The long-term cognitive outcomes of Alzheimer's disease

— influence of APOE genotype, NSAID therapy, and cholinesterase inhibitor treatment

Wattmo C, Minthon L, Wallin Å K

Clinical Memory Research Unit, Department of Clinical Sciences, Malmö, Lund University, Sweden

Conclusions

In this 3-year AD study in routine clinical practice, the response to ChEI treatment and longitudinal cognitive outcome was better for those receiving a higher dose of ChEI, non-carriers of the APOE ϵ 4 allele, and for patients treated with NSAIDs/acetylsalicylic acid. The type of ChEI did not influence the outcome.

Introduction and objectives

Heterogeneity in cognitive outcomes and response to treatment has been described in Alzheimer's disease (AD). Using the method of mixed models, higher resolution can be obtained to identify potential predictors of long-term outcomes. The aim of this presentation is to analyse the impact of the APOE genotype, non-steroidal anti-inflammatory drug (NSAID)/acetylsalicylic acid therapy, and cholinesterase inhibitor treatment (ChEI) on the longitudinal cognitive outcomes in AD.

Methods and subjects

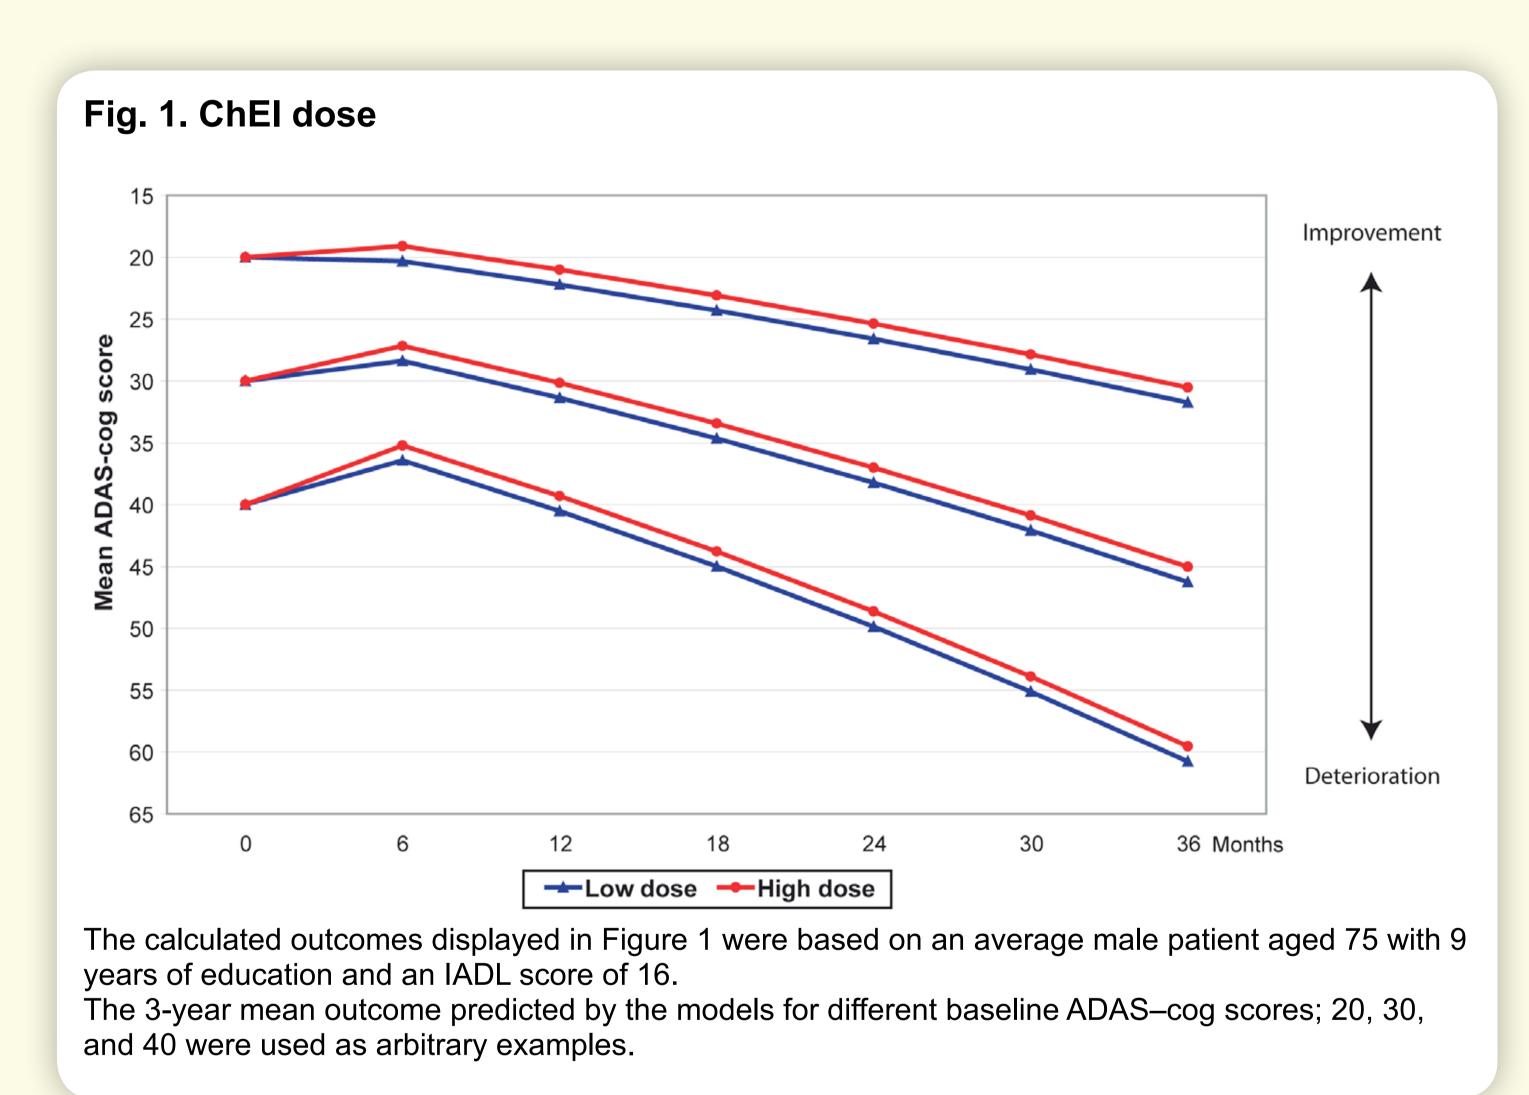

The Swedish Alzheimer's Treatment Study (SATS) is a 3-year, open, prospective, non-randomized, multicentre study in a routine clinical setting. In total, 843 patients treated with donepezil, rivastigmine or galantamine were included in this study. At baseline and every 6 months, the patients were assessed using several rating scales, including the Alzheimer's Disease Assessment Scale–cognitive subscale (ADAS–cog), and the dose of ChEI was recorded. The mean dose used during the entire follow-up period was calculated for each patient, and the median values for this mean dose were used as the cut-offs (low vs high dose): donepezil 7.1 mg, rivastigmine 6.5 mg, and galantamine 16.0 mg. Sociodemographic and clinical characteristics were investigated. The relationships of the predictors to longitudinal cognitive ability were analysed using linear and non-linear mixed-effects models, adjusting for sex, age at onset and at baseline, years of education, and disease severity at baseline.

In this study, we used a mixed-effects statistical model. This method takes into account the correlation within subjects, variations in the number of follow-up assessments available for the participants, and the actual time intervals between the collected data points. Thus, the mixed models are especially suitable for longitudinal studies.

Baseline characteristics	
Number of patients (n)	843
Gender (males / females)	37% / 63%
APOE ε4 carrier	68%
NSAID/acetylsalicylic acid therapy	30%
Estimated age at onset ^a	71.9 ± 7.4
Age at start of ChEI treatment ^a	75.0 ± 7.1
Duration of AD, years ^a	3.0 ± 2.1
ADAS-cog, range 0 - 70 ^a	20.6 ± 8.9
^a mean ± SD.	

Results

- The type of ChEI agent (donepezil, rivastigmine, galantamine) had no impact on the outcome.
- A higher mean ChEl dose was associated with an improved 6-month response to treatment and a more positive long-term outcome (p < 0.001), Figure 1.

- Patients with lower cognitive ability at baseline exhibited an improved 6-month response to ChEI treatment.
- Patients receiving NSAID/acetylsalicylic acid therapy showed an improved 6-month response to ChEI treatment, and a more positive long-term outcome (p = 0.017).
- Non-carriers of the APOE $\epsilon 4$ allele showed an improved 6-month response to ChEI treatment and a more positive long-term outcome, compared with $\epsilon 4$ -carriers (p = 0.012). No significant difference regarding 1 or 2 $\epsilon 4$ alleles was observed.
