28 **Abstract**

29 Most patients with IgA nephropathy exhibit complement deposition in the glomerular  
30 mesangium. Certain cases of IgA nephropathy have been associated with reduced levels of  
31 factor H. A recent study could not demonstrate mutations at the C terminal of factor H. We  
32 describe a novel heterozygous mutation in factor H, position A48S (nucleotide position 142  
33 G>T, alanine>serine), detected in exon 2 of a 14 year old girl with IgA nephropathy. The  
34 patient exhibited reduced levels of C3 and factor H, the latter suggesting that the mutation  
35 affected factor H secretion. The patient developed initial signs and symptoms of  
36 glomerulonephritis at the age of 9 years but presented again at the age of 14 years with weight  
37 gain, renal failure, nephrotic-range proteinuria and malignant hypertension. Blood tests  
38 suggested the development of microangiopathic hemolytic anemia (MAHA) but the renal  
39 biopsy was mostly indicative of chronic changes associated with IgA nephropathy as well as  
40 vascular changes associated with malignant hypertension. Immunofluorescence exhibited  
41 depositis of IgA, C3 and IgM. Screening of the factor H gene revealed, in addition to the  
42 mutation, three heterozygous hemolytic uremic syndrome-associated risk polymorphisms (-  
43 257 c/t, 2089 a/g and 2881 g/t) which may have increased the patient's susceptibility to the  
44 occurrence of MAHA triggered by malignant hypertension. Thus the combined clinical  
45 picture of IgA nephropathy and MAHA may have been partly related to the alterations in  
46 factor H.

51 **Introduction**

52 IgA nephropathy (IgAN) is characterized by glomerular deposits of aberrantly glycosylated  
53 IgA1 and complement proteins [10,17]. Complement components deposit mainly in the  
54 mesangium and include C3, C4d, C4-binding protein, factor H, mannose-binding lectin, C5b-  
55 9 and properdin [1,7,8,13,15,17,20,21]. Polymeric IgA may activate both the alternative and  
56 lectin pathways of complement [11,16,17] and studies have suggested that complement  
57 activation during IgAN involves the alternative and lectin pathways [17]. Mechanisms by  
58 which complement activation occurs during IgAN are not fully understood. It has been  
59 suggested that inadequate complement regulation could lead to complement activation in vivo  
60 and progressive glomerular disease [7].

61

62 Factor H is the main fluid phase regulator of the alternative pathway of complement.  
63 Dysfunction of factor H has been associated with certain renal diseases such as atypical  
64 hemolytic uremic syndrome (HUS) and membranoproliferative glomerulonephritis as well as  
65 the ophthalmological condition termed age-related macular degeneration [reviewed in 27].  
66 Factor H is deposited in the kidneys during IgAN [1]. Urinary levels of factor H have been  
67 found to be increased and related to disease activity [26]. A recent study investigated 46  
68 patients with IgAN and found normal factor H levels and no mutations in the C terminal of  
69 factor H, the region responsible for host cell recognition [6].

70

71 In this study we present a girl who primarily developed IgAN followed several years later by  
72 malignant hypertension and microangiopathic hemolytic anemia (MAHA). The latter led us to  
73 investigate the patient's factor H levels which were found to be low. A novel mutation was  
74 detected at the N terminal of factor H. In addition to the mutation, three polymorphisms,  
75 associated with increased risk for HUS, were detected in the factor H gene.

76

77 **Patient and family member**

78 A currently 18 year old Caucasian girl was admitted to Karolinska University Hospital at the  
79 age of 9 years with macroscopic hematuria and proteinuria after a severe tonsillitis. Her serum  
80 creatinine was slightly elevated at 67  $\mu\text{mol/L}$  (normal reference value  $< 60 \mu\text{mol/L}$ ). Within  
81 the following two months she recovered with persistent microscopic hematuria but no  
82 proteinuria after which she was lost to follow-up. She was readmitted at the age of 14 years  
83 with a history of weight gain during a few months as well as progressive fatigue, weakness,  
84 headache and blurred vision during the days before admission. There was no history of  
85 diarrhea. Upon admission her blood pressure was 250/150 mmHg, she had altered sensorium  
86 and was in respiratory distress. She exhibited severe oliguric renal failure with high levels of  
87 creatinine (1360  $\mu\text{mol/L}$ , reference value  $< 90$ ) and BUN. In addition, laboratory values  
88 showed low serum albumin (31 g/l, reference value: 40-51 g/L), hemolytic anemia  
89 (hemoglobin 65 g/L (110-160), lactate dehydrogenase 16.5  $\mu\text{kat/L}$  ( $< 6.2$ )) and  
90 thrombocytopenia ( $69 \times 10^9/\text{l}$ , 150-400). C3 was low 0.52 g/L (0.67-1.43), C3dg elevated 11.5  
91 ( $< 5\text{mg/L}$ ) and C4 normal. Urinalysis revealed microscopic hematuria and nephrotic-range  
92 proteinuria.

93

94 Serologic analysis for anti-nuclear antibodies, anti-double stranded antibodies, anti-  
95 phospholipid antibodies, anti-neutrophil cytoplasmic antibodies, anti-glomerular basement  
96 membrane antibodies, hepatitis B and C, HIV were all negative. Fundoscopic exam revealed  
97 papilledema, exudates and retinal hemorrhages. She was treated with continuous veno-venous  
98 hemofiltration, anti-hypertensive medications and pulses of methyl-prednisolone.  
99 Ophthalmologic and cardiovascular involvement as well as hemolytic anemia remitted and  
100 blood pressure normalized.

101

102 Renal biopsy showed 17 glomeruli, 11 exhibited total sclerosis (Figure 1A), and two crescents  
103 (Figure 1B). The remaining exhibited mesangial proliferation (matrix and cells). There was no  
104 evidence of thickening or double contours of the glomerular basement membrane. Tubules  
105 showed marked atrophy with mononuclear infiltrates in the interstitium. There were no visible  
106 thrombi in the renal blood vessels, but arterioles displayed myointimal proliferation in a  
107 concentric pattern typical for “onion-skin” lesions (Figure 1C). Immunofluorescence showed  
108 intense mesangial deposits of IgA (Figure 1D) and to a lesser degree IgM and C3 (not shown).  
109 The electron microscopy sample did not contain glomeruli. She did not regain renal function  
110 and underwent a successful renal transplant donated by her father 16 months later. She has not  
111 had a recurrence of IgA nephropathy or MAHA since transplantation in June 2007.

112

113 Serum and whole blood in EDTA tubes were obtained from the patient and her father. The  
114 project was performed with the informed written consent of the patient and her parents and  
115 the approval of the Ethics committee of the Medical Faculty, Lund University.

116

## 117 **Materials and Methods**

### 118 *Factor H levels and mutation analysis*

119 Factor H levels were measured by rocket immunoelectrophoresis as previously described  
120 [22]. Factor H size was detected by immunoblotting [22]. Extraction of genomic DNA and  
121 sequencing of the factor H gene were performed as described [22].

122

### 123 *ADAMTS13*

124 ADAMTS13 activity in plasma was detected by a modified collagen binding assay as  
125 previously described [9].

126

127 **Results**

128

129 Factor H levels were repeatedly low at 50 % (reference value: 69-154) upon admission at the  
130 age of 14 years, and 52 % three years later, after transplantation. Immunoblotting revealed a  
131 weak factor H band at 150 kD (data not shown) indicating normal size.

132

133 Genomic DNA from the patient and her father were screened for mutations in the factor H  
134 gene. A novel heterozygous mutation in exon 2, corresponding to short consensus repeat  
135 (SCR) 1, was found at G142T leading to replacement of alanine by serine: A48S. In addition,  
136 three heterozygous polymorphisms were identified in the factor H gene: -257 c/t (promoter  
137 region), 672 a/g A2089G in exon 14 (silent) and G2881T: E936D in exon 19. These  
138 polymorphisms have been previously described as risk-associated with HUS [3]. The patient's  
139 father did not bear the mutation but had all three heterozygous polymorphisms. DNA was not  
140 available from the patient's mother. ADAMTS13 function was normal.

141

142 **Discussion**

143 A novel mutation at the N terminal of factor H is described in a girl with evidence of IgAN  
144 and one episode of MAHA in conjunction with malignant hypertension. The mutation is  
145 located in SCR 1 of factor H. Factor H is a co-factor of factor I in cleaving C3b. The cofactor  
146 and complement-regulating domain of factor H is ascribed to SCRs 1-4 which bind C3b. This  
147 region is active in decay acceleration, displacing factor B from the C3 and C5 convertase [12].  
148 Low levels of factor H have been previously described in certain patients with IgAN  
149 [23,24,25]. The patient exhibited low levels of factor H at separate time points suggesting that  
150 the heterozygous mutation interfered with secretion of the product of the mutated allele. The  
151 mutation is in proximity of a cysteine residue at codon 52 (<http://www.fh-hus.org/>) possibly  
152 altering a disulphide bridge and/or the stability of SCR1. Thus we suggest that the mutation  
153 may affect complement regulatory functions and may partially block secretion of factor H  
154 from cells as has been demonstrated for other N terminal mutations in factor H, mostly  
155 associated with membranoproliferative glomerulonephritis [5, 22].

156

157 The pathological findings were indicative of IgAN due to intense mesangial deposition of  
158 IgA. Membranoproliferative glomerulonephritis was ruled out due to lack of typical changes  
159 such as glomerular basement membrane thickening with double contours. The clinical history,  
160 with a glomerulonephritis in association with pharyngeal infection at the age of 9 years,  
161 indicates that the primary lesion was IgAN. The combined clinical picture of IgAN and HUS  
162 has been reported [4,14] in association with chronic advanced IgA nephropathy and malignant  
163 hypertension as was evident in our patient. Malignant hypertension in itself has been  
164 associated with MAHA (reviewed in [2]). This may be due to endothelial cell injury with  
165 narrowed microvasculature and enhanced shear stress [18]. MAHA may have developed in  
166 this patient secondary to progressive IgAN and malignant hypertension but the presence of

167 three HUS-associated polymorphisms in factor H [3] could have contributed to this process.  
168 Recently patients with IgAN have been investigated regarding allele frequency and these  
169 three polymorphisms were not associated with IgAN [6]. However, the presence of these  
170 polymorphisms in an IgAN patient with malignant hypertension and vascular damage may be  
171 a predisposing factor reducing complement regulation and precipitating MAHA. This raises  
172 the ethical issue of if a patient with a factor H mutation, and three factor H polymorphisms  
173 associated with increased risk to develop HUS, should undergo renal transplant. In patients  
174 with HUS and factor H mutations the risk of HUS recurrence after renal transplant, leading to  
175 graft loss, is high [19]. The primary diagnosis in the patient described herein was IgAN and  
176 she developed MAHA as a secondary phenomenon due to malignant hypertension. As N  
177 terminal factor H mutations have not been explored in a larger cohort of IgAN patients it is, as  
178 yet, unclear if these genetic alterations can increase the risk of IgAN recurrence after renal  
179 transplantation.

180

181 There may be several mechanisms for complement activation in IgAN via both the alternative  
182 and lectin pathways. Although we describe only one patient with an N terminal mutation in  
183 factor H, we suggest that the mutation and the three polymorphisms in factor H may have  
184 contributed to complement dysregulation and C3 deposition in the glomeruli.
