Multilevel analysis is today considered a more appropriate way to monitor health care performance, as it allows a less biased estimation of uncertainty, and can also separate and quantify contextual (as opposed to individual) effects. Multilevel analysis should be applied as the standard methodology for hospital comparisons. A greater awareness of this question in future Journal articles may be in order.

Key words: Hospital comparisons, Multilevel analysis

My colleagues and I have an article in press that will shortly appear in the journal Medical Care [1]. It explores an issue indirectly related to a recently published study in the European Journal of Epidemiology by Capon et al. [2]. We investigate variance in neonatal mortality in Sweden, while the study by Capon et al. is concerned with variability in caesarean section in Italy. The data in both articles are based on a large number of hospitals and deliveries, and both have a clear methodological style. In fact, the title of Capon's article itself suggests a methodological concern.

I was attracted by the question raised by Capon et al. and read their paper with considerable interest. It was rather disappointing to find that this article, although it presents itself as methodologically founded, avails itself of a rather old-fashion epidemiology. In doing so, it naively overlooks the modern methodological considerations pertaining to hospital comparisons.

The authors begin with a clear exposition of the hierarchical structure of their data, outlining factors related to the mother, physician profiles, and hospital characteristics as elements that may contribute to the propensity for caesarean sections. However, they do not at all mention that this multilevel structure conditions a dependence on the residuals that needs be dealt with by employing suitable analytical techniques. The authors include in their model 60 dummy variables identifying single hospitals, instead of a simple random term for hospital effects. This outmoded procedure contains many disadvantages and has been seriously criticised for several years [3, 4], especially since appropriate epidemiological techniques, such as multilevel regression analysis, have been well-developed in Europe [5].

Multilevel analysis is today considered a more appropriate way to monitor health care performance, as it allows a less biased estimation of uncertainty, and can also separate and quantify contextual (as opposed to individual) effects. Multilevel analysis should be applied as

the standard methodology for hospital comparisons. A greater awareness of this question in future Journal articles may be in order.
