Abstract

Lupus nephritis is a cause of significant morbidity in systemic lupus erythematosus (SLE) and its genetic background has not been completely clarified. The aim of this investigation was to analyze single nucleotide polymorphisms (SNPs) for association with lupus nephritis, its severe form proliferative nephritis and renal outcome, in two Swedish cohorts. Cohort I (n = 567 SLE cases, n = 512 controls) was previously genotyped for 5676 SNPs and cohort II (n = 145 SLE cases, n = 619 controls) was genotyped for SNPs in STAT4, IRF5, TNIP1 and BLK. Case-control and case-only analysis of patients with lupus nephritis, proliferative lupus nephritis, severe renal insufficiency were performed. In the case-control analysis of cohort I, four highly linked SNPs in STAT4 were associated with lupus nephritis with genome wide significance with \( p = 3.7 \times 10^{-8} \), OR 2.20 for the best SNP rs11889341. Strong signals of association between IRF5 and an HLA-DR3 SNP marker were also detected in the lupus nephritis case versus healthy control analysis (\( p < 0.0001 \)). An additional six genes showed an association with lupus nephritis with \( p < 0.001 \) (PMS2, TNIP1, CARD11, ITGAM, BLK and IRAK1). In the case-only meta-analysis of the two cohorts, the STAT4 SNP rs7582694 was associated with severe renal insufficiency with \( p = 1.6 \times 10^{-3} \) and OR 2.22. We conclude that genetic variations in STAT4 predispose to lupus nephritis and a worse outcome with severe renal insufficiency.

Introduction

Lupus nephritis (LN) constitutes one of the main clinical challenges in patients with systemic lupus erythematosus (SLE) and is a cause of significant morbidity and mortality. LN occurs in 15–55% of patients with SLE with the higher incidence in Asian and African populations [1]. Proliferative glomerulonephritis, classes III/IV, is considered to be the most severe form of nephritis and requires aggressive immunosuppressive treatment [2]. Despite improved treatment regimens, approximately 10% of all LN patients develop end-stage renal disease (ESRD) [1]. Several non-HLA susceptibility genes for SLE have been identified through candidate gene and genome wide association studies (GWAS). Among these, polymorphisms in signal transducer and activator of transcription 4 (STAT4), interferon regulatory factor 5 (IRF5), the family with sequence similarity 167 member A-B lymphoid tyrosine kinase (FAM167A-BLK) locus, TNFAIP3 interacting protein 1 (TNIP1) and integrin–2α integrin–2β (ITG2A-M-ITG6A-X) display high signals of association that have been convincingly replicated [3-6].
The aim of this study was to further elucidate the genetic component in LN using data on more than 5000 SNPs generated in our previous study on SLE [6]. In addition, the association between LN susceptibility genes and proliferative nephritis as well as the development of severe renal insufficiency was investigated.

Materials and Methods

Patients and controls

Cohort I consisted of 567 Swedish Caucasian patients with SLE and 512 controls. The patients originate from the rheumatology clinics in the Uppsala (n = 143) and Lund (n = 155) University Hospitals and the Karolinska University Hospital, Stockholm (n = 269), Sweden. The controls were individually matched for age, gender and area of residence and consisted of healthy blood donors from Uppsala (n = 132) and Lund (n = 91) while the controls from Stockholm (n = 289) were samples from the population-based Epidemiological Investigation of Rheumatoid Arthritis (EIRA) cohort [20]. Cohort II consisted of 145 Swedish SLE patients of Caucasian origin from Linköping University Hospital, and 619 healthy Swedish blood donor controls. Five hundred and fifty two cases and 499 controls in cohort I and 144 cases and all controls in cohort II were previously described in a study by Wang et al [19]. All patients fulfilled the 1992 ACR criteria for SLE [21]. Clinical data was extracted from the patient files.

Definition of lupus nephritis

Occurrence of LN was defined according to the ACR criteria and onset of nephritis was defined as the year of fulfilling ACR nephritis criteria. Renal biopsies were performed in 159 patients in cohort I, for which 152 histopathology results were available. In cohort II, 26 patients were subjected to renal biopsies, all with available histopathology results. LN according to the WHO classification system was verified in 160 patients (134 in cohort I and 26 in cohort II) [2], while in cohort I, 18 biopsies showed vascular changes including thrombotic microangiopathy (data not shown). Patients having WHO class III or IV at any time were defined as the proliferative nephritis group (Table 1).

Renal insufficiency outcome

The follow-up time from nephritis onset was until December 31st 2009 (median 14 years, range 0–46). The glomerular filtration rate (GFR) was calculated at follow up with the Modification of Diet in Renal Disease (MDRD) formula. Renal function was classified according to the chronic kidney disease (CKD) system where stage 4 and 5 (GFR <30 mL/min/1.73 m²) were defined as severe renal insufficiency [22]. Patient characteristics are presented in Table 1.

Ethics statement

The study was conducted according to the Declaration of Helsinki. All patients from Stockholm, Lund and Linköping gave their verbal and written informed consent and the patients from Uppsala gave their verbal consent recorded in the patient files. The study and consent procedure was approved by the local ethics committees; the committee for research ethics at Karolinska hospital in Stockholm, the Regional Ethics Board Lund University, the Regional Ethics committee in Linköping and the Regional Ethical Review Board in Uppsala, Sweden. Clinical and laboratory data is coded and stored on paper and in a research database. According to all local ethical rules only the principal investigators have the identity key (i.e. can trace the data back to the individual patient) for this database.

Genotyping

All individuals in cohort I were genotyped on custom 12 k Illumina Select BeadArrays as previously described by Gateva et al [6] and had passed rigorous genotype quality control, including removal of population outliers. A total of 5676 SNPs remained after genotype quality control filters and exclusion of ancestry informative markers. The samples in cohort II were genotyped with a custom 384plex Illumina VeraCode GoldenGate assay (Illumina Inc, CA, USA). For this assay SNPs were excluded which did not conform to Hardy-Weinberg equilibrium (Chi-square test, p <0.01), had genotype call rates <90% or reproducibility <95.5% as determined by replicated genotyping of 5% of samples.

Statistical analysis

Patient characteristics were compared between SLE patients with and without LN. Frequencies were compared with Chi square test and continuous variables with Mann-Whitney U-test and one-way ANOVA using Statistica® software version 10. Allele frequencies in case-control and case-only analyses were compared using Fisher’s exact test, conditioning on the matched pairs and meta-analysis was performed with the Cochran-Mantel-Haenszel test and linkage disequilibrium (LD) between SNPs was obtained from the genotypes of 512 controls, using the PLINK software version 1.07 [23]. Association analyses including age or disease duration and gender as covariates were performed using logistic regression in PLINK. A quantile-quantile (Q-Q) plot of observed versus expected p-values was generated from the results of the LN case-control study in cohort I and statistical power was estimated using the Software Qtole v1.2.4 (http://hydra.usc.edu/gxe) assuming a log-additive model. For the case-only analysis of 13 SNPs in nine genes where the two SNPs in each of STAT4, IRF5, TNIP1 and BLK are in high LD, a Bonferroni correction for nine loci was performed and p <0.006 was considered significant. In the case-control and case-only meta-analysis of four SNPs in cohort I and II, the significant Bonferroni corrected p-value was <0.0125. Unadjusted p-values are presented.

Results

Patients

The LN patients in both cohorts were significantly more often men, younger at disease onset and fulfilled more ACR criteria compared with the SLE patients without nephritis (Table 1). There was no difference in disease duration between patients with or without LN in cohort I whereas in cohort II, patients with LN had significantly longer disease duration compared with SLE patients without nephritis. The renal biopsies showed a proliferative nephritis in 92/152 (60.1%) in cohort I and 20/26 (76.9%) in cohort II [2]. A total of 31 patients, 28 (14.7%) in cohort I and 3 (8.6%) in cohort II had developed severe renal insufficiency at follow up (Table 1). In both cohorts, patients with severe renal insufficiency had a significantly longer disease duration compared with SLE patients without nephritis. The renal biopsies showed a proliferative nephritis in 92/152 (60.1%) in cohort I and 20/26 (76.9%) in cohort II [2]. A total of 31 patients, 28 (14.7%) in cohort I and 3 (8.6%) in cohort II had developed severe renal insufficiency at follow up (Table 1). In both cohorts, patients with severe renal insufficiency had a significantly longer disease duration compared with SLE patients without renal insufficiency; in cohort I 28.0 ± 11.0 versus 20.7 ± 11.5 years (p = 7.6 × 10^{-4}), and in cohort II 27.3 ± 7.7 versus 13.7 ± 10.3 years, (p = 0.03) (data not shown). Proliferative nephritis was the most frequent cause of developing severe renal insufficiency. Out of the 31 patients with severe renal insufficiency at follow up, 24 had undergone a previous renal biopsy where 12 (50%) of the patients had a proliferative nephritis. Conversely, of the 112 patients with proliferative nephritis, outcome data was available for 110. The 12 patients whose outcome was severe renal insufficiency constituted 11% of all patients with proliferative nephritis (data not shown).

Case-control association with lupus nephritis

In cohort I, we performed a LN case versus healthy control association analysis. The strongest signals of association were detected for four highly linked SNPs in \textit{STAT4}; rs11889341, rs7574865, rs7568275 and rs7582694 (\(r^2 = 0.98\)), with p-values reaching genome wide significance (p < 5x10^-8) (Figure S1). The most significant SNP in \textit{STAT4} was rs11889341 with p = 3.7x10^-10, odds ratio (OR) 2.20 (95% confidence interval (CI) 1.70–2.84). Strong signals of association with LN were also detected for two nearly perfectly linked SNPs in \textit{IRF5}, (rs2070197 and rs10488631, \(r^2 = 1.0\)) and the \textit{HLA-DR3} marker SNP rs3153594, all p < 1x10^-4. In addition, SNPs in the postmeiotic segregation increased 2 \textit{(PMS2)}, \textit{TNIP1}, caspase recruitment domain family, member 11 \textit{(CARD11)}, \textit{ITGAM}, \textit{BLK} and interleukin-1 receptor-associated kinase 1 \textit{(IRAK1)} genes were associated with LN with p-values < 0.001 and OR between 1.53 and 2.21 (Table S1 and Figure S1). Table S2 lists the best SNP in each of the nine genes that displayed an association with LN with p < 0.001 and for \textit{STAT4}, \textit{IRF5}, \textit{TNIP1} and \textit{BLK} also the SNPs used for further meta-analysis, see below. A Q-Q plot of the results from the LN versus healthy controls association analysis shows p-values deviating from the expected distribution indicating the presence of true associations (Figure S1).

Case-control association with proliferative nephritis and outcome

The nine genes that had shown an association with LN in cohort I with p < 0.001 were further studied. First association analysis of patients with proliferative nephritis (n = 92) versus healthy controls was performed. The \textit{STAT4}, \textit{IRF5} and \textit{HLA-DR3} SNP proxy were all found to be associated with proliferative nephritis, with p < 0.001, OR between 2.17 and 2.44 (Table S2). Next the association between these genes and the outcome measure severe renal insufficiency was analyzed. Despite the low number of cases, LN patients who had developed severe renal insufficiency (n = 28) displayed signals of association with \textit{STAT4} with p = 7.6x10^-4 and OR 3.61 (95% CI 2.09–6.23) (Table S2). When adjusting for age and gender, the effect measures (OR, 95% CI) were largely unchanged (Table S2) and conditioning on the matched pairs yielded analogous results (data not shown).

Case-only sub-phenotype analysis

Next a case-only association analysis was performed of the 13 SNPs in the nine genes that were associated with LN in cohort I. The risk allele frequencies were compared between patients with or without LN, proliferative nephritis and severe renal insufficiency, respectively. A nominal association was found with LN for SNPs in the \textit{PMS2} and \textit{TNIP1} genes (p < 0.05) while there were no associations with proliferative nephritis. Signals of association between \textit{STAT4} and the development of severe renal insufficiency were identified, with a p-value of 0.02, OR 1.91 (95% CI 1.11–3.28) for SNP rs11889341 (Table S2). However, correcting for the nine loci analysed, none of the associations remained significant. There was 64% power to detect an association between the \textit{STAT4} risk allele rs11889341 and severe renal insufficiency (Table S3).

Meta-analysis

To evaluate the robustness of our findings we used data from 145 patients with SLE from an additional Swedish cohort (cohort II) where detailed renal data were available (Table S1) and 619 healthy Swedish controls. The \textit{STAT4}, \textit{IRF5}, \textit{TNIP1} and \textit{BLK} genes had been genotyped in cohort II. The SNPs genotyped in both cohort I and II, used for meta-analysis, were \textit{STAT4} rs7582694 (\(r^2 = 0.98\) with rs11889341), \textit{IRF5} rs10488631 (\(r^2 = 1.00\) with rs2070197), \textit{TNIP1} rs7708392 (\(r^2 = 1.00\) with rs6889239) and \textit{BLK} rs13277113 (\(r^2 = 0.87\) with rs922483) (Table S2). In the LN case versus healthy controls (n = 1131) meta-analysis, the SNPs in \textit{STAT4} and \textit{IRF5} were associated with LN with genome wide significance (p < 5x10^-8). An association between the \textit{STAT4} SNP rs7582694 and severe renal insufficiency

5Unadjusted p-value and OR for differences in allele frequencies between patients and controls.
6Adjusted p-value and OR from logistic regression analysis including age and gender as covariates. Number of cases and controls; lupus nephritis, n = 194, proliferative nephritis, n = 91, severe renal insufficiency, n = 28, SLE, n = 566, controls, n = 504.
7doi:10.1371/journal.pone.0084450.t002
at the genome wide significance level was also detected (Table 3). In the case-only meta-analysis of the two cohorts there was a significant association between the STAT4 SNP rs7582694 and severe renal insufficiency with \( p = 1.6 \times 10^{-3} \), OR 2.22 (95% CI 1.34–3.70) (Table 4).

LN patients with severe renal insufficiency had a longer disease duration compared with SLE patients without this adverse outcome. We therefore investigated whether there were any differences in disease duration between the three genotypes in STAT4, IRF5, TNIP1 and BLK. There were no differences in disease duration between patients homozygous for the risk allele (minor allele), heterozygous or homozygous for the non-risk allele (major allele) for STAT4, IRF5, TNIP1 or BLK when comparing all SLE patients or LN patients alone (Table S4). In both cohorts there were a significantly higher proportion of men in the SLE with LN group, compared with the SLE without LN group (Table 1). However, there were no differences in genotypes between the genders for the risk alleles in STAT4, IRF5, TNIP1 or BLK (Table S5). When adjusting for the potential confounders age and gender in the case-control analyses, the effect measures (OR, 95% CI) were largely unchanged. Finally, disease duration and gender were included as covariates in the case-only meta-analysis of the two cohorts. In this analysis the association between the STAT4 SNP rs7582694 and severe renal insufficiency was no longer significant after correction for multiple analyses (\( p = 0.020 \), OR 1.91, 95% CI 1.11–3.30) (Table 4).

### Discussion

Here we demonstrate that polymorphisms in the STAT4 gene are associated with LN with genome wide significance in a LN case-versus-health controls analysis of Swedish SLE patients. Furthermore an association between the STAT4 SNP rs7582694 and severe renal insufficiency was present in our case-only meta-analysis of two independent SLE cohorts. Although we were not able to detect a significant association with STAT4 in our case-only analysis of LN versus non-LN SLE patients, possibly due to a lack of power, our results support previous observations that STAT4 is particularly strongly associated with a more severe SLE phenotype with renal engagement [18]. In the study by Taylor and coworkers [18] an association between the STAT4 SNP rs75784865, in strong LD (\( r^2 > 0.99 \)) with the SNP rs7582694 here studied, and LN was found in a case-control and case-only analysis. Here we extend the knowledge and present for the first time the association between STAT4 and the severe form of proliferative nephritis in a case-control analysis. We also demonstrate for the first time in our case-only analysis, an association between STAT4 and a worse outcome in terms of severe renal insufficiency defined as a GFR \(< 30 \text{ mL/min/1.73 m}^2 \) at follow up.

The highly linked SNPs rs11889341, rs75784865, rs7568275 and rs7582694 (\( r^2 = 0.98 \)) in STAT4, which showed an association with LN in our case-control study, are all located in the large third intron. While there are no common coding STAT4 SNPs in LD with these intronic SNPs, their possible functional role has been investigated. Allelic expression analysis have observed an overexpression of the STAT4 risk allele (rs6179673, \( r^2 = 0.95 \) to rs7582694) in human cells of mesenchymal origin but not in transformed B-cells, indicating that these intronic SNPs may regulate gene expression in different tissues [16]. There are several possible mechanisms by which STAT4 may contribute to the development of LN. The main STAT4 activating cytokines are interleukin 12 (IL-12) and IL-23 leading to Th1 and Th17 differentiation with IFN-\( \gamma \) and IL-17 production, which are key players in a pro-inflammatory immune response [24].

### Table 3. Case-control meta-analysis of cohort I and cohort II in a total of 712 SLE cases and 1131 controls.

pro-inflammatory properties are crucial in both the initiation and progression of the inflammatory renal disease process as reviewed in [25]. There is, in particular, increasing evidence implicating a role for IL-17 in LN pathogenesis. High levels of IL-17 at LN onset have been associated with a less favourable histopathological response to treatment and IL-17 producing cells have been detected in renal biopsies from LN patients [26,27].

STAT4 also signals via the type I IFN receptor. SLE patients carrying the STAT4 risk allele rs7574865 have an increased sensitivity to IFN-α signaling, measured as an increased expression of IFN-α regulated genes [28]. An increased activation of IFN stimulated genes (ISG) will promote the autoimmune process by activating a number of cells in the immune system as reviewed by Rønnow et al in [29]. One such ISG is TNFSF13B that encodes B cell activating factor (BAFF)/B lymphocyte stimulator (BLyS) which promotes B cell differentiation and autoantibody production, including antibodies against double stranded DNA (anti-dsDNA) [30,31]. Several investigators have also detected high signals of association between STAT4 and anti-dsDNA autoantibodies [16,18,32,33]. Consequently, risk-variants of STAT4, via several different effects in the immune system, could promote a progressive autoimmune process in the kidney, which ultimately may lead to renal failure.

Polymorphisms in IRF5 display strong signals of association with SLE in populations of different ethnicities [5,34–36]. No particular SLE phenotype has been associated with IRF5 in case-only analyses but an association with the presence of anti-dsDNA antibodies has been demonstrated [32]. A case-control analysis in an Asian population demonstrated an association between LN and IRF5; however, this could represent the strong association with SLE per se [37]. Here we found the association with LN to be of similar strength as the association with SLE. This is in concordance with other studies where IRF5 polymorphisms have been strongly associated with SLE regardless of disease phenotype [33,38].

The TNIP1 SNP rs7708392 has been associated with LN in case-control studies of Asian and Caucasian populations [19,39]. In our previous case-only analysis of an SLE patient cohort largely overlapping with this study, a nominally significant association with LN was shown, notwithstanding multiple testing correction [19]. In this study we extended the investigation and explored the association with proliferative nephritis and renal outcome. However, no associations with these sub-phenotypes were shown. The FAM167A-BLK locus intergenic SNP rs13277113 was recently associated with LN in a case-only analysis [8] whereas previous studies have failed to find an association between this SNP and LN [3,14]. In this study we did not detect any significant associations with BLK in our case-only analysis of LN, proliferative nephritis or renal outcome.

Cohort I was analysed for association with LN using a large set of SNPs. Interestingly, in the case-control analysis, the HLA-DR3 (DRB1*0301) SNP marker was not as strongly associated with LN as STAT4. While the HLA-DR3 allele confers a 2-3 fold increased risk of SLE in Caucasian populations the role of the MHC in LN has been less well elucidated [7,40]. One study found an association between an HLA-DR3 SNP proxy and LN [33] whereas we detected similar minor allele frequencies for the HLA-DR3 (DRB1*0301) SNP proxy in LN, LN sub-phenotypes and all SLE cases (Table 6).

An association between the SNP rs1143679 in ITGAM and LN has previously been demonstrated in both case-control and case-only analyses in patients of European and Asian ancestry with SLE [11,14,41]. Here we replicate the results in the LN case versus control analysis in cohort I. The association between LN or SLE...
and SNPs in the *PMS2* and *CARD11* genes, both located on chromosome 7, has hitherto not been reported. The *PMS2* gene encodes a DNA mismatch repair endonuclease and mutations have been associated with malignancies, in particular colorectal cancer [42]. Mutations in *CARD11* have been associated with diffuse large B cell lymphomas [43], the dominating lymphoma subtype in SLE [44]. The polymorphisms detected here in association with LN and SLE are intriguing and warrant further investigations. Finally, we found an association between *IRAK1* and LN in our case-control analysis while the case-only analysis displayed an unadjusted p-value of 0.05 for association with LN. Polymorphisms in *IRAK1* have previously been associated with SLE but the possible association with LN remains to be established [45].

The strength of this study is the availability of renal biopsies from the majority of patients as well as the longterm follow-up data on renal outcome. Approximately two thirds of our LN patients with available biopsies were diagnosed with a proliferative nephritis, which is linked to a less favourable renal outcome [46]. In this study 11% of the patients with proliferative nephritis had progressed to severe renal failure at follow up. This is in concordance with previous reports where approximately 10% of all patients with LN develop ESRD [1]. Only half of our patients with severe renal insufficiency where a previous biopsy was available had progressed from a proliferative nephritis. We therefore conclude that the two groups proliferative nephritis and severe renal insufficiency are not completely overlapping and that the case-only association between *STAT4* and severe renal insufficiency cannot be explained by an association with proliferative nephritis.

Renal biopsies had not been performed in 36/195 (18%) of the LN patients and 7 histopathology results could not be retrieved in cohort I, while in cohort II 9/35 (26%) of the LN patients had not undergone a biopsy. There are various reasons for not performing a renal biopsy, including a bleeding diathesis, uncontrolled hypertension, patients’ or physicians’ choice or for practical reasons. It is also possible that patients presenting with a clinically milder nephritis are less likely to undergo a biopsy. LN patients without biopsies were excluded from the case-only analysis of proliferative nephritis versus non-proliferative nephritis and the results presented are based on available data. However, the lack of complete biopsy data from all our LN patients has decreased the power to detect genetic associations with the sub-group proliferative nephritis.

A further weakness of our study is the low power to detect significant differences in the LN or renal outcome case-only analyses. The power to detect a possible association between *STAT4* and LN in our case-only analysis of cohort I was only 22% and for *TNIP1* 62% (Table S2). We had 62% power to detect an association between the *STAT4* risk allele rs7582694 and severe renal insufficiency in our case-only analysis of cohort I. However, the addition of cohort II increased the strength of the association between *STAT4* and severe renal insufficiency. Unfortunately, detailed clinical data on renal biopsies and outcome is not readily available from all centres, which has limited the inclusion of additional cohorts in this study.

One can hypothesize that there is a genetic contribution to the type of nephritis an individual patient will develop as well as to outcome, as here demonstrated. Males with SLE are more likely to develop LN. We found no differences in genotypes between the genders and correcting the case-control analyses for age and gender did not affect the OR for association. We therefore conclude that in the case-control analyses, the genetic associations here presented are with LN, proliferative nephritis and severe renal insufficiency per se, regardless of age and gender. LN patients with severe renal insufficiency have a longer disease duration compared with patients without such adverse outcome. We found no differences in disease duration between the genotypes for *STAT4*, *IRF5*, *TNIP1* and *BLK*. While adjusting for disease duration and gender, the association between *STAT4* and severe renal insufficiency did not remain significant after Bonferroni correction. However, we conclude that in this study, the *STAT4* risk allele is associated with an adverse renal outcome and not with disease duration or gender. There are many reasons for an unfavourable outcome, including renal atherosclerosis, but certain susceptibility genes may contribute to a worse prognosis. Interestingly, the *STAT4* risk allele has been shown to be a risk factor for stroke and anti-phospholipid antibodies in patients with SLE [47].

In conclusion, this LN case versus healthy control study has demonstrated an association between *STAT4* and LN with genome wide significance. In the case-only meta-analysis the *STAT4* risk allele displayed signals of association with a poor renal outcome with severe renal insufficiency. Future studies will try to define the precise role for this *STAT4* genetic variant in LN pathogenesis.
