The use of the phospholipid fatty acid (PLFA) composition of microorganisms to detect previous self-heating events was studied in naturally self-heated peat and in peat incubated under temperature-controlled conditions. An increased content of total PLFAs was found in self-heated peat compared to that in unheated peat. Two PLFAs, denoted T1 and T2, were detected only in the self-heated peat. Incubation of peat samples at 25 to 55°C for 4 days indicated that T1 and T2 were produced from microorganisms with different optimum temperatures. This was confirmed by isolation of bacteria at 55°C, which produced T2 but not T1. These bacteria produced another PLFA (denoted T3) which coeluted with 18:1ω7. T2 and T3 were identified as 10-cyclohexylundecanoic acid and 10-cyclohexylundecanoic acid, respectively, indicating that the bacteria belonged to the genus Alicyclobacillus. T1 was tentatively identified as 7-cycloheptylundecanoic acid. T2 was detected 8 h after the peat incubation temperature was increased to 55°C, and maximum levels were found within 5 days of incubation. The PLFA 18:1ω7-T3 increased in proportion to T2. T1 was detected after 96 h at 55°C, and its level increased throughout the incubation period, so that it eventually became one of the dominant PLFAs after 80 days. In peat samples incubated at 55°C and then at 25°C, T1 and T2 disappeared slowly. After 3 months, detectable levels were still found. Incubation at 25°C after heating for 3 days at 55°C decreased the amounts of T2 and 18:1ω7-T3 faster than did incubation at 5°C. Thus, not only the duration and temperature during the heating event but also the storage temperature following heating are important for the detection of PLFAs indicating previous self-heating.

Peat is widely used as organic growth substrate in horticulture. Properties like a high cation exchange capacity, a high proportion of air-filled pores, and a low content of weeds and pathogens makes it an ideal growth medium for plant production. After harvesting, the peat is stored in stockpiles. During this storage, self-heating may occur. The use of self-heated peat is generally avoided, since toxic substances produced during self-heating may inhibit seed germination and plant growth (24). Test methods have been developed to detect if peat has been exposed to self-heating. These tests are based on biological, chemical (13), or physical (20) analyses. However, they require access to unheated peat samples for comparison, which make the tests cumbersome, and today they are no longer in use.

The self-heating process in peat has not been well studied, but it is assumed to be analogous to self-heating in compost and hay (9). During self-heating, a succession from a mesophilic to a thermophilic microbial community is expected (7, 18, 22). After the peak temperature is attained, there will be a selection pressure favoring a mesophilic community, and a reversion from a thermophilic to a mesophilic community will take place (21). Analyses of phospholipid fatty acids (PLFAs) have been used to detect these changes, e.g., in different types of composts (6, 11, 12, 16, 17). The initial thermophilic phase appeared to cause immediate and drastic changes in the PLFA pattern within a day, whereas changes during the later mesophilic curing phase were much slower. Even 3 to 12 months after the thermophilic phase, PLFAs characteristic of this phase were detected (6, 16). This indicates that the PLFA pattern might be used to detect self-heating of peat long after the actual event.

The objectives of the present study were (i) to determine if the PLFA analysis can be used as a method for detection of self-heating in peat and (ii) to study how mesophilic and thermophilic temperatures affected the microbial community structure of peat. This was done by studying naturally self-heated peat stored for up to 6 months after the heating event and peat incubated under temperature-controlled conditions.

MATERIALS AND METHODS

Peat samples. Peat samples were collected from stockpiles containing ground sod peat or vacuum-harvested milled peat. The stockpiles were located on the mires where harvesting had taken place. All mires were situated in southern Norway and were dominated by different Sphagnum species with a low degree of humification (von Post H2 to H4). Sampling was done 4 to 6 months after harvesting. One sample per stockpile was analyzed. pH was measured in a peat-water suspension (1:1.5, vol/vol). NO3-N and NH4-N were measured after extraction in a 2 M KCl solution. Dissolved organic carbon (DOC) was measured in the water extract from the pH measurement. The C/N ratio was determined using dry combustion in an excess of oxygen, with thermal conductivity detection of evolved CO2 and N2O.

Peat treatments. Mire and stockpile number are used to identify the peat samples. A single sample from a stockpile was used as a replicate for temperature-controlled laboratory experiments. Typically, two or three replicates were used per experiment; these are indicated in the descriptions of the experimental design. Before the peat samples were incubated, ultrapure Milli Q water was added to increase the water content of the peat to 80%. During the experiments, the samples were kept in autoclave bags and maintained at constant moisture content. The desired temperatures in the peat were reached within an hour. To differentiate between abiotic and biotic effects of temperature, three peat...
PLFAs in self-heated and unheated peat. All peat samples were acidic, with C/N ratios ranging from 42 to 61 (Table 1). Naturally self-heated peat was defined as peat that had been exposed to temperatures above 35°C. The total amount of PLFAs (totPLFA) was significantly larger \((P < 0.05)\) in the self-heated peat than in the unheated peat \((1,160 \pm 99 \ [n = 18]\) and 760 \pm 106 \ [n = 9]\) nmol g^{-1}, respectively). Thus, the absolute amounts of many of the individual PLFAs were significantly larger \((P < 0.05)\) in the self-heated peat than in the unheated peat (15 of 28 samples [data not shown]). In the self-heated peat, two fatty acids (denoted T1 and T2) not detected in any of the unheated peat samples were found. These two PLFAs usually appeared together, although sometimes only T2 was detected. T1 varied between 0 and 0.42 mol% of totPLFA (mean, 0.08%), and T2 varied between 0.08 and 1.55 mol% of totPLFA (mean, 0.10%).

$^e$ NA, not analyzed.

and 0.66 mol% of totPLFA (mean, 0.30%) in the self-heated peat.

A PCA score plot differentiated between self-heated and unheated peat samples (Fig. 1A). The self-heated peat samples were found mostly to the right of the unheated peat samples (Fig. 1A). The self-heated peat samples and 0.66 mol% of totPLFA (mean, 0.30%) in the self-heated peat were found mostly to the left. Of the total variation, 34% was accounted for by the first principal component while 24% was accounted for by the second principal component. There was a significant difference between the scores of self-heated and unheated peat samples along the first component (P < 0.01). The loading values of the individual PLFAs showed that unheated peat samples were characterized by relatively high proportions of the PLFAs 15:0, 16:1ω5, 16:1ω7, 16:1ω9c, 15:0, and 11:0ω05, while the self-heated peat samples had relatively high proportions of the PLFAs 18:0, 16:1ω7-T3, 15:0, 17:0, and 17:1ω8 (Fig. 1B).

Effects on PLFA composition after autoclaving, gamma irradiation, and heating at 55 and 90°C. Autoclaving, gamma irradiation, and incubation at 90°C (for 3 days) reduced the amounts of totPLFA compared to those in unheated control samples (Table 2). Incubation at 90°C reduced totPLFA the most. Subsequent incubation at 55°C for 3 days did not alter the amounts of totPLFA. Only the 55°C incubation of unsterilized peat resulted in the production of T1, T2, and 18:1ω7-T3, indicating that microorganisms produced these PLFAs. These PLFAs were not found in the controls, except for T1 in the Bliksrud sample, which had previously been subjected to self-heating.

Incubation at 25, 35, 45, and 55°C for 4 days. Heating of the peat to 55°C caused a significant reduction (P < 0.05) in totPLFA compared to the 25°C treatment, while the 35°C treatment did not differ from the 25°C control (Fig. 2). A PCA showed that differences in the PLFA pattern between peat samples were found in the first component (38% of the variation accounted for) while the second component (22% of the variation) differentiated between the different temperature treatments (data not shown). The loading values for the second component showed that the separation of the high-temperature treatments was mainly due to an increase in the amounts of T1, T2, and 18:1ω7-T3. The increases in the amounts of the last two PLFAs were closely correlated. The relative concentrations of T2 and 18:1ω7-T3 were highest in the 55°C treatment, while T1 had the highest relative concentration in the 45°C treatment (Fig. 2). T1 and T2 were not detected in the peat incubated at 35°C, and 18:1ω7-T3 had not increased in this treatment compared to the 25°C control.

$^a$ Mean values ± standard error for three different peat samples (Bliksrud 3, Killingmo 2, and Komnes 2). Different capital letters indicate significant differences within rows (ANOVA, P < 0.05).
Short-term incubation at 55°C. During the 96-h incubation at 55°C, the amount of totPLFA decreased from around 600 to around 450 nmol g\(^{-1}\) (dry weight) of peat (data not shown). Therefore, the amounts of most of the PLFAs decreased during this time. However, after about 4 to 8 h, the relative concentrations of the PLFAs 18:1\(_ω\)-T3 and T2 started to increase (Fig. 3); they stabilized after approximately 40 h. T1 was detected only in the two last samplings and thus had a different time course (Fig. 3).

Long-term incubation at 55°C and reestablishment of mesophilic microorganisms after heating to 55°C. Peat samples were incubated at 55°C for 3 days and then at 25°C for up to 80 days. A PCA of the data showed that the changes in the PLFA pattern due to temperature alterations were similar in the different peat samples (Fig. 4A). The first principal component accounted for 26% of the variation in the data, and the second component accounted for 21%. The initial 55°C temperature treatment shifted the peat samples to the right in the PCA plot, while the subsequent incubation at 25°C shifted them to the lower left (indicated by arrows). The 55°C treatment was characterized by relatively large amounts of T2 and 18:1\(_ω\)-T3 (Fig. 4B). During the 25°C incubation, the amounts of these PLFAs decreased and those of i15:0, 16:1\(_ω\)-7c, cy17:0, and cy19:0 increased (Fig. 4B). However, the effect of the initial 55°C temperature treatment for 3 days was still evident, since the PLFA pattern was not restored even after 80 days at 25°C.

totPLFA decreased during the 80 days incubation at 55°C, from about 600 to around 300 nmol g\(^{-1}\) (dry weight) (Fig. 5A). When the peat incubation temperature was shifted from 55 to 25°C, totPLFA started to increase, irrespective of whether the temperature shift was made after 3 or 11 days at 55°C.

The relative concentration of the PLFA T1 increased with incubation time at 55°C, until T1 eventually became one of the dominant PLFAs (about 10 mol% of totPLFA) after 80 days (Fig. 5B). This was also found in a separate experiment, where the amount of T1 increased to 9.5% ± 0.1% (n = 2 peat samples) after 2 months of incubation at 55°C. The amount of T2 increased rapidly during the first 3 days and stabilized at 5 to 8% of totPLFA throughout the study period (Fig. 5C). The amount of 18:1\(_ω\)-T3 increased from 7 to over 30% by day 10 and remained stable at this level (Fig. 5D).

T1 and T2 were affected differently by the temperature shift to 25 after the 55°C incubation. The relative concentration of T2 started to decrease a few days after the transfer, after both 3 and 11 days at 55°C, eventually ending up at around 1% of totPLFA after 80 days of incubation at 25°C (Fig. 5C). The relative concentration of T1 still increased for several days.

FIG. 3. Moles percent of the PLFAs T1, T2, and 18:1\(_ω\)-T3 in peat samples incubated at 55°C. Results are the mean values of two peat samples (Killingmo 2 and Komnes 2). Standard errors are indicated by bars.

FIG. 4. PCA of the PLFA pattern of peat samples incubated at different temperatures. Gj, Gjødalsmosan; Kil, Killingmo; Kom, Komnes; Gr, Grenimosan. Bold abbreviations indicate peat incubated at 25°C for 3 days, 55 indicates peat incubated at 55°C for 3 days, and 25 indicates peat incubated at 55°C for 3 days followed by incubation at 25°C for 80 days (Gj 1 and Kil 2), 30 days (Kom 2), or 50 days (Gr 3). (A) Score plot of the different peat samples. (B) Loading plot of the individual PLFAs. The PLFAs T1, T2, and 18:1\(_ω\)-T3 are in bold.
after the temperature shift, but eventually the amount of T1 started to decrease (Fig. 5B). However, after about 80 days at 25°C, both T1 and T2 were detectable. The amount of PLFA 18:1ω7-T3 started to decrease when the temperature was lowered from 55 to 25°C (Fig. 5D), and after 80 days similar levels to those before the 55°C incubation treatment were found.

Two PLFAs, cy17:0 and cy19:0, showed different responses to temperature compared to T1, T2, and 18:1ω7-T3. The relative concentrations of these PLFAs decreased slowly in peat samples incubated at 55°C (Fig. 5E and F), but after the temperature shift to 25°C, both started to increase after a few days. In particular, cy17:0 became relatively more abundant than at the start of the experiment.

Effect of different incubation temperatures after a heating event on the stability of PLFAs. To simulate the effect of different temperatures during storage of peat after a heating event, samples were incubated for 3 days at 55°C and then transferred to different temperatures (5, 15, and 25°C). The amounts of the PLFAs T2 (Fig. 6A) and 18:1ω7-T3 (Fig. 6B) increased rapidly to around 6 and 30 mol% (of totPLFA), respectively, in the samples incubated at 55°C and then remained approximately stable for 40 days. After incubation at
lower temperatures, the amounts of both these PLFAs decreased. This decrease appeared most evident at 25°C, while the decrease at 5°C was much smaller. After 2 months at 25°C, the amount of T2 constituted less than 1 mol% of the totPLFA. No other PLFAs, except the ubiquitous 16:0 and 18:0, were detected. These PLFAs in peat samples with the gas chromatography (GC) setup used.

The lack of silver adducts showed that T1, T2, and T3 were saturated fatty acid methyl esters. They had 19, 20, and 18 carbons atoms, respectively, as indicated by high-resolution mass spectrometry (MS). The long GC retention times indicated a cyclic ring structure at the terminal end of the fatty acyl chain. The increased abundance, compared to normal acyl chains, of m/z 83, as well as 227 (M – 83; T2) and 199 (T3), indicated a terminal saturated hexyl ring. A standard preparation of fatty acids from *Alicyclobacillus* (courtesy of Karl Poralla, Tübingen University, Tübingen, Germany) showed that methyl ω-cyclohexyltridecanoate eluted with the same retention time as T2 and methyl ω-cyclohexylundecanoate eluted with the same retention time as T3. No standard was compared with T1. However, the presence of relatively high levels of m/z 97 and 199 (M – 97) suggest that T1 could be methyl ω-cycloheptylundecanoate. The mass spectrum was similar to those published for this compound (19).

**DISCUSSION**

The PLFAs T1 and T2 appeared to be good indicators of a previous period of high temperature in peat. They were never detected in unheated peat in our study, and PLFAs with similar retention times in the GC analyses were not found in natural peat samples (3, 23). These PLFAs have not been observed in a variety of soils (1, 2, 8), and they were not reported from different composts (6, 16).

The PLFAs T1 and T2 are most probably produced by two different organisms, since they did not have the same development pattern, with respect to both the effect of different incubation temperature on them (Fig. 2) and their growth pattern over time (Fig. 5B and C). T1 is probably produced by an organism with a lower temperature optimum for growth, since it was produced faster at 45°C than at 55°C, while the opposite was the case for T2 (Fig. 2). The organism producing T1 appeared to be able to grow slowly at 55°C (Fig. 5B) and could also present. On TSA, several branched PLFAs, like i15:0 and i17:0, were present in amounts equal to that of T2. There were also traces of a15:0, t16:0, and i17:0. Incubation at 45°C gave a similar PLFA pattern to that at 55°C. T1 was never found. No growth was detected at 25°C.

**GC-MS.** The methyl ester of the PLFA T1 had a relative retention time of 1.022 compared to that of the standard 19:0. The relative retention times for T2 and T3 were 1.067 and 0.912 (coeluting with 18:1o7), respectively. The mass spectrum of the methyl ester of T1 (measured on one heated peat sample) is characterized by major peaks at 55, 74, 97, 143, 199, 253, and 296, the last being the molecular weight (MW) of the methylated fatty acid. The mass spectra of the methyl ester of T2 (measured on two pure culture isolates and one heated peat sample) had major peaks at 55, 74, 83, 143, 199, 267, and 310 (the MW). The methyl ester of T3 (measured on two pure culture isolates) is characterized by major peaks at 55, 74, 83, 143, 199, 239, and 282. The MW, 282, was clearly different from that of 18:1o7 (MW, 296). In a heated peat sample, the 18:1o7-T3 peak had a mass spectrum with peaks at both 282 and 296, indicating that we could not separate these two PLFAs in peat samples with the gas chromatography (GC) setup used.
probably compete well with other organisms, since T1 became a dominant PLFA after prolonged incubations at 55°C.

The identification of T1 as an o-cyclohexyl and T2 and T3 as o-cyclohexyl fatty acids indicated that the microorganisms were members of the genus *Alicyclobacillus*, which is characterized by large amounts of these rare fatty acids (4, 10, 19). Among *Bacillus*-related genera, *Alicyclobacillus* is characterized as thermophilic, aerobic, heterotrophic, and preferring acid conditions (4, 5), which fits with the environmental conditions in heated peat.

Besides the production of specific PLFAs during heating, the turnover of these PLFAs under the following mesophilic conditions is of utmost importance if they are to be used as indicators of an earlier heating event. It is assumed that the decomposition of PLFAs is fast once the organisms die (15, 25). The initial decomposition of phospholipids involves the removal of the phosphate group by phosphatases. This alters the polar phospholipid into a neutral lipid, which is not included in the analysis. When mesophilic microorganisms were killed by heating in a compost, a fast turnover was found during the heating phase, with half-lives of some PLFAs of 1 day (16). A high temperature kills the mesophilic organisms, and the activity of enzymes decomposing the phospholipids is high. The situation is different when a temperature lower than the temperature permissible for growth is studied. A low temperature does not directly kill the organisms but just renders them inactive. Furthermore, once they have died, decomposition is slow due to low temperatures making enzymatic reactions proceed more slowly. This appeared to be the case in the compost study (16), where the PLFA 17:0 produced by thermophilic organisms had a half-life of 1 week when the temperature decreased to 30°C. In a recent study (6), PLFAs produced during the thermophilic phase could even be detected in 1-year-old composts.

In the present study, the amount of T2 decreased slowly when the peat samples were incubated at 25°C after 3 or 11 days at 55°C (Fig. 5C). Even after 3 months at 25°C, T2 was still detected, indicating a slow turnover. Similar results were found for T1 (Fig. 5B). In this case, the relative concentration of the PLFA did not decrease until after about 2 weeks, indicating that growth of the organism responsible for producing T1 was possible at 25°C.

When the temperature is lowered, the two processes (inactivation-death and decomposition) responsible for the disappearance of the PLFAs will have different influences on the PLFAs from thermophilic organisms. The lower the temperature, the more likely it is that a thermophilic organism will become dormant or die, since the selection pressure against thermophiles would increase as the temperature decreases. Thus, one would expect PLFAs from thermophilic organisms to disappear faster at lower temperatures than at temperatures close to the minimum for growth. This was the case with the thermophilic bacterial activity (measured as thymidine incorporation [21]). When peat samples were incubated at 55°C to favor thermophilic microorganisms and then shifted to 25, 15, or 5°C, the thermophilic bacterial activity disappeared immediately at 5°C, within 7 days at 15°C, and after 1 month at 25°C. The second process (the decomposition of the PLFAs), on the other hand, proceeds more slowly as the temperature is reduced. The decomposition of PLFAs indicative of thermophilic organisms appeared to be the most important factor, since both T2 and 18:1o7-T3 disappeared faster at 25 than at 5°C (Fig. 6). Therefore, the faster the temperature decreases and the lower it stays after a heating event, the more likely it is that T2 and T3 will be detected after a long storage period.

When mesophilic conditions (25°C) were restored after incubation at 55°C, mesophilic organisms started to grow and the amounts of PLFAs from these organisms increased. This was, for example, the case with cy17:0 and cy19:0 (Fig. 5E and F). Cyclopropane fatty acids are common in gram-negative bacteria (26), indicating that the proportion of gram-negative bacteria increased during the mesophilic conditions. This is also commonly found in composts after the heating phase (12, 16, 17). The increase in the numbers of gram-negative bacteria after the heating event is probably not only due to the mesophilic temperature conditions, but also due to fresh nutrients being released by the heat treatment (see Table 1). Gram-negative bacteria are known to thrive under conditions of ample nutrient supply, with high microbial activity, for example, occurring in the rhizosphere (14).

Low temperatures appeared to both preserve PLFAs characteristic for the thermophiles (T2 and 18:1o7-T3) and slow the recovery of PLFAs indicative of mesophiles. The former result has been discussed above. The reason for the latter is that mesophilic organisms have optimum temperatures for growth at 25 to 30°C. The recovery would be faster at temperatures around the optimum temperatures for growth than at lower temperatures. To be able to interpret the temporal changes in PLFA pattern under different temperature regimes, one has to take into account the fact that the effect of temperature on death and growth rate, as well as on the decomposition rate of PLFAs from dead organisms, is different for mesophilic and thermophilic organisms. Therefore, an interpretation of the temporal changes in PLFA pattern is difficult. The use of techniques that measure direct activity, like the thymidine incorporation technique (21), should be helpful in such interpretations, since these techniques are not dependent on the decomposition of a specific substance to measure a decrease in the amount of an organism group.

The production of T2 and T3 (the latter measured as an increase in the amount of 18:1o7-T3) was fast in heated peat, and maximum levels were found within 3 days at 55°C, when little or no T1 was detected (Fig. 2 and 3). In the self-heated peat, the relative concentration of T2 was mostly higher than the concentration of T1; only once was T1 detected in a sample where no T2 was found. This may indicate that the shift in temperature in the stockpiles during self-heating was fast, not permitting T1 to form in detectable amounts, or that the temperature became too high for the organism producing T1. This suggests that T2 or T3 might be the best PLFAs to use as characteristic for heated peat.

To use the PLFAs T1, T2, and T3 as indicators of previous self-heated peat, it will be important to determine whether the production of these PLFAs can be correlated with the production of compounds toxic to plant growth. If this is the case, it would be possible to use the presence of T2 and T3 to detect such peat samples. However, as stated above, the conditions after the heating event will affect the amounts of these PLFAs detected.
