Assessment of using liquidity index for the approximation of undrained shear strength of clay tills in Scania

Dagnija Andreasson

Andreasson, D., 2018: Assessment of using liquidity index for the approximation of undrained shear strength of clay tills in Scania *Dissertations in Geology at Lund University*, *No. 900, 41pp. 45 hp (45 ECTS credits)*.

Abstract: Undrained shear strength is a crucial parameter of the clay-rich sediments commonly used in the design process of geotechnical structures and is determined by several tests. As a considerable part of these tests are costand time consuming, it is of interest to investigate the potential relationship with shear strength (c_u) with alternative, easily measurable parameters, such as liquidity index (I_L). In this study, several field and laboratory methods were applied to collect samples, analyse physical properties, and determine undrained shear strength of three clay tills of Stångby and Simrishamn in the province of Scania in southern Sweden. In total, 23 disturbed samplings, 13 cone penetration tests (CPT), and 11 vane shear tests (VST) were performed. The natural water content and liquid and plastic limits were established from all disturbed samples and undrained shear strength was determined from CPT and VST. The results show that the liquidity index varies between -0.10 and 0.34 at Stångby and between -0.35 and 0.23 at Simrishamn. The undrained shear strength varies between 57 and 256 kPa at Stångby and between 179 and 763 kPa at Simrishamn. Only a partial relationship between the liquidity index and undrained shear strength was found in this study. The study shows that the wide range of the consistency of clay-rich sediments is crucial for the correlation between I_L and c_w which was demonstrated by the relation being found only at Simrishamn.

Keywords: clay till, undrained shear strength, liquidity index, CPT.

Bedömning av att använda flytindex för att uppskatta den odränerade skjuvhållfastheten av lermorän i Skåne.

Dagnija Andreasson

Andreasson, D., 2018: Assessment of using liquidity index for the approximation of undrained shear strength of clay tills in Scania. *Examensarbeten i geologi vid Lunds universitet*, Nr. 900, 41sid. 45 hp.

Sammanfattning: Den odränerade skjuvhållfastheten är en viktig geoteknisk parameter som man behöver ha en god uppfattning om i samband med byggnation på lerrika jordarter. Då flertalet av de vanligen tillämpade undersökningsmetoderna är väldigt tidskrävande och kostsamma, finns det ett stort intresse för att undersöka hur alternativa och samtidigt mer enkelt mätbara parametrar, så som flytindex (I_L), förhåller sig till skjuvhållfastheten (c_u). I denna studie användes flera olika typer av laboratorietester och fältmetoder för att analysera fysikaliska egenskaper hos tre olika moränleror från Stångby och Simrishamn och därmed bestämma den odränerade skjuvhållfastheten hos dessa. Totalt togs 23 störda prover och på samma djup utfördes 13 spetstrycksonderingar (CPT) och 11 vingförsök (VST). Den naturliga vattenkvoten, flytgränsen och plasticitetsgränsen fastställdes på alla störda prover medan den odränerade skjuvhållfastheten bestämdes med hjälp av CPT och VST. Resultaten visar att flytindex varierar mellan -0.10 och 0.34 i Stångby och mellan -0.35 och 0.23 i Simrishamn. Den odränerade skjuvhållfastheten varierar mellan 57 och 256 kPa i Stångby och mellan 179 och 763 kPa i Simrishamn. Endast en partiell relation kunde fastslås mellan flytindex och odränerad skjuvhållfasthet, och tydligast samband kunde påvisas på proverna från Simrishamn. Studien visar att det krävs analys av en stor mängd prover med mycket stor skillnad i konsistens för att fastslå sambandet mellan flytindex och odränerad skjuvhållfasthet.

Nyckelord: lermorän, odränerad skjuvhållfasthet, flytindex, CPT.

1 Introduction

Building on clay-rich sediments can be challenging and includes several geotechnical issues. They have a complex interaction between clay minerals and water, which in turn provides low bearing and strength capacity. As the physicochemical interaction between clay particles, the water that fills the voids between the particles and the ions in the water affect the mechanical behaviour of clays, high clay mineral content in the soil contributes to clay minerals being more "active" as a result, such deposits are highly compressible, very plastic, have a low permeability and are subjected to shrinkage and swell (Mitchell and Soga, 2005). Water is strongly connected to clay particle surfaces, which results in plasticity.

In 1911, the Swedish agriculturist Albert Atterberg described two qualitative (liquid and plastic) limits based on the varying water content of clay. These limits are used for identification, characterization and classification of clay-rich sediments. Plasticity index (I_P) is the difference between liquid (w_L) and plastic (w_P) limits and is the range of water content at which clay-rich sediments display plastic properties, while the liquidity index (I_L) describes the relative consistency of the clay-rich sediments. After Karl von Terzaghi (1925) discovered the potential of the Atterberg limits in soil mechanics, many further studies were performed to establish relationships between various mechanical properties of clayey sediments, such as compression modulus and shear strength, and liquidity and plasticity indices. While there have been many studies carried out worldwide to establish the correlation between liquidity index and undrained shear strength (c_u) , such investigations are not common in Sweden. Larsson (2008) and Vardanega and Haigh (2014) also write that the Atterberg limits give an introductory assessment of mechanical properties of soils. Interestingly, the plasticity index also gives a preliminary insight into the potential geotechnical issues since the clay content is quantitatively estimated by the plasticity index (Duncan et al., 2014). Therefore, the higher the index, the more clay in the soil.

Geotechnical investigations are very important

since they provide significant information about various physical and mechanical soil properties which affect the design of upcoming constructions. This study investigates the relationship between the liquidity index and undrained shear strength. Undrained shear strength of clay-rich sediments is not a characteristic property of the material, but is dependent on the water content (w). Thus, it is suggested to correlate to a state-dependent index parameter, the liquidity index (Knappett and Craig, 2012). Undrained shear strength is defined as an internal resistance to failure per unit area of a material and is commonly used to analyse soil stability and lateral pressure on geotechnical structures. In clayey sediments, it is the undrained shear strength that controls the bearing capacity. There are several approaches to determine undrained shear strength. It is common that undrained shear strength is derived from cone penetration tests (CPT) and used in further calculations, as the direct shear test methods, such as vane shear test (VST), are less cost- and time-effective. Thus, it is of interest to test the potential relationship with shear strength obtained using different methods by applying alternative, easily measurable parameters such as liquidity index. In this study, indirect empirical equations are considered using the CPT and direct in-situ VST methods.

This master's thesis was developed in collaboration with the consultancy company Tyréns, and after the evaluation of Quaternary deposit maps, it was determined to take part in fieldwork at two sites: Stångby and Simrishamn. Sampling at both sites was performed during October and November 2017. As a fieldwork plan was followed, it largely determined the location of investigation points. Results from previous studies and proposed shear strength estimations from liquidity/plasticity indices are discussed in this thesis.

To carry out this thesis, a literature study of clayey sediments in the province of Scania was conducted. The aim of this study, which is based on a literature review complemented by selected field and laboratory analyses, is to evaluate the relationship between liquidity index and undrained shear strength to assess the possibility of using liquidity index as a means of estimating the undrained shear strength of clay tills in Scania.

Different limitations may arise when clay till is being analysed. Firstly, a clay till is inhomogeneous and generally includes large clasts as well as layers of coarse-grained sorted material. Thus, large clasts might influence or even interrupt the disturbed sampling. Secondly, not only the sampling is affected by clay till inhomogeneity, but also other in-situ testing methods. CPT is applicable to soft sediments and if the clay till contains coarse sand or gravel at the investigation point, the risk that the CPT will be interrupted is high. VST is another method that is sensitive to the presence of coarse material, since it might give higher undrained shear strength values.

At the Stångby and Simrishamn sites clay till was exposed at the surface. The initial observation of disturbed samples showed that the clay till at Stångby had enough clay to implement VST. In contrast, the clay till at Simrishamn was sandy, and so only CPT was carried out there. Clay content and grain size variations affect not only the choice of in-situ methods but also might have impacts on the results in laboratory tests.

2 Theoretical background

2.1 Clay till and its properties

2.1.1 Liquid and plastic limits

At the initial stage, the natural water content (w) of each sample is determined and calculated:

$$w = \frac{m_w}{m_s} (\%)$$

where m_w is the mass of water and m_s is the mass of a dry sediment sample (Swedish Standards Institute, 2008)

The water content at which a physical state of clayey sediments or their consistency changes from liquid to plastic and from plastic to brittle are defined as the liquid limit (w_L) and plastic limit (w_P), respectively (Fig. 2.1).

Figure 2.1. Atterberg limits (modified from Knappett and Craig, 2012).

The liquid limit (w_L) is determined by the fall cone method and calculated in the following way:

$$w_L = M \cdot w + N$$
 (%)

where w is the water content of the sediment sample and M and N values are derived from appendix A (Larsson, 2008).

Named in honour of Albert Atterberg, this method is widely used due to its accessibility and simplicity for evaluation of consistency of clayey sediments.

Lastly, the plastic limit is determined as the lowest water content of the sediment sample at which the consistency changes from plastic to brittle.

2.1.2 Plasticity and liquidity indices

The plasticity index is the water content range in the clay-rich sediment sample at which it displays plastic properties, and it is defined as the difference between liquid and plastic limits (Venkatramaiah, 2006):

$$I_p = w_L - w_P (\%)$$

The greater this difference is, the more plastic the sediments are (Murthy, 2002).

The liquidity index describes the moisture level in the clay-rich sediments in the field and thus determines the plastic range of the sediments.

$$l_L = \frac{(w - w_p)}{l_p}$$

If the liquidity index is 1, the material is at its liquid limit and is soft, whereas if the liquidity index is 0, the material is at the plastic limit, and is brittle (Murthy, 2002). The consistency of clay till and other clay-rich sediments is classified with respect to liquidity limit (see Tab. 2.1).

Table 2.1. The classification of clay-rich sediments with respect to the liquidity index (modified from Venkatramaiah, 2006).

Liquidity index, (I_L)	Consistency
< 0.00	Very brittle
0.00 to 0.250	Brittle
0.251 to 0.50	Medium-soft
0.501 to 0.750	Soft
0.751 to 1.00	Very soft
>1.00	Liquid

2.2 Assessment of undrained shear strength from Atterberg limits and derived indices

Depending on the geological material being analysed, different test and calculation methods are applied to determine undrained shear strength. Although there are many studies that suggest shear strength estimations from liquidity and plasticity indices for clay, not many studies are available that are correlating shear strength and the described indices for clay till. Apart from the relations described above, an application of an appropriate cone factor (N_{kt}) is of interest, as this factor is used to calculate undrained shear strength from CPT. A part of estimations described in this section was applicable to the results gained in this study, and the test results are observed and discussed in subsection 6.5.

The assessment of shear strength from Atterberg limits is closely related to the development of empirical calculations of shear strength from both CPT and VST. Studies by Skempton and Northey (1952) and by Schofiled and Wrother (1968) led Wroth and Wood (1978) to propose a new equation to estimate shear strength from liquidity index for clayey sediments (Vardanega and Haigh, 2014).

$$c_u = 170e^{-4.6 I_L} = 1.7 \cdot 10^{2(1-I_L)} \text{ (kPa)}$$

This equation indicates that the undrained shear strength should be 170 kPa at the plastic limit and 1.7 kPa at the liquid limit (Wroth and Wood, 1978). Later, an alternative correlation was proposed by Leroueil et al. (1983) which is applicable for liquidity indices between 0.5 and 2.5:

$$c_u = \frac{1}{(I_L - 0.21)^2}$$
 (kPa) $0.5 < I_L < 2.5$

where c_u is the undrained shear strength, e is a mathematical constant and I_L is the liquidity index.

Locat and Damers (1988) proposed an equation suited for sensitive clays with high liquidity indices:

$$c_u = \left(\frac{1.167}{I_L}\right)^{2.44}$$
 (kPa) $1.5 < I_L < 6.0$

When estimating undrained shear strength from VST, the Bjerrum correction factor (μ) is applied as a constant value. Initially, Bjerrum (1954) stated that undrained shear strength in clays increases with depth, meaning that this relation can be expressed as a constant ratio of undrained shear strength to effective vertical stress. In later studies, Bjerrum (1973) suggested using a correction against the soil plasticity, known as the Bjerrum's correction factor μ , when calculating the shear strength in clay-rich sediments from VST:

$c_u = \mu c_{uVST}$

where μ is correction factor and c_{uVST} is a shear strength from VST.

Bjerrum suggested that the correction factor might be determined from the plasticity index (I_p) as the effects of anisotropy and strain rate on the shear strength were considered (Fig. 2.2)

Figure 2.2. Bjerrum's correction factor with respect to plasticity index (Bjerrum, 1973).

In contrast, Dolinar (2010) did not find a constant criterion to determine the normalized undrained shear strength from the plasticity index for all clayrich sediments, as the normalized undrained shear strength can only be correlated with the plasticity index for non-swelling clays.

Kayabali et al. (2015) suggested that the effect of plasticity on the undrained shear strength of clayey sediments is better represented when the measured undrained strength values are correlated with the liquidity index.

When calculating shear strength from CPT results, a constant value of cone factor (N_{kt}) is used to calculate the undrained shear strength:

$$c_u = \frac{q_t - \sigma_{v0}}{N_{kt}}$$

where q_t is a total cone resistance (cone resistance, corrected for pore pressure effects), $\sigma_{v\theta}$ is the effective vertical stress and N_{kt} is the cone factor.

The Swedish Geotechnical Institute (SGI) suggests a constant value for the cone factor N_{kt} =11 (Larsson, 2015), which is used to determine the undrained shear strength of clay tills in Sweden. While a cone factor value of 11 (N_{kt}) is used in Sweden, a value of 10 is established and used in Denmark based on the tests of the Storebæltsbroen area (Steenfelt and Sørensen, 1995).

Luke (1996) found that the plasticity and the content of impurities in the material may influence both the friction ratio and the cone factor and suggested the following calculation for the cone factor:

$$N_{kt} = 15 \cdot R_f^{-0.4}$$

where R_f is the ratio between the sleeve friction (f_s) and the cone resistance (q_c), (%).

Young and Daehyeon (2011) suggested a new empirical equation for estimation of the cone factor in different counties in Indiana, USA:

$N_{kt} = 0.285 I_P + 7.636$

Aas et al. (1986), Young and Daehyeon (2011), Nwobasi and Egba (2013) found that the cone factor increases as the plasticity index rises, which conforms with some studies, while other researchers reported decreasing trends (Lunne et al., 1976). Luke (1994) in her study did not find any pronounced relation although it was found that the plasticity index and the plastic limit affect the cone factor.

In summary, since K. von Terzaghi discovered the potential of the Atterberg limits in soil mechanics, in 1925, many studies have been performed to correlate shear strength and liquidity and plasticity indices in clayey sediments, and several authors offered empirical shear strength calculations. Furthermore, different cone factors (with respect to both indices) and Bjerrum correction factors have been proposed to calculate shear strength from CPT and VST. The results have been inconclusive. While one research group found that the shear strength fits well with the liquidity and plasticity indices, other results contradict such a relationship and provide opposite results.

2.3 Previous studies on clay till

To carry out this thesis, a literature study of clay-rich sediments in Scania was conducted. The general development of southwestern Scania in connection with the new Öresund Link to Denmark has led to deeper knowledge of the local clay tills (Larsson, 2001). Therefore, diverse studies have been conducted in this area, while just a general description of the Simrishamn area was found in Daniel (1986).

Dueck (1998) and Larsson (2001) studied The latter authors describe the two different types of till referring to Baltic and Northeast tills, which are not geological terms and only indicate the provenance of clasts. Further in the text the Baltic clay till is named as Lund Till consistent with the terms used in other studies (Berglund and Lagerlund, 1981; Ringberg, 2003; Anjar, 2013). Lund Till is found from the ground surface down to 3 m depth and contains a large amount of sedimentary bedrock particles. The grain size distribution indicates that the Lund Till is a clay till or a sandy clay till (Fig. 2.3).

The groundwater level at Tornhill is situated 1.5 m below the ground surface (Dueck, 1998). A good cor-

relation between plasticity index and the liquid limit of

the Lund Till has been found (Dueck, 1995).

Figure 2.3. Grain size distribution for seven samples from Lund Till (Dueck, 1998).

To determine different properties of the Lund Till, a significant number of various tests were implemented by Dueck (1997) and Larsson (2001) (see Tab. 2.3).

Table 2.3. The summary of different properties and undrained shear strengths of Lund Till. Modified from Dueck (1997, 1998) and Larsson (2001). * Plasticity index was estimated from a relation $I_P = 0.79 (w_L - 0.12)$

Properties	Lund Till (Dueck, 1997, 1998)	Lund Till (Larsson, 2001)
w %	14 - 21	13 - 17
w_L %	47	20 - 37
$w_P \%$	19	13 - 16
I _{P %}	-	8 - 12*
c _u (Triaxial)	175 - 350	165 - 175
c _u (CPT) kPa	50 - 400	30 - 400
c _u (VST) kPa	80 - 420	300 - 400

As it can be seen, physical properties of the Lund Till are quite close, while the undrained shear strengths scatter widely as not only the heterogeneity of the till but also sampling, the precision of measurements and other factors affect the results of undrained shear strengths.

Undrained shear strength from CPT showed that results scatter widely. However, a comparison between CPT and VST suggests that a cone factor between 10 and 12 would be appropriate (Larsson, 2001).

Jacobsen (1970) and Hartlén (1974) proposed undrained shear strength relations for clay till taking the void ratio (e_0), water content (w) and clay content (l_c) into account. However, the comparison with the measured undrained shear strengths from triaxial tests showed that estimated undrained shear strengths are mainly lower (Larsson, 2001).

A very detailed division of the tills by characteristic mineral composition has been performed by Ekström (1936, 1950), who states the shale-crystalline till is the most widespread till in Scania (Daniel, 1986; further discussed in section 6). Meanwhile, the division of clay tills by the percentage of clay particles is used to visualize tills in the Quaternary sediment map (Sveriges Geologiska Undersökning, 1985; Sveriges Geologiska Undersökning, 1987; Daniel et al., 2000; Ringberg, 1987).

3 Geology

3.1 Bedrock of Scania

The information presented in this section is based on maps and general descriptions from the National Atlas of Sweden (Sveriges Nationalatlas, 1999).

Scania is located at the boundary between the Baltic shield and the younger Central European sedimentary bedrock area. This unique location provides the variety of bedrock of Scania which formed between 1700 and 50 million years ago. The Precambrian bedrock mainly lies directly under the Quaternary deposits in the northern part of Scania and primarily consists of orto gneiss, gneiss-granite, syenite and monzonite. On the contrary, younger sedimentary bedrock, including sandstone, clay shale, limestone and claystone, and Quaternary deposits cover this older bedrock in the southern part (Fig. 3.1). The tectonic movements have developed the bedrock surface that is observed today. A wide tectonic zone, the Protogine Zone, divides the Precambrian bedrock into a western part consisting of mainly gneiss, and an eastern part consisting of volcanic rocks and granite. This zone stretches from the Romele Horst up to the county border in the north. Another, younger tectonic structure, the Tornquist zone, crosses Scania from northwest to southeast (see fault zones in Fig. 3.1). This zone began to develop during the younger Carboniferous-Permian Periods, and resulted in raised fault blocks (horsts) and

Figure 3.1. Map of the bedrock of Scania. Study sites are marked with red circles and names. Modified from Sveriges Nationalatlas (1999).

Figure 3.2. Map of Quaternary deposits in Scania and deglaciation recession from 17 to 14 kya BP. Study sites are marked with red circles and names. Modified from Sveriges Nationalatlas (1999).

subsided areas (grabens). These subsided areas are filled with clay, clay shale and sandstone from the Triassic-Jurassic Period, while only the higher Precambrian horsts are exposed at the surface.

During the Cretaceous-Neogene Periods, Scania was exposed to significant vertical movements which led to the development of smaller basins, such as the Kristianstad and Vomb depressions. A part of Scania around Kristianstad and the southernmost part of Scania, from Landskrona to Ystad down to the Falsterbo Peninsula, was covered by the sea and subsequently limestone was deposited. Today this limestone, rich in fossils, forms up to 1400 m thick sedimentary bedrock layer in the southern part of Scania and only up to 400 m around Kristianstad.

3.2 Quaternary deposits in Scania

The bedrock surface of Scania is covered by Quaternary deposits, with a thickness varying from a few to more than 130 meters, depending on bedrock surface undulations (Sveriges Geologiska Undersökning, 1980 and Sveriges Geologiska Undersökning, 2017). Where the bedrock surface is elevated, the Quaternary deposits are usually thin, whereas in depressions the thickness increases.

The Quaternary deposits are composed of till, glaciofluvial sands and gravel, glaciolacustrine finegrained sediments, postglacial sand, clay, peat and gyttja. The deposition of the Quaternary sediments we observe today began in the Late Weichselian (25-11.7 kyr BP), when the Scandinavian ice sheet reached its maximum extent (ca 23 kyr BP; Fig. 3.3). Later ice sheet re-advanced and glacio-isostatic rebound during the following deglaciation period led to deposition of tills, gravel and sand, silt and clay.

When the Scandinavian Ice Sheet reached its maximum extent at 25-21 kyr BP it covered the province of Scania, the eastern part of Denmark and extended into the northern parts of central Europe. During this advance, the Dalby Till was deposited in Scania. The deglaciation phase (20-15 kyr BP) was the next essential step in the geological development of Scania. At ca 20-17 kyr BP southern Sweden and Denmark were exposed to several re-advances, different studies give contradictory results regarding the deglaciation. At ca 17 kyr BP the ice margin had retreated along the Swedish west coast, and the Kullen Peninsula in northwest Scania is believed to have become ice-free for the first time (Sandgren et al., 1999; Fig. 3.3).

Figure 3.3. The maximum distribution of Scandinavian Ice Sheet during the Late Weichselian glacial period. The province of the Scania is encircled with orange. Modified from Patton et. al 2017.

The next phase in the deglaciation of Scania is characterized by the formation of periglacial surfaces and a last re-advance (Anjar, 2013). The deglaciation was interrupted by the last Öresund re-advance (ca 17 kyr BP) of the Young Baltic Ice stream, which extended over southwestern Scania to south and west of the Romele Horst, depositing the Lund Till (Ringberg, 2003; Anjar, 2013; Anjar et al., 2014; Houmark-Nielsen and Kjær 2003). As the ice sheet was thin, and shortly after advancing vast territories in low-lying areas along the south and west coast of Scania became ice free.

3.3 Clay tills at the Stångby and Simrishamn sites

During tens of thousands of years, Scania experienced several glacier advances from different directions, and clasts of various origin were incorporated in the sediments and later deposited by glaciers. Ekström (1936) studied tills in Scania and divided them into several areas based on the characteristic mineral clasts incorporated (Fig. 3.4).

Figure. 3.4. Areas of clay tills in Scania. Study sites are marked with red circles. The cross-section between Löddeköpinge and Eslöv cities is marked with a grey line. Modified from Ekström (1936).

As can be seen the chalk and sedimentary bedrock clasts are typical for the till in the southwestern part of Scania (light green area in Fig. 3.4). Ringberg (1987) describes that the till rich in clay and chalk lies in southwestern Scania and its thickness varies from 1 to 20 m. A cross-section in west-southwest to east-northeast directions shows that clay till is mainly the thinnest in the western part (approx. 1m) and increases in thickness (up to approx. 20 m) as it approaches the border of its distribution. This sketches the noticeable borders in the Quaternary map (Ringberg, 1987; Sveriges Geologiska Undersökning 1987). The clay content in the clay-rich till generally varies between 25 and 40%, but might reach up to 40 to 60%, occasionally surpassing 60% (Fig. 3.5).

The clay-rich till also lies in a narrow area along the coastline near Simrishamn. It is assumed that two potential processes might have contributed to the high clay content. From one side, it is believed that either this clay-rich till has formed by reworking sedimentary clay, or by the weathering of chalk and limestone of the uppermost part of the till.

The same phenomenon is observed in southwestern Scania (Daniel, 1986). Ringberg (2003) and Anjar (2013) concluded that the clay-rich till was deposited by the Öresund re-advance by the Young Baltic Ice stream ca 17 kyr BP.

Figure 3.5. The grain-size distribution of clay tills at Stångby (right) and Simrishamn sites (both images) according to Quaternary deposit maps SGU 1987; SGU 1985. Modified from Ringberg (1987).

In contrast, the Simrishamn site lies on the border of two till areas: the one till includes crystalline mineral clasts while the other has shale and chalk (red/ dark green area in Fig. 3.4). Moreover, the whole Simrishamn area represents the very shifting thickness of Quaternary sediments being dependent on the morphology of the underlying sedimentary bedrock (Cambrian sandstone); the till cover is missing almost completely west and northwest of Simrishamn (Daniel, 1986).

3.4 Field site geology

The digital map generator allows us to gain information about the Quaternary deposits at the Stångby and Simrishamn sites from the website of the Geological Survey of Sweden (Sveriges Geologiska Undersökning kartvisare, 2018a and 2018b) (Fig. 3.6 and 3.8). Since the sites vary greatly in size, different scales were used in the maps. The legend for both maps is found below the Stångby map.

3.4.1 Site I - Stångby

The Stångby area is located approximately 3 km north of Lund and lies approximately 45 m above sea level. The investigation area is dominated by cultivated land. According to the website of the Geological survey of Sweden (Sveriges Geologiska Undersökning) digital map (Sveriges Geologiska Undersökning kartvisare, 2018a) clay till with a clay content >15 % overlies the sedimentary bedrock and forms up to 10 m thick Quaternary sediments (Sveriges Geologiska Undersökning, 2018a; Sveriges Geologiska Undersökning, 2017) (Fig. 3.6.).

Figure 3.6. The study site at Stångby is marked with a purple dashed line. Modified from SGU (2018a).

Geological investigations (Tyréns, 2017a) show that a clay till rich with humus lies 0.0-0.3 and 0.0-0.8 m deep, overlies clay till which lies approximately to a depth of 1.8 m (Fig. 3.7, 6.1, 6.2.).

Figure 3.7. Clay till with chalk clast at Stångby. Photo by the author, 2018

Below these two layers, a clay till with occasionally embedded 30 to 60 cm thick sand lenses is situated at 1.8-4.0 m depth. This separate clay till with sand lenses was found only at the three points located in the western part of the site and was not included in this study.

3.4.2 Site II - Simrishamn

Compared with Stångby, the Simrishamn site is a small area located in the middle of Simrishamn city. A clay till with a clay content of 15-25% dominates the area (Fig. 3.8 and the labels under 3.6.).

Figure 3.8. The study site at Simrishamn is marked with a purple square. Modified from SGU (2018b)

This till overlies the Cambrian sandstone, which lies approximately 10 m deep (Sveriges Geologiska Undersökning, 2018b; Sveriges Geologiska Undersökning, 1985). Apart from that the clayey till areas with a clay content lower than 5% (light blue areas in Fig. 3.8) were found near the study site, and vast fields with postglacial sand and gravel (orange areas) cover the coastal areas and parts of the city.

Geological investigations (Tyréns, 2017b) shows that the medium sand overlies brown, sandy and silty clay till which is situated at 0.7 - 3.6 m depth (Fig. 3.9 left). Below this clay till, a brown silt layer is underlied by grey clay at 3.6 - 4.0 m depth. A grey clay till lies at the base of the borehole 4.0 - 6.0 m depth (Fig. 3.9 right).

Figure 3.9. A sandy, silty brown clay till (left) and a clay-rich, grey clay till (right) with clasts from Simrishamn site. Photo by the author, 2018

4 Methods

In this study, several field and laboratory methods were applied to collect samples, analyse physical properties and determine undrained shear strength of clay tills from Stångby and Simishamn. Test standards and guidelines of the Swedish Standard Institute were followed. To obtain test samples, disturbed sampling was accomplished with a GeoTech 604 drill rig. CPT no. 4907 and CPT 4933 were used to implement cone penetration tests and the Danish vane V5 type was used for vane shear tests and to calculate the undrained shear strength. Considering field descriptions of the previous studies and various limitations of the equipment, a maximum depth of 2.0 m at Stångby and 5.9 m at Simrishamn was reached in this study. Altogether 12 disturbed samplings, 10 CPT soundings and 11 field vane tests at 8 points were performed at the Stångby site from 0.3 to 2.0 m depth (see Tab. 4.1).

Table 4.1. Th	he summary o	of test	methods	performed	in this	study
---------------	--------------	---------	---------	-----------	---------	-------

Site	Disturbed samples	CPT points	VST points	
Stångby	12	10	11	
Simrishamn	11	3	-	

Both the 11 disturbed samplings and CPT were conducted at 3 points from 1.2 to 5.9 m depth at the Simrishamn site. Results from VST and CPT were analysed for the same sampling depth. Disturbed samples were obtained for further determination of Atterberg limits: the liquid limit and the plastic limit, and related indices. To calculate both plasticity and liquidity indices, the percentage of natural water content was also determined. In addition to the investigation methods mentioned above, many empirical calculations were tested, as undrained shear strength estimation from Atterberg limits has been of interest since 1925 (Terzaghi, 1925). Finally, the results were mainly displayed in graphs and the correlations between shear strength and liquidity and plasticity indices were estimated using either linear or exponential regressions.

4.1 Field methods

4.1.1 Disturbed sampling

The most common method for sampling is a disturbed sampling. While the basic methods include sampling from the test pits or with a hand auger, more advanced sampling with a drill rig provides disturbed sampling from greater depths. In this study a screw auger mounted on a drill rig was used for obtaining the disturbed clay till samples. The screw auger is a sampler designed as a screw on a steel rod and the diameter varies from 30 to 200 mm, although a diameter of 60 to 100 mm and 1 m height is most frequently applied (Svenska Geotekniska Föreningen (SGF), 2013; see Fig. 4.1.left).

Figure 4.1. The screw augers of the different sizes, (left, SGF, 2013); a drill rig with the lifted screw auger (right). Photo by the author (2018)

The screw auger is primarily used for clay-rich sediments down to 5 m depth, although drilling down to 15 m is possible. During sampling, the auger is screwed into the ground to the desired depth and then pulled out (Fig. 4.1.right). The clay till remains on the ribs of the auger as it is pulled out, representing the geological profile of the depth interval (Svenska Geotekniska Föreningen, 2013). Finally, clay till samples are carefully taken and placed in plastic bags and the boring number and the depth of the samples are noted. Notes are made in a field book including simple descriptions of the clay till samples.

4.1.2 Cone penetration tests

When performing a CPT sounding, a cylindrical probe with the total cross-sectional area of 1000 mm² and a cone with 60° apex angle is pushed into the ground with a constant rate of 20 mm/s. During the test the following quantities are measured: cone resistance (q_c) , sleeve friction (f_s) and pore pressure (u) which is measured in a porous ring between the cone and cylinder (Larsson, 2015)(see Fig. 4.2).

Figure 4.2. A cone penetration probe (left), modified from Larsson, (2015) and a CPT equipment in use at Simrishamn (right). Photo by the author (2017)

Typically, CPT sounding is a complementary method for disturbed sampling in the field and principally constructed to ascertain the ground profile. However, sounding also gives information about continuous shear strength variations in the sediments (Svenska Geotekniska Föreningen, 2017), and this is a method widely used in Sweden. CPT is used to a large extent to empirically calculate undrained shear strength. Alternatively, a dynamic penetration test can be applied as this method is adjusted to a coarser material. However, its main aim is to determine the ground profile (Swedgeo, 2017). Sounding results are influenced by various conditions, like particle size, density, overburden and horizontal stresses in the layer. Therefore, CPT sounding data should be regarded as complex, considering relations and variations of all three measured features: cone resistance (q_c) , sleeve friction (f_s) , and pore pressure (u). For example, the coarser the material is, the higher is the cone resistance and the lower friction ratio (R_f) (a relation between cone resistance and sleeve friction) and lower pore pressure. The undrained shear strength usually is calculated using measured cone resistance (q_t) values, and effective vertical stress (σ_{v0}) :

$$c_u = \frac{q_t - \sigma_{vo}}{N_{kt}}$$
 (kPa)

where q_t is the total cone resistance, σ_{v0} is the effective overburden stress, and N_{kt} is the cone factor (Larsson et al., 2007).

4.1.3 Vane shear tests

The vane shear test is a simple in-situ method to determine the shear strength of soft to medium brittle clays. This method is widely used in geotechnical investigations due to its time and cost effectiveness and simplicity. Moreover, the VST enables measurement of the undrained shear strength at a certain point, thus it is used as a complementary method to validate CPT sounding results (Svenska Geotekniska Föreningen, 2017). A Swedish field vane is designed for soft clays and considered not to be suitable to measure the shear strength in clay tills. The Danish vane instrument is more appropriate due to its design, which was created on a basis of surveying firm clay tills in Denmark (Larsson, 2001; Fig. 4.3).

Figure 4.3. A - a schematic picture of the Danish field vane; B - the geometry of the vane; C - the cross-section. Modified from Dansk Geoteknisk Forening, 1998

Since the Lund Till in southwest Scania and Denmark was formed during the same ice advance, the Danish vane instrument is broadly used in geotechnical investigations in southwest Scania.

The Vane instrument consists of a four-bladed vane which is mounted on a cylindrical rod. To reach the required depth, the holes are pre-bored and then the VST probe is lowered at the bottom of these prebored holes. A rod is pushed into the undisturbed sediment until the base of the vane reaches a depth up to twice the height of the vane (see Fig 4.3A). Next, a torque wretch is attached to the rod and slowly rotated until the moment at which the sediments reach failure.

Although the operating principle is the same, various vane sizes are used depending on the expected undrained shear strength. Vane types V4, V5, HVA and HVB are used down to 20 cm depth from the bottom of the borehole, while V7.5 and V9.2 are used approximately down to 30 cm depth from the bottom of the borehole (Dansk Geoteknisk Forening, 1998). For vanes V4 and V5, a repetition of the shear test procedure can be made at 20 cm depth from the first test point. To implement vane shear test at Stångby, the V5 type Danish vane instrument was used (see Tab. 4.2).

Table 4.2. Measurements of different Danish vanes, vane load capacity and a constant applied to undrained shear strength calculations. Modified from Dansk Geoteknisk Feltkomité, 1998.

Typ e	h (mm)	d (mm)	r (mm)	c _{v, max} (kPa)	M(m ³) (constant)
V4	80	40	10.0	715	$0.2097 \cdot 10^{-3}$
V5	100	50	12.5	366	$0.4096 \cdot 10^{-3}$
V7,5	150	75	18.8	109	$1.3820 \cdot 10^{-3}$
V9,2	350	92	23.0	32	$4.7588 \cdot 10^{-3}$
HV A	66	33	7.0	333	0.1201.10-3
HVB	96	48	10.0	108	0.3703 · 10 ⁻³

Next, the measured peak torque was used to calculate the vane strength (c_v) :

$$c_v = \frac{P_a}{M'}$$
 (kPa)

where P_a is a peak torque (Nm) and M' is a constant (m^3) , depending on the dimensions and shape of the field vane (Dansk Geoteknisk Forening, 1998). It is considered that the vane strength value measured in

the clay till is about the same as the undrained shear strength value, thus:

$$c_v \approx c_u \ (kPa)$$

4.2 Laboratory methods: liquid and plastic limits

To implement laboratory tests, the informational booklet of the Swedish Geotechnical Institute (Larsson, 2008) and the Swedish Standard (Swedish Standards Institute, 2008) were followed. At the initial phase, the natural water content of each sample was determined. First, a specimen was taken out of the bag, weighted and put into the oven at 105°C to dry out for 24 hours. Next, the sample was taken out of the oven and weighed again (Larsson, 2008).

The liquid limit was determined by the fall cone method. A paste of moisture sediment was put in a bowl and inserted into a fall cone device. A cone with a mass of 60 g and tip angle of 60° was lowered until it almost reached the surface of the sample and then released (Fig. 4.4).

Figure 4.4. A schematic image of the fall cone device (left), modified from Larsson, 2008; and the fall cone in use (right), photo by the author (2017).

When the cone had dipped, the cone imprint was measured and the liquid limit was calculated according to guidelines of Swedish Geotechnical Institute (Larsson, 2008).

The plastic limit, also called a rolling limit, is the lowest water content in the sample at which it retains its physical ability to be rolled out to a 3 mm thick thread without falling apart. The water content was calculated according to Swedish standard (Swedish Standards Institute, 2014) and the result obtained was determined as the plastic limit.

5 Results

The relationship between the liquidity index (I_L) and the undrained shear strength (c_u) was tested for clay tills from the two sites in Scania. To visualize and analyse the undrained shear strength with both plasticity (I_P) and liquidity indices the determined indices were attributed to the whole disturbed sample and the point values of the shear strength at the particular depths were extracted from CPT and VST measurements. The analysis of the liquidity index and the undrained shear strength was combined with empirical estimations from the previous studies described in the subsection 2.2.

5.1 Site I - Stångby

Results from the Atterberg tests show that the liquidity index (I_L) in the clay till samples varies from -0.10 to 0.34 with only one sample having a negative value (see Tab. 5.1). The average value of 0.22 indicates that according to the consistency classification, Lund Till at Stångby can be generally classified as having a very brittle to brittle consistency (Tab. 2.1).

The undrained shear strength obtained from the two methods shows different values: while c_{uCPT} varies between 57 and 256 kPa, the c_{uVST} shows lower values, between 42 and 208 kPa. Interestingly, the aver-

age values from the two methods are very close, 126 and 125 kPa respectively.

5.2 Site II - Simrishamn

The liquidity index of 8 samples from Simrishamn varies between -0.35 and 0.23 and has primarily negative values (see Tab. 5.2). With an average liquidity index of -0.07, the clay till is classified as a having very brittle consistency (Tab. 2.2). The undrained shear strength calculated from CPT varies between 179 and 763 kPa with an average value of 337 kPa. It should be pointed out that an undrained shear strength higher than 350 kPa is more typical for frictional rather than cohesive sediments.

6 Analysis and discussion

6.1 Liquidity and plasticity indices at Stångby and Simrishamn

Firstly, there is no systematic change in the natural water content (*w*) with depth at both Stångby and Simrishamn sites (Fig. 6.1), and a higher variation of natural water content was found at the Simrishamn site than at the Stångby site. Secondly, as the liquidity index is directly dependent on the natural water content, no relation was observed when the liquidity index was plotted against depth (Fig. 6.2). At the Stångby site, the highest and lowest I_L values were found at the same depth of 1.1 m. In addition to I_L , I_P does not show any change with depth either.

Table 5.2. A summary from the Simrishamn site

Several factors affect the variability of the indices. First, Skempton (1984) found that the plasticity of clay increases linearly with the percentage of the claysize fraction. Therefore, the plasticity index directly demonstrates the composition of the clay till: the higher the I_P value, the higher the clay percentage of deposits, independent of depth. Second, I_L is dependent on the sediment composition and the water content.

It is common that clay-rich sediments above the groundwater table are saturated, and this is related to the capillary rise. The height of the capillary rise depends on the grain size and the size of pores in the material: for coarse sand the capillary rise is 0.03 to 0.12 m, while for clays it is more than 8 m (Larsson, 2008). Results from groundwater monitoring at

Stångby from the 4-year period indicate yearly variations of the groundwater table: the highest level is observed from February to May and the lowest level is reached from August to October (Tyréns, 2017a). In this study groundwater table varies between 0.2 and 3.67 m depth. Therefore, it is expected that the natural water content of the clay tills might be higher from February to May, which might increase I_L at both study sites to some extent.

To summarize, the plasticity index is dependent only on the clay content of the sediments, whereas the liquidity index is affected by both the plasticity index and the natural water content. It is expected that the rise of the groundwater table during February to May will increase the natural water content of the clay tills,

Figure 6.1. Variations of natural water content with depth

Figure 6.2. Liquidity index plotted against depth at the Stångby and Simrishamn sites

which in turn would result in the slightly higher liquidity index values, considering that the plasticity index is the crucial variable which provides a major impact on the liquidity index.

6.2 Liquidity index and undrained shear strength at Stångby

The shear strength values from the CPT and VST methods are scattered differently, between 199 and 166 kPa range respectively (see maximal and minimal undrained shear strength values from the CPT and VST in Tab.5.1.). This suggests that the CPT might be more susceptible to inhomogeneities of clay till than VST, giving occasionally higher cone resistance values and, consequently, higher undrained shear strength values. As Mayne et al. (2009) describes, the general difference in the shear strength is due to the different methods.

Related to this, Rémai (2012) describes that the measured undrained shear strength depends on the test method, the strain rate and many other factors. Also, Karpovics (2010) points out that the geotechnical behaviour of clay till is influenced by granulometric composition, the state of the consolidation, soil texture, deposition, conditions of sedimentation and postsedimentation changes. Finally, CPT and VST measurements in this study were performed within a small

distance (ca 30 cm) from each other, which also leads to different shear strength values.

The results from Stångby show that the undrained shear strength is higher in the very brittle consistency zone and decreases when the liquidity index slightly increases (Fig. 6.3).

Figure 6.3. Undrained shear strength and liquidity index relationship at Stångby; An extremely high c_{uCPT} value is encircled with a solid and the only one negative I_L value is encircled with a dashed circle.

This would confirm a common knowledge of the soil mechanics, which states that the higher the water content, the higher the liquidity index and the lower the density of the sediments should be. Therefore, the lower the density is, shear strength should also be lower. However, it is very important that no relation can be found when an extreme value of c_{uCPT} and the only one negative liquidity index value are excluded.

With respect to the classification to liquidity index, in principle, all results lie in the brittle consistency zone

(I_L from 0.2 to 0.3) and the undrained shear strength varies mainly from 50 to 200 kPa.

It is assumed that the lack of direct measurements of the shear strength and a constant cone factor value of all clay tills lead to some level of uncertainty of the calculated shear strength from the cone penetration test. The cone factor, (N_{kt}) which is a constant of 11, is used to calculate the shear strength from CPT, not considering the inhomogeneity of the clay till (Larsson, 2015):

$$c_u = \frac{q_t - \sigma_{v0}}{N_{kt}} \, (\text{kPa})$$

where N_{kt} is the cone factor, q_t is the total cone resistance and σ_{v0} is the vertical stress.

Thus, the constant of 11 applied to the whole clay till layer may provide incorrect shear strength values. The results from VST were used to back-calculate the cone factor for each point of interest:

$$N_{ke} = \frac{q_t - \sigma_{vo}}{c_{uVST}}$$

where c_{uVST} is the shear strength from vane shear test.

The empirical cone factor values vary from 4.6 to 29.6 with a general assemblage between 5 and 10 and an average value of 12.8 for 11 points (Tab. 5.1). The great variation of cone factor values suggests an individual assessment of the bulk density (ρ , kg/m³) for each sample since bulk density is used in the determination of the unit weight (γ , kN/m³) when estimating the shear strength from cone penetration test:

$$\rho = \frac{m}{v}$$

where *m* is the weight of the sediment sample (kg) and *V* is a volume of the sample (m^3);

 $\gamma = \rho g$

where ρ is the density of the material (mass per unit volume, kg/m³) and g is standard gravity (m/s²) = 9.81 m/s².

Aas et al. (1986), Young and Daehyeon (2011) and Nwobasi and Egba (2013) found that I_P increases as N_{ke} increases, whereas later studies do not confirm this tendency. Neither the relation described above, nor the one between I_L and N_{ke} , was found in this study.

While there is no relation between N_{ke} and the two indices, the empirical cone factor correlates weakly with the net tip resistance $(q_t - \sigma_{v0})$ (Fig. 6.4).

Figure 6.4. The empirical cone factor (N_{ke}) and net tip resistance $(q_{\Gamma}\sigma_{\nu0})$; two extremely high cone factor values are marked with a red outline. The dashed linear regression line includes all points, while the solid regression line excludes the two extremely high values.

The relation with all empirical cone factor values (blue triangles) shows a slight fit (coefficient of determination $R^2 = 0.40$), although after the elimination of the extremely high cone factor values (triangles with red outline), the relation shows better fit ($R^2 = 0.56$ Therefore, this might indicate that the N_{ke} is dependent on the total cone resistance, and to get correct c_u values, q_t should be divided by higher N_{ke} values. Concerned about the influence of the cone factor on the undrained shear strength results from CPT, many researchers have conducted their own studies with the aim to present different cone factors, either applicable locally or to a particular sediment type. A few of them, appropriate to this study, are discussed in subsection 6.5.

6.3 Liquidity index and undrained shear strength at Simrishamn

The results show that undrained shear strength varies between 179 and 763 kPa limits and the undrained shear strength tends to diminish when liquidity and plasticity indices increase. It is clearly seen that the undrained shear strength correlates better with the liquidity index ($R^2 = 0.76$) than with the plasticity index ($R^2 = 0.49$) (Fig. 6.5 and 6.6).

Figure 6.5. The liquidity index (I_L) and the undrained shear strength (c_{uCPT}) relationship expressed with an exponential regression line.

Figure 6.6. The plasticity index (I_P) and the undrained shear strength (c_{uCPT}) relationship expressed with an exponential regression line.

Therefore, Kayabali et al.'s (2015) hypothesis, that the effect of plasticity on the undrained shear strength of clay-rich sediments is better represented when measured undrained strength values are correlated with the liquidity index, was confirmed.

6.4 Liquidity index and undrained shear strength at Stångby and Simrishamn

When comparing the undrained shear strength from both sites, it is noticeable that shear strength values at Simrishamn are higher and vary within the 584kPa range from 179 to 763 (Tab.5.2.), whereas at Stångby they vary only within the 199kPa range (from 97 to 256 kPa, Fig.6.7 and Tab.5.1). In Parallel to observations in the laboratory, this provides additional evience of the higher variability of the proportion of clay at Simrishamn, while clay till at Stångby can be considered as more homogeneous.

Apart from the low variability of the shear strength, the liquidity index also shows generally similar values varying from -0.10 to 0.34 at Stångby, which, unfortunately, resulted in a data assembly with no correlation. Although the coefficient of determination for both

Figure 6.7. A summary of undrained shear strength and liquidity index from both Stångby and Simrishamn expressed by the exponential regression lines.

 c_{uCPT} and c_{uVST} shows some relation, no relation is observed when the data set is evened out, suggesting that the undrained shear strength cannot be estimated if I_L values are closely distributed within one consistency zone (Tab.2.2.).

On the contrary, a quite pronounced correlation was found at Simrishamn, implying that the composition of the clay till contributes to a significant variation of I_L and c_{uCPT} (Fig 6.5). The low clay and natural water content of clay till lead to negative values of the liquidity index. A steep increase in the shear strength is observed in the very brittle consistency zone. The relation between q_c and I_P shows that I_P is the conclusive variable, which affects q_c , displaying higher q_c and lower I_L values for clay till with sandy impurities in comparison with those with the higher clay content. The reduction of I_P by 3.12% also lowers the I_L by 0.06 (from -0.29 to -0.35), which in turn leads to the rise of the undrained shear strength to 321 kPa (Fig.6.5.).

6.5 The undrained shear strength proposed by other authors

Considering properties of the clay till at Simrishamn and Stångby, estimations of undrained shear strength proposed by Wroth and Wood (1978), Luke (1996) and Young and Daehyeon (2011) were applied (see subchapter 2.2) and compared to the obtained undrained shear strength values from this study (Tab. 6.1 and Fig. 6.8). While Wroth and Wood (1978) proposed an estimation of undrained shear strength using the liquidity index and a mathematical constant, Luke (1996) and Young and Daehyeon (2011) suggested a multi-step alternative. First, estimate the cone factor (N_{kl}) employing the friction ratio (R_f) and then the plasticity index (I_P) . Afterwards, the undrained shear strength is estimated from CPT measurements by applying the calculated cone factor values.

The analysis shows that the suggested undrained shear strength estimations generally capture the trend. However, it is clearly seen that the shear strength values proposed by Wroth and Wood (1978) and Young and Daehyeon (2011) are underestimated in the brittle and medium soft consistency zones (the purple and gray frames in Fig. 6.8.) and overestimated in the very brittle consistency zone (the red frame in Fig. 6.8).

Figure 6.8. A correlation between undrained shear strength and liquidity index from various authors and the results obtained in this study, expressed with exponential regression lines.

The proposed estimation of Luke and the obtained undrained shear strength in this study display principally similar values, albeit even here indicating a small difference of undrained shear strength in the brittle consistency zone, where c_u varies within 4 to 45 kPa range. Additionally, a larger contrast is observed in the very brittle consistency zone where c_u varies within 5 to 219 kPa range. Despite the divergence in the two consistency zones, the correlation between liquidity index and shear strength shows a quite high fit with the three proposed estimations, with $R^2= 0.70$ for Luke (1996), 0.71 for Young and Daehyeon (2011), and 0.72 for measurements obtained in this study (Fig 6.8).

6.6 Geological aspects

The clay-rich till at the Stångby site, also called Lund Till, was deposited by the Öresund re-advance of the Young Baltic Ice stream at ca 17 kyr BP (Ringberg, 2003; Anjar, 2013). It has a clay content of >25% and a brittle to medium-soft consistency (Tab. 2.2, Fig. 3.5. and 6.9). The characteristic Palaeogene chalk content representing the bedrock of the Baltic Sea was observed in clay till samples (Fig. 3.6).

The plasticity index characterises the plasticity of the sediments, while the liquid limit is the moisture content at which clay-rich sediments change consistency state. The good relation between the liquid limit and the plasticity index found by Dueck (1995) for the Lund Till at Tornhill, was also observed in this study at the Stångby site. Therefore, it indicates that the plasticity of the clay till depends on both the natural water content and the clay content. Unfortunately, the narrow liquidity index range made it impossible to correlate it with the undrained shear strength, as the variations in grain size are crucial for the correlation of these properties.

It is believed that two clay tills were found at the Simrishamn site: a lower, clay-rich, grey till with occasional small rounded Palaeozoic limestone clasts and a clay content of >25%, and an upper, sandy, silty brown clay till with a clay content between 15 and 25% (Fig. 3.5 and 6.9). Considering that the bedrock near Simrishamn and at the bottom of the Baltic Sea consist of shale, sandstone and Palaeozoic limestone

Figure 6.9. Approximate geological cross-section in Stångby and Simrishamn.

(Fredén,1994) it is likely that both tills found at Simrishamn, originated from the Baltic ice advance. However it is assumed that the lowermost grey till might also be deposited by the Bælthav re-advance and the upper by the Öresund re-advance.

Dueck's observed correlation between the liquid limit and the plasticity index for the Lund till at the Tornhill was also found for the assumed two tills at the Simrishamn. The large variation of the grain size in clay tills provided the wide range of liquid and plastic limits as clay particles have large specific area which retain the water. This, in turn, provided a pronounced correlation between the liquidity index and the undrained shear strength. Considering all given information, it is clearly seen that the grain size distribution of the clay till is the main crucial property, which is the prerequisite for the correlation of liquidity index and undrained shear strength.

In conclusion, clay tills in Scania can be categorized in two ways: by the percentage of clay or by the characteristic clasts incorporated in the tills. The analysis in laboratory, CPT and VST shows that the homogeneous Lund Till was deposited at Stångby, possibly two different tills were deposited at Simrishamn. The wide range of grain size in these two tills provided the wide range of liquidity indices and shear strength values. Although all three tills were deposited by the Baltic Ice advance, the grain size distribution and mineralogy varies significantly between them, suggesting that undrained shear strength from liquidity index should be estimated locally.

7 Conclusions

The undrained shear strength is one of the critical strength parameters of a sediments, which is commonly used to analyse stability and lateral pressure at the different stages of the construction projects. Most part of the undrained shear strength tests are cost- and time consuming, thus it is of interest to test the potential relationship with shear strength obtained by different methods by applying alternative, easily measurable parameters such as the liquidity index.

The relationship between the liquidity index and the undrained shear strength in this study was found only partially, as several factors affect these parameters. The liquidity index or consistency of clay tills at the Stångby and Simrishamn sites scatter between 0.44 and 0.58. It is primarily dependent on the composition of the sediments (plasticity index) and less on the natural water content. The study showed that the wide range of the consistency is crucial for the correlation between I_L and c_u .

The undrained shear strength of the clay till is

influenced by the granulometric composition, the state of consolidation, the texture, depositional conditions and post-sedimentation changes.

The undrained shear strength from both CPT and VST at Stångby scatter within 199 and 166 kPa range, suggesting that the different methods give different shear strength values and CPT is more susceptible to the inhomogeneities.

While no correlation between the liquidity index and the undrained shear strength was found at Stångby, results from Simrishamn show a quite good correlation ($R^2=0.76$), suggesting that it is possible to estimate the undrained shear strength from the liquidity index if at least two consistency zones are tested.

8 Proposed further research

This study has provided evidence that the undrained shear strength can be estimated from the liquidity index and that the plasticity of the clay till is a significant property in this relation. The plasticity depends not only on the amount of clay, but also on the type of clay minerals present in the sediments, as the different clay minerals of the clay fraction (2 μ m) yield the different activity (Skempton, 1984; Dolinar, 2010). Although clay till samples taken from this limited area will presumably show only variations in the percentage of clay, it would be of interest to analyse to what extent various clay minerals of different origin affect the mechanical properties.

Several difficulties should be considered when performing related studies. Firstly, it was found highly complicated to carry out the fall cone test for sandy clay till samples, as the mineral grains were large enough to decelerate the cone from the immersion in the clay till mixture. Therefore, values of liquid limit obtained from sandy clay till might not be highly correct. Secondly, based on the sensitivity of the method to sediment impurities different shear strength methods give different values. Therefore, it is suggested to consider applying only one shear strength method.

9 Acknowledgements

The project was conducted in collaboration with the division of Geotechnical Engineering at the Faculty of Engineering LTH, and the consultancy company Tyréns in Malmö.

My deepest thanks to my supervisors Erika Tudisco and co-supervisor Ola Dahlblom from LTH, who guided me through the geotechnical parts of the thesis. I am grateful to my supervisor, Dan Hammarlund for the inspiration. To my friend, Tove Hernnäs, who went with me to the field and helped to drill and take samples, thank you so much! Also Victor Myrström and Jonas Åkerman from Tyréns made valuable contributions to my thesis, clarifying calculations and discussing results of various laboratory tests. I am grateful Mats Svensson for believing in me. I also want to thank my family for the greatest patience and support and Karina Antonenko, Kyle Bruce, Johan Striberger and Anica Mercado for comments on my manuscript.
