There are many on-going programmes dedicated to elucidate the nuclear structure of SuperHeavy Elements (SHE atomic number  $Z \geq 104$ ) based on different methods [1]. The SHE are accessed in heavy-ion induced fusion-evaporation reactions, with the nuclear spectroscopy experiments typically performed at in-flight recoil separators.

An alternative approach exploits a chemical isolation system either directly or after separator [2], this was adopted in different experiments [3-5]. A significant improvement of the background conditions was observed applying this method.

A next generation setup for measurements of ALpha-BETA-Gamma decays (ALBEGA) after chemical isolation was recently built. ALBEGA is dedicated to simultaneous measurements of  $\alpha$  particles, electrons, photons and fission fragments. Volatile chemical species adsorb on a cooled segmented Si detector. Radiation emitted in the decay is measured with surrounding detectors, cf. Fig.1. The

Figure 1: A schematic of ALBEGA, where the arrows indicate the gas flow inside the tight channel (a). A picture of the  $\alpha$  detector mounted on the cooling support and connected to the capillaries for gas flushing.

core is a “sandwich” of two segmented Si detectors with a gas channel inside, sensitive to charged particles (“ $\alpha$  detector”). A round channel is etched in both wafers, glued together to form a tight channel. At both sides and parallel to the  $\alpha$  detector two thicker, segmented Si detectors are mounted (cf. Ref. [6]). The Si detectors are backed by two 3-cm-thick broad energy Ge detectors for X and  $\gamma$  rays. All

the detectors were assembled in a packed configuration to maximize the geometrical efficiency.

Figure 2: The  $\alpha$  particles are emitted isotropically at various angles in the narrow channel (a). Depending on their incident angle, they pass through different effective thicknesses of detector dead layer and gas, thus undergoing energy loss to a different degree, before entering the active detector area. Accordingly,  $\alpha$  peaks show characteristic low-energy tailing, e.g. the  $^{140}\text{Ce}(^{50}\text{Ti}, 6-7n)$  reaction energy spectrum (b). The measured energies corresponding to the two particles  $\alpha_1$  and  $\alpha_2$  are indicated, they have the same initial energy but different path. The distribution pattern observed in the experiment (c) is due to the Hg retention on the inner channel Au coating, and the maximum is observed on the segments at the channel entrance.

The setup was first tested and calibrated with  $\alpha$  particles and  $\gamma$  rays produced by decay chains of  $^{219}\text{Rn}$  emanated from an  $^{227}\text{Ac}$  source. Then the  $^{140}\text{Ce}(^{50}\text{Ti}, 6-7n)$  reaction was used to produce  $^{184,183}\text{Hg}$ , which was pre-separated in TASCA [3] and then transported to ALBEGA with rapidly flowing of Ar gas. The energy spectrum and the distribution pattern measured are shown in Fig. 2.
