (Supplemental Figure 9E). Although future studies will be needed to characterize the functional role of these DA neuron markers, our data demonstrate that SSRLA of mESCs can be used to identify genes expressed in human development.

Discussion

Numerous studies have demonstrated the use of ESC-derived DA neurons for grafting in animal models of PD (17); however, it has remained unclear which stage of differentiation and what particular population of cells is most effective at inducing functional benefits upon transplantation in vivo. Fetal tissue studies have focused on the grafting of ventral mesencephalic tissue isolated at a stage in which the majority of developing DA neurons are postmitotic, which is E12–E13 in mice (18) and E14–E15 (19) in rats. In human fetal grafting studies, increased survival of TH⁺ neurons has been reported for tissue derived from embryos at 5 to 8 weeks after conception when using suspension grafts and up to 9 weeks after conception for solid grafts (20). In all of those cases, however, the grafted population was composed of a heterogeneous pool of cells at various stages of differentiation and typically contained less than 20% DA neurons (21). One recent study used purified DA neurons derived from a *Pitx3::GFP* plasmid reporter line established by gene targeting (4). The authors reported a requirement for coculture

with primary astrocytes to achieve robust in vitro survival of FACS-purified DA neurons and observed less robust in vivo survival rates. Nevertheless, the study did demonstrate functional engraftment of purified DA neurons in at least a subset of animals (4).

In this study, we observed excellent in vitro and in vivo survival for DA neurons derived from both the *Nurr1::GFP* and *Pitx3::YFP* lines without astrocyte coculture, thus providing clear evidence that transplantation of purified early-stage DA neurons is a promising option for PD grafting. The requirement for double sorting to eliminate tumorigenic cells was associated with a lower survival rate of TH⁺ cells. While animals with double-sorted grafts received half the number of cells compared with those with single-sorted grafts (due to our limited scalability), TH⁺ cell survival in double-sorted grafts was 10 times lower. This lower DA neuron survival rate could be due to factors secreted by contaminating cells in single-sorted grafts or increased mechanical stress involved in the double-sorting process or point to a critical threshold of total cells needed for graft survival and integration. Despite the decreased survival rate, the number of DA neurons delivered via double sorting was sufficient to provide therapeutic benefits in our behavioral assays. It has been shown that as few as 400 TH⁺ neurons can provide up to 50% reduction in behavioral deficits of hemiparkinsonian rats 6 weeks after surgery (22). TH⁺ cell numbers in our study clearly surpassed this threshold in both single- and double-sorted populations, and we commonly observed contralateral rotations in our single-sorted grafts following amphetamine stimulation, a finding in often interpreted as overcompensation. Among the 3 stages of DA neuron development tested here, in vivo TH⁺ cell yields were highest in reporter⁺ cells from the *Nurr1::GFP* line, without evidence of reduced specificity in DA neuronal fate. Therefore, transplantation of purified early postmitotic DA neurons at the *Nurr1*⁺ stage may be a particularly promising approach for eventual clinical translation. However, it should be noted that recovery of behavioral deficits was not statistically significant in the cylinder or apomorphine tests. This could be due to various factors including limited fiber outgrowth of the DA neurons; low levels of DA release; or technical limitations of our study, such as measuring performance in only a single test both before and after grafting, low sample size, and limitations of the mouse as opposed to the more commonly used rat 6-OHDA model. However, in terms of recovery of amphetamine-induced motor deficits and overall DA neuron cell survival of single- and double-sorted grafts, we found that the *Nurr1* stage of differentiation is ideal for grafting ESC-derived DA neurons.

Future studies will be needed to address the effect of glial cells, or lack thereof, at the time of grafting. Our data indicate that graft-derived DA neurons are surrounded by glia from the host. But currently it is unclear whether the host glia help or hinder DA neuron survival and function. In double-sorted cells, there was a trend toward a more robust behavioral recovery in *Hes5::GFP*⁺ grafts compared with that in *Pitx3::YFP*⁺ grafts, despite similar or higher numbers of TH⁺ cells in the *Pitx3::YFP* group. One potential explanation could be that the presence of graft-derived astrocytes from the *Hes5::GFP* line promotes DA neuron function. Future studies will be needed to assess the survival and function of FACS-purified DA neurons in the presence or absence of astroglia.

The present findings underscore the need to graft populations highly enriched in neuronal fates in order to prevent tumor formation. When grafting cells at high concentrations in an immunocompromised host brain, we found that a percentage of less than

1% contamination (175–1,600 SSEA1⁺ cells) at the time of grafting represents an unacceptable tumor risk. In addition to the double-sorting technique presented here, we could also largely prevent tumor formation by gating cells that were negative for SSEA1 expression during the initial reporter⁺ cell sort, similar to previous work (23). We found the SSEA1-647 antibody to be particularly effective in reducing SSEA1 contaminants after sorting (Supplemental Figure 3). Attempts at reducing potentially tumorigenic cells prior to transplantation via short-term replating could decrease, but not fully eliminate, SSEA1⁺ cells (Supplemental Figure 3, C and F), which is in agreement with the more rare overgrowth behavior observed in previous work (2). Tumor formation from SSEA1⁺-grafted cells occurred within 2 weeks following transplantation in our study, which is in contrast to the much slower time course observed in hESC-based neural grafts that more commonly show neural overgrowth rather than teratoma formation (1, 2). The differences in teratoma risk between mESCs and hESCs may be related to their respective pluripotent states, with hESCs being developmentally aligned to mouse epiblast stem cells (24), which are more primed for differentiation and exit of pluripotency. The lack of tumor formation at 6 weeks reported here indicates that double sorting is an effective approach at improving graft safety in the context of mESCs.

A factor that may have contributed to tumor formation in our single-sorted groups was the use of the immunocompromised mice. We observed that similar allografts in wild-type Sv129 hemiparkinsonian mice produced a much lower rate of tumor formation, with only 3 out of 46 animals exhibiting overgrowth. This indicates that there is a substantial risk of tumor formation, particularly when large numbers of mESC-derived neurons are grafted into the brains of immunocompromised mice. Future PD grafting studies will likely involve immunosuppression, suggesting that even under allograft conditions it will be important to proceed cautiously on the road toward future clinical translation of ESC-derived cell types.

A critical issue for DA neuron replacement paradigms in PD is the use of an appropriate cell source. While previous studies in mESCs have demonstrated *in vivo* functionality in murine PD models, there has been some concern that naive ESC-derived DA neurons may be less effective at alleviating behavioral symptoms as compared with fetal midbrain DA neurons. Several studies suggested that efficient DA neuron generation and engraftment occurs only upon transgenic modification of the cells using transcription factors such as NURR1 (25), LMX1A (26), or BCL-XL (27). This study shows that DA neurons derived from naive ESCs achieve robust behavioral recovery. Therefore, the variable results obtained in previous studies using naive ESC sources may have been caused by a low percentage of authentic DA neurons, rather than reflecting a true requirement for the expression of transgenic DA neuronal fate determinants.

In this study, the authenticity of FACS-purified midbrain DA neurons was confirmed at the molecular level for both *Nurr1::GFP*⁺ and *Pitx3::YFP*⁺ cells. *Nurr1* expression in the developing mouse brain is not exclusive to the midbrain DA neuron lineage (28). However, under the conditions of our differentiation protocol, *Nurr1::GFP*⁺ cells were consistent with the midbrain DA neuron phenotype based on both global transcriptome analysis and characterization of the grafted cells *in vivo*. Therefore, the incomplete marking of TH⁺ cells by FOXA2 upon replating *Nurr1::GFP*⁺ cells after sorting (Figure 2, B and J) likely reflects

transient downregulation of the transcription factor, rather than alternative fate choice.

Gene discovery via the 3 reporter lines identified several relatively novel transcriptional regulators shown to be localized to the ventral midbrain, such as *Foxp2* (29) and *Ebf3* (30). The transcription factors, *Uncx4.1* (31) and *Pbx1*, were confirmed via qRT-PCR (Supplemental Figure 7A), with *Uncx4.1* being enriched under both paradigms and *Pbx1* being enriched only under the intraline analysis. Supporting this observation, *Pbx1* expression was found throughout the E10.5 mouse midbrain (Supplemental Figure 7D) and had a much broader domain than *UNCX4.1* in the developing human midbrain (Figure 6H), therefore suggesting a broader role for this transcription factor in CNS development. However, these genes continue to be expressed in the adult SN (Figure 6, A–D) and therefore are particularly attractive for future studies aimed at exploring the potential functional roles for these transcriptional regulators in midbrain DA neuron specification and/or maintenance. Additionally, the ability to purify midbrain DA neurons from hESC cultures will be necessary for any clinical translation, and therefore it is encouraging that CHRNA6 and CHRN3 are cell surface markers expressed in the developing mouse and human midbrain, respectively (Supplemental Figure 9). Furthermore, a recent study has also confirmed the midbrain DA neuron specificity of the most significant cell surface marker gene on our gene list, *Gucy2c* (32) (Table 2 and Supplemental Tables 1–4). So while our data clearly demonstrate the applicability of SSRLA toward gene discovery, it would be interesting to compare our approach head-to-head with alternative approaches such as the use of transcription factor-driven lineage selection (33) or FACS-based isolation of primary DA neurons.

In conclusion, our study emphasizes the importance of identifying the appropriate cell type and differentiation stage in achieving safe and efficacious DA neuron engraftment. We found that early postmitotic DA neurons at the *Nurr1*⁺ or later stage represent a promising cell source for future translational studies. The use of BAC transgenic reporter lines may not be suitable for human clinical translation due to the need for transgene insertion and reporter gene expression. However, our profiling studies present multiple candidate surface markers that may enable comparable antibody-mediated cell isolation strategies. The ultimate goal for translation may be, similar to that of drug-based therapies, to establish fully characterized, scalable, and ready-to-use populations of NURR1-stage DA neurons that can be properly dosed and standardized for therapeutic applications. While many hurdles remain on the road toward this goal, we recently described a novel strategy for deriving midbrain DA neurons from hESCs that resulted in excellent *in vivo* survival and function (34). The choice of DA neuron differentiation stage used in this study was influenced by the current BAC reporter data, as we specifically aimed at transplanting hESC-derived DA neurons at the *Nurr1* expression stage. However, formal comparisons using hESC-based BAC or knockin reporter lines will be required to formally address these questions in purified human cells. While DA neuron replacement in PD represents a symptomatic treatment unlikely to affect all disease-related symptoms, access to pure populations of engraftable DA neurons will be a major step forward toward testing the full potential of DA neuron replacement therapies in PD. Finally, we believe that SSRLA is a powerful application of ESCs for gene discovery that could be used for generating refined genetic signatures in other specific ESC-derived cell types.

research article

Methods

BAC transgenic ESC line production. RP23-236113 (GENSAT-modified) BAC for NURR1 and RP11-946K20 (Children's Hospital Oakland Research Institute; YFP recombining into the entire coding sequence was performed by S. Kriks according to a previously described protocol; ref. 6) BAC for PITX3 were retrofitted with a Kan/G418 cassette for mammalian selection according to protocol (6). Purified DNA was produced with the PSI Ψ Clone BAC DNA Kit according to the manufacturer's protocol and nucleofected into 6×10^6 cells as previously described (6). Nucleofected cells were plated onto Neo-resistant mouse embryonic fibroblasts (Globalstem) for 2 days, upon which G418 selection was performed at a concentration of 200 $\mu\text{g}/\text{ml}$ for 7 to 10 days. Colonies were manually picked and expanded clonally and differentiated in 6-well plates according to a previously described protocol (8). Reporter⁺ clones (observed at ~day 10 for NURR1 and day 12 for PITX3 lines) were further characterized for proper protein expression in vitro using the rabbit anti-NURR1 antibody (Perseus Proteomics; 1:1,000) and rabbit anti-PITX3 antibody (Zymed; 1:100) to double stain with GFP (Abcam; 1:1,000). Upon confirmation of proper protein expression, reporter⁺ colonies were differentiated at large scale for 2 weeks, reporter⁺ and reporter⁻ cells were FACS-purified, and RNA was isolated in TRIzol (Invitrogen) according to the manufacturer's protocol. qRT-PCR was then performed for each lines' corresponding RNA enrichment at the Memorial Sloan-Kettering Cancer Center (MSKCC) Genomics Core Lab using the housekeeping gene *HPRT* to normalize the data transcripts. BAC FISH was performed with purified BAC DNA (see above) and submitted to the Molecular Cytogenetics core facility. The *Nurr1::GFP;Ubc::RFP* and *Hes5::GFP;Ubc::RFP* cell lines were clonally selected after viral transduction with a modified plasmid driving RFP under the ubiquitin C promoter (10).

mESC culture, differentiation, and FACS preparation. J1 mESCs were grown on mouse embryonic fibroblasts in mESC medium (knockout DMEM, 20% FBS, 2 mM glutamine, 0.1 mM MEM-nonessential amino acids, and 55 μM β -mercaptoethanol) supplemented with 1,400 U/ml LIF (ESGRO, Invitrogen). Differentiations for grafting and FACS were performed under a modified version of the MS5-based protocol previously reported (8). Briefly, ESCs were trypsinized and plated onto a dense MS5 feeder layer at a concentration of 20,000 cells per 10-cm dish. The same protocol was applied, except using a different sonic hedgehog (SHH), C25II SHH (R&D Systems) at 50 ng/ μl , and the whole protocol was shifted 1 day earlier (neural induction as day 4).

Initial sorting methods consisted of dissociation via resuspension in HBSS with 0.25% trypsin (1:100) for 1 hour at 37°C and manual trituration and resuspension in N2 with propidium iodide (2 $\mu\text{g}/\text{ml}$). Propidium iodide-negative cells were plotted for PE and FITC, and cells were caught into FBS. After the observation of tumors, cells were dissociated in accutase for 45 minutes at 37°C, triturated, resuspended in 0.1% BSA/PBS and SSEA1-PE antibody (BD Pharmingen) for 20 minutes on ice, washed with PBS, resuspended in 0.1% BSA/PBS with 25 μM HEPES and 7-AAD (BD Pharmingen, catalog no. 559925) (PBS⁻), and caught in N2 medium. However, our best sort results, as assayed by SSEA1 levels after sorting, occurred when we replaced the SSEA1-PE with the SSEA1-647 antibody, as they use different lasers for their analysis (compensation is not necessary). All graftings were performed under propidium iodide-negative- and SSEA1-647-negative-gated conditions. Double sorting was performed by spinning down the reporter⁺-sorted cells and resuspending them in PBS⁻. All cells for grafting and in vitro analysis were resuspended in N2 with BDNF (20 ng/ml) and ascorbic acid (200 μM) at a concentration of between 50,000 and 100,000 cells per μl . For in vitro analysis, 1- to 2- μl drops were spread onto PO/Lam- or Matrigel-treated (according to the manufacturer's protocol) Permanox chamber slides (Labtek) for 5 minutes, resuspended in N2/BDNF/AA, and analyzed after 24 hours or 7 days.

Lesioning and grafting. Fox Chase SCID beige mice (Charles River Laboratories) were housed and treated according to the MSKCC IACUC and NIH guidelines. At 6 to 8 weeks of age, mice were anesthetized with ketamine/xylazine (Fort Dodge) or pentobarbital (Nembutal, Abbot Laboratories), and hemiparkinsonian lesions were performed according to a previously described protocol (2). Briefly, unilateral stereotactic injections of 6-OHDA (Sigma-Aldrich) were made in the striatum at the following coordinates: anteroposterior [AP], +0.5; mediolateral [ML], -1.8; dorsoventral [DV], -3.2. Transplantation of 150,000 to 200,000 cells, at a concentration of 75,000 to 100,000 cells per μl , was performed with a Hamilton syringe (26 gauge) at a rate of 1 μl per minute at the following coordinates: AP, +0.5; ML, -2.0; DV, -3.3. Animals recovered for 3 weeks before behavioral testing.

Behavioral analysis. All behavioral tests were performed 2 weeks after lesioning and 3 weeks after grafting of cells and in the same order. Three separate amphetamine tests were performed weekly according to the previously described protocol (2). Briefly, 3 weeks after grafting, mice were injected with 10 mg/kg D-amphetamine sulfate (Sigma-Aldrich) intraperitoneally once a week for 3 weeks. Ten minutes after injection, mice were videotaped in a bowl for 30 minutes and scored via ipsilateral (positive) or contralateral (negative) rotations. After the final amphetamine test, mice underwent a single cylinder test 1 week later to test behavioral abnormalities when mice explore a novel environment (35), which was performed according to a previously described modified protocol (2). Briefly, mice were placed in a new cage, and 20 rearing observations were analyzed for paw placement on the wall of the cage. This assay is a measurement of forelimb akinesia, as ipsilateral paw placement is preferred in lesioned mice in contrast to contralateral and simultaneous paw placements. Apomorphine tests were performed the following day (1 week before cell grafting and for 7 weeks after grafting) similarly to amphetamine injections, except R-Apomorphine hydrochloride hemihydrate (Sigma-Aldrich) was dissolved in 2 mg/ml ascorbic acid in water (shaken at 37°C for 30 minutes) and injected at 40 mg/kg. Contralateral rotations were scored as positive in this case and ipsilateral were scored as negative.

Electrophysiological analysis. After sorting, high-density cells were plated on Matrigel-treated glass coverslips and cultured in N2/AA/BDNF for 7 days. Resting membrane potentials from *Nurr1* cells were -43 ± 2 mV, with input resistance of 1.6 ± 0.2 GOhm. Twenty-four out of twenty-eight cells from *Nurr1* coverslips fired action potentials in response to depolarizing current injection from -60 mV. The resting membrane potential from *Pitx3* cells was -38 ± 2 mV, with input resistance of 1.6 ± 0.2 GOhm. All 14 cells from *Pitx3* coverslips fired action potentials in response to current injection.

Immunofluorescence and microscopy. Mice were given a lethal dose of pentobarbital and transcardially perfused with PBS followed by 4% paraformaldehyde. Brains were removed and fixed overnight at 4°C and then transferred to 30% sucrose overnight. Brains were embedded in O.C.T. (Tissue-Tek) and stored at -80°C until serial cryosectioning at 30 microns in 5 bottles. For fluorescence immunohistochemistry, sections were blocked in 10% normal goat serum (NGS; Gibco) with 0.2% Triton X-100 (Triton was omitted for surface antigens) for 30 minutes at room temperature. Primary antibodies were applied overnight in 2% NGS (1% BSA for FOXA2 staining) at 4°C, followed by appropriate fluorochrome-conjugated secondary antibodies (Alexa Fluor conjugates; Molecular Probes) for 1 hour at room temperature. Slides were then washed and counterstained with Vectashield with DAPI (Vector Laboratories). Primary antibodies included rabbit anti-TH (1:200; Pel Freez Biologicals), mouse anti-TH2 (1:1,000; Sigma-Aldrich), rabbit anti-GFAP (1:1,000; Dako), rabbit anti-LMX1A (1:2,000; Millipore), goat anti-FOXA2 (1:100; Santa Cruz Biotechnology Inc.), rabbit anti-PBX1 (1:500; Cell Signaling Technology), rabbit anti-GIRK2 (1:80; Alomone Labs), rabbit anti-NECAB1 (1:1,000; Sigma-Aldrich), mouse anti-Calbindin (1:500; Abcam), mouse anti-CHRN3 (1:500; Sigma-Aldrich), rabbit

anti-UNCX4.1 (1:100; Sigma-Aldrich), and rabbit anti-PITX3 (a gift from the laboratory of M.P. Smidt). Immunocytochemistry for in vitro characterization of midbrain DA neuronal fate included both polyclonal and monoclonal TH antibodies (see above) and mouse anti-Engrailed (1:100; clone 4G11, DSHB) antibodies. Human fetal mesencephalic tissue was collected from routine terminations of pregnancies (6–8 weeks after conception, determined by crown-rump length), with approval of the Swedish national board of health and welfare (Socialstyrelsen, Dnr. 23 11667/2008 and Dnr. 23 2981/2009).

Microarray analysis. mRNA transcriptome analyses were performed using Illumina Mouse-6 BeadChip technology for mRNA comparisons of 3 separate sorts for the *Hes5::GFP^{+/+}*, *Nurr1::GFP^{+/+}*, and *Pitx3::YFP^{+/+}* populations. Data were analyzed using Partek software (<http://www.partek.com/>). Significance was based on an ANOVA analysis of all sorted populations, and significant gene lists were created under the criteria of an unadjusted *P* value of ≤ 0.05 . Only transcripts enriched or depleted more than 2 fold were analyzed.

Quantification and statistical analysis. The number of surviving TH⁺ neurons was assessed using stereological methods. Uniform random sampling was performed to obtain sections for graft quantification. Stereological software (Stereo Investigator, v6.0; MicroBrightfield) was used to design and implement optical fractionator probes at a Gundersen-Jensen coefficient of error of 0.05. Data throughout the paper are expressed as average \pm SEM.

Statistical analysis for behavioral data at various time points after transplantation was performed by 1-way ANOVA.

Study approval. All mouse in vivo studies were performed following NIH guidelines and were approved by the local IACUC (MSKCC, New York, New York, USA).

Acknowledgments

We are grateful for excellent technical support from the Molecular Cytogenetics Core, the SKI Stem Cell Facility, Flow Cytometry, and the Genomics Core Laboratories at MSKCC. We also would like to thank Dimitris Placantonakis, Stuart Chambers, Gabsang Lee, and Agnete Kirkeby for helpful discussions on the manuscript. M. Parmar is funded by Swedish Research Council. This work was supported by the Starr Foundation, by the European Commission project NeuroStemCell, and by grant support from NINDS (NS052671).
