Abstract — Sequential decoding for the Gilbert-Elliott channel is considered. The decoding procedure capacity \( C_D \) is defined to be the supremum of the rates for which there exists a code that gives arbitrarily small decoding error probability. For different assumptions of the decoder's knowledge of the channel states expressions for \( C_D \) are derived.

I. INTRODUCTION

Assume that a tree code is used together with sequential decoding to communicate over the Gilbert-Elliott channel. Let \( P(E) \) denote the average probability of decoding error over the ensemble of random, infinite depth tree codes. In this paper we address the question: "When will \( P(E) \to 0 \)?"

Consider the Gilbert-Elliott channel model and denote the error probabilities in the Good and Bad states by \( p_G \) and \( p_B \), respectively. Furthermore, let \( B_G \) and \( B_B \) denote the fraction of time spent in the Good and Bad states, respectively.

II. DECODING PROCEDURE CAPACITY

Let us define the decoding procedure assumptions, \( D \). The optimistic assumption, \( D = o \), assumes that the decoder has a complete knowledge of the channel state, which could be given by a genie. The pessimistic assumption, \( D = p \), assumes that the decoder neither is given any channel state information nor tries to make any estimate of it. Given the decoding procedure assumption \( D \) and the use of the Gilbert-Elliott channel, let \( C_D \) denote the supremum of the rates for which we can guarantee that there exists a code that gives an arbitrarily small decoding error probability \( P(E) \). We will call \( C_D \) the decoding procedure capacity.

We have proved that the decoding procedure capacities are given by

\[
C_o = B_G \cdot C_{\text{sec}}(e_G) + B_B \cdot C_{\text{sec}}(e_B)
\]

and

\[
C_p = B_G \cdot (C_{\text{sec}}(e_G) - h(b)) + B_B \cdot (C_{\text{sec}}(e_B) - h(g)) = C_o - (B_G \cdot h(b) + B_B \cdot h(g)),
\]

where \( b \) and \( g \) denote the transition probabilities from Good to Bad and from Bad to Good, respectively, in the channel model.

Theorem 1 Given the Gilbert-Elliott channel and the decoding procedure assumptions, the use of a rate \( R \), random, infinite depth tree code with the stack decoder, then for any rate \( R < C_D \), and \( \eta \in \mathbb{N} \),

\[
P(N \geq \eta) \to 0 \quad \text{if} \quad \eta \to \infty,
\]

where \( N \) is the number of computations in an incorrect subtree.

When we wish to transmit over an ordinary discrete memoryless Channel at rates (above \( R_{\text{comp}} \) and) close to its capacity, it is sufficient to allow the number of computations of sequential decoding to go to infinity to be able to guarantee that \( P(E) \) can be chosen arbitrarily small. We will show that this is also sufficient for transmission close to rates \( C_D \), which is the motivation why we call these rates "decoding procedure capacities".

Theorem 2 Given the assumptions of Theorem 1, then for any rate \( R < C_D \), the average probability of decoding error

\[
P(E) \to 0,
\]

if the number of computations, \( N \), is allowed to go to \( \infty \).

Since the important condition in Theorem 2 is that \( R < C_D \), it is clear that the theorem's statement, given the decoding procedure assumptions, is equivalent to stating that the maximal transmission rate over the Gilbert-Elliott channel is at least the rate \( C_D \).

In the pessimistic case we can interpret this as follows. For arbitrarily small \( P(E) \), there exists a code such that the transmission rate will be (at least) \( C_D \), even without any knowledge of the channel state or any attempt to estimate it.

III. CHANNEL CAPACITY

A common method to lowerbound \( C_{\text{sec}} \) is to calculate \( C_{\text{sec}}(\epsilon) \), where \( \epsilon = B_G \cdot e_G + B_B \cdot e_B \), but it turns out that \( C_D \) is a better lower bound for channels with a stable behaviour. The optimistic case helps us to find a stronger result:

Theorem 3 Given that the receiver has a complete channel state knowledge, then the channel capacity for the Gilbert-Elliott channel \( C_D \) is equal to

\[
C_D = C_{\text{sec}}.
\]

From the proof of Theorem 3 follows immediately

Corollary 4 Given that both transmitter and receiver have complete knowledge of the channel state sequence then for the channel capacity of the Gilbert-Elliott channel \( C_{\text{sec}} \), we have

\[
C_{\text{sec}} = C_D.
\]

It should be noted that the capacities \( C_{\text{sec}} \) and \( C_D \), in contradiction to what is the case for \( C_p \), are parameters purely dependent of the channel's properties and that nothing is assumed about the decoding method. In the derivations of \( C_D \) we assume sequential decoding, but by deriving them we show that they are achievable rates such as, given the decoding procedure assumptions.
