Abstract

Treatment of injuries to major nerve trunks in the hand and upper extremity remains a major and challenging reconstructive problem. Such injuries may cause long lasting disabilities in terms of lost fine sensory and motor functions. Today there is no surgical repair technique that can ensure recovery of tactile discrimination in the hand of an adult patient following nerve repair while very young individuals usually regain a complete recovery of functional sensibility. Posttraumatic nerve regeneration is a complex biological process where the outcome depends on multiple biological and environmental factors such as survival of nerve cells, axonal regeneration rate, extent of axonal misdirection, type of injury, type of nerve, level of the lesion, age of the patient and compliance to training. A major problem is the cortical functional reorganisation of the hand representation which occurs as a result of axonal misdirection. Although protective sensibility usually can occur following nerve repair tactile discriminative functions seldom recover – a direct result of the cortical remapping. Sensory re-education programmes are routinely applied to facilitate understanding of the new sensory patterns provided by the hand. New trends in hand rehabilitation focus on modulation of central nervous processes rather than peripheral factors. In the initial phase following nerve injury and repair (phase 1) principles are being evolved to maintain the cortical hand representation by using the brain capacity for visuo-tactile and audio-tactile interaction. After reinnervation of the hand has started (phase 2), selective de-afferentiation, such as cutaneous anaesthesia of the forearm of the injured hand, allows expansion of the nerve injured cortical hand representation, thereby enhancing the effects of sensory relearning. Recent data support the view that training protocols specifically addressing the relearning process will substantially increase the possibilities for improved functional outcome after nerve repair.

Key words: Brain plasticity, cortical reorganisation, hand function, nerve regeneration, nerve repair

Peripheral nerve lesions remain serious conditions and are one of the most challenging surgical reconstructive problems, especially in the upper extremity and hand. Nerve injuries may seriously interfere with an individual's capacity to function adequately, and the acquired disability is often dramatic: a hand without sensibility is usually a hand without function. Most frequently nerve injuries are seen in the upper extremity of young males (McAllister *et al.* 1996, Noble *et al.* 1998), there is a high probability of work loss (Jaquet *et al.* 2001) and the quality of life for the patient may be greatly impaired. There is often lifelong hand function impairment, pain, dysaesthesia and cold intolerance. There is also a substantial economic impact of nerve injuries of the patient as well as society: the cost for an employed person in Sweden who has sustained a median nerve injury is more than 51,000 € (Rosberg *et al.* 2005).

Despite an enormous amount of new data and evolving new scientific concepts nerve injuries still belong to the most challenging and difficult surgical reconstructive problems. Today there is no surgical technique which can ensure recovery of tactile discrimination in the hand of an adult after a median nerve lesion. Thus, considering the impact of nerve injuries on quality of life as well as working capacity and economy there are good reasons to re-evaluate and revise some of the current principles for nerve repair.

The sensational hand

The human hand is not only a working tool but a delicate instrument of great importance for our daily activities and well-being. It's an organ that protects us by the sense of touch and one that makes our expression to the world heard via body language or via the art of painting or music. The hand has an enormous capacity to perceive, to execute and to express – simultaneously, in the explorative act of touch (Gibson 1962).

Besides the capacity for delicate motor functions the hand represents a sense organ with extremely well developed sensory functions. Besides protective sensibility the term *tactile gnosis* is often used to illustrate the specific aspects of functional sensibility representing the interplay between peripheral function of the nerve and the interpretation of sensory impressions in the somatosensory cortex of the brain (Moberg 1958). The discriminative touch, one aspect of tactile gnosis, is dependent on cutaneous mechanoreceptors in the hand sensitive to pressure, vibration and stretching. The physiology of function and distribution of the mechanoreceptors in the subepidermal, dermal and subcutaneous layers of the volar glabrous skin of the hand have been well defined and described in numerous investigations (Johansson & Vallbo 1983, Johansson & Vallbo 1979, Stark *et al.* 1998, Vallbo & Hagbarth 1968, Vallbo & Johansson 1984). This is a function that enables perception and localisation of touch, discrimination of touch and recognition of qualities and identification of objects without using vision. In this view the hand can be described as a sense organ, strongly linked to the brain (Lundborg 2003, Lundborg 2004, Wynn-Parry 1986). The well developed feedback system between the hand and the brain, with continuous proprioception and tactile input that are coordinated with memory systems in the brain, is a prerequisite for regulation of grip force and grip speed (Johansson 2002). The feedback from a functioning sense of touch is also essential for the body awareness (Ramachandran & Hirstein 1998). A nerve injury leaving the hand with impaired sensation will have a high impact on the patient's capacity to use the hand and there are not only medical disabilities but also a considerable social disability.

Regeneration and repair – physiological aspects

Restoration of motor and sensory functions in the hand after nerve repair is a complex process based on multilevel cellular, chemical and functional changes – from the fingertips to brain cortex (Lundborg 2004). Axonal outgrowth and orientation is dependent on complex

molecular mechanisms in the microenvironment with various types of mechanisms for axonal attraction or repulsion, stimulating or inhibiting the advancement of axons.

Following transection of a nerve the reactions at cell body level is a shift in metabolism from a mode of maintenance to a mode of growth expressed in structural and functional changes of the nerve cell bodies (Aldskogius & Arvidsson 1978, Dahlin *et al.* 1987, Grafstein 1975, Lieberman 1971). As a result of the axonal transection a large number of neurons die as a result of apoptosis. There may be a cellular loss of 20-50% of neurons in the dorsal root ganglia (Aldskogius & Arvidsson 1978, Liss *et al.* 1996, Ygge 1989) and also motor cells may die although to a lesser extent (Li *et al.* 1994, Novikov *et al.* 1995). Several factors may have an influence on the posttraumatic neuronal loss in the dorsal root ganglia such as age, time laps from injury to repair and proximity of injury. Immediate repair of a nerve may reduce the posttraumatic cell death (Ma *et al.* 2003).

A major problem is the axonal misdirection which, regardless of the repair technique, always occurs at the repair site so that sensory axons grow into motor Schwann cell and vice versa (DeFelipe & Jones 1991, Lundborg 2004, Ramon y Cajal 1928, Witzel *et al.* 2005). In the distal segment there is a wallerian degeneration and the Schwann cells start to proliferate and produce a number of various growth factors such as nerve growth factor (NGF) (Heumann 1987, Thoenen *et al.* 1988), ciliary neurotrophic factor (CNTF), brain derived neurotrophic factors (BDNF) and NT-3, NT-4/5 and NT-5-6 (Funakoshi *et al.* 1993, Lundborg 2004). Invading macrophages release interleukin-1 which triggers and increased NGF transcription and NGF receptor density in the Schwann cells (Heumann *et al.* 1991, Taniuchi *et al.* 1986). For details of the physiology of regeneration and the importance of growth factors see, for instance, Fu and Gordon (Fu & Gordon 1997), Terzis *et al.* (Terzis *et al.* 1997), Frostick and Kemp (Frostick & Kemp 1998), Yin *et al.* (Yin *et al.* 1998), McAllister *et al.* (McAllister *et al.* 1999),

Terenghi (Terenghi 1999), Lundborg (Lundborg 2000a, Lundborg 2004) and Dahlin (Dahlin 2004, Dahlin & Brandt 2004).

A crucial factor is the extent of “specificity” in axonal growth. The existence of “preferential motor regeneration” under strict laboratory conditions have been stressed by Brushart and co-workers (Brushart 1988, Brushart 1990, Brushart 1993, Brushart & Seiler 1987) implying that motor fibres preferentially innervates distal motor Schwann cell tubes in contrast to distal sensory Schwann cells. The bases for this has been suggested to be the presence of specific “recognition molecules” in motor Schwann cell tubes as opposed to sensory Schwann cell tubes (Kunemund *et al.* 1988). However, according to Maki and associates there is specificity in sensory regeneration but not in motor regeneration. According to Maki the outgrowth of Schwann cells in the distal nerve segment has an important role in this context. Although the issue of specificity in axonal regeneration is a crucial issue opinions vary regarding the expression of specificity in experimental regeneration models. It is not known if, or to what extent, specificity mechanisms are active in clinical situations.

Regeneration after nerve repair – clinical aspects

Repair of nerves was long regarded primarily as a technical problem and various techniques have been described to make the adaptation of nerve ends as accurate as possible. Following a nerve transection the surgeon can approximate and suture the two nerve ends by putting sutures in the outer nerve sheath (epineurium) or in deeper epineurial layers to adapt separately bundles of fascicles (Lundborg 2004). It may even be possible to suture separate fascicles individually. However, the surgeon can never address individual Schwann-cell tubes or axons. Thus, regardless how accurate the repair technique is, axonal misdirection is unavoidable and constitutes the base for cortical functional reorganisations when incorrect peripheral targets are reinnervated by regenerating axons (Witzel *et al.* 2005).

The classic technique is to suture only the external epineurium (Diao & Vannuyen 2000, Lundborg 2004, Rowshan *et al.* 2004, Trumble & McCallister 2000). Although the epineural repair gives a nice appearance of the suture site there may be dysalignment of the interior fascicles. An improved orientation of fascicles is achieved by the group fascicular repair technique where individual bundles of fascicles are repaired separately (Diao & Vannuyen 2000, Lundborg 2004, Rowshan *et al.* 2004). With this technique fascicular groups are carefully freed by dissection under high magnification, the epineurial tissues resected over a short distance from the cut nerve ends and the fascicular bundles are sutured individually. This technique gives an improved accuracy in fascicular orientation, but there is no evidence that this technique, in general, results in improved functional outcome as compared to the epineurial technique (Lundborg 2004).

Tubes of various types have been used for primary and secondary repair of nerves (Lundborg *et al.* 2004). Silicone tubes were used for primary repair of human median and ulnar nerves at wrist level by Lundborg and associates (Lundborg *et al.* 2004), and various types of tubes, resorbable and non-resorbable, have since been used in experimental animals and clinical praxis (Archibald *et al.* 1991, Archibald *et al.* 1995, Schlosshauer & Lietz 2004). Tube repair a short space, about 5 mm in length, is deliberately left between the nerve ends inside the tube. A gap is rapidly filled with fibrin and is thereafter invaded by microvessels, fibroblast, Schwann-cells and axons (Lundborg 2004).

Assessment of hand function after nerve repair

Assessment of hand function following nerve repair is not an easy task since several tests, addressing different aspects of hand function should be conducted. For appreciation of the overall function of the hand different measures are needed to quantify the outcome in a setting of modalities, such as sensibility, motor function, pain and discomfort (Jerosch-Herold 2005,

MacDermid 2005, Rosén 1996, Rosen & Lundborg 2003, Szabo 2001). Historically the most commonly used scale for assessment of sensory and motor functions of the hand is the MRC-scales (Medical Research Council & committee 1954). The sensory scale is however based on subjective findings, and thus it has psychometric drawbacks. Several attempts have been made to quantify the outcome over the years. The most recent is the *Model Instrument for Outcome After Nerve Repair* which is a model for routine documentation and quantification of the functional outcome after nerve repair at wrist or distal forearm level including sensory and motor function as well as problems from pain and discomfort in a summarised scoring-system (Rosén & Lundborg 2000). Specific sensibility tests can hierarchically be divided into detection tests, discrimination tests and identification tests (Fess 1990). Detection of a single stimulus is required, such as the light pressure from a filament. Most commonly Semmes-Weinstein monofilaments (SWM) or von Frey's hair (von Frey 1922) are used. Nylon filaments of different thickness are used and the test is performed in a standardised way where the subject indicates when touch by the filament can be felt. Thereby the smallest per touch/pressure can be defined (Bell-Krotoski 2002).

Various tests for tactile discrimination have been described. A commonly used test for discriminative capacity is a two-point discrimination (2PD) test which among surgeons and therapists are commonly used to assess functional hand sensibility. The classic static-two-point discrimination test was developed by Weber and popularised by Moberg (Moberg 1958, Moberg 1962). In this test one or two points are randomly applied to the tested skin area and the subject is asked whether one or two points are perceived. It is important that 2PD results always are accompanied by a detailed description as to how the test was performed since the amount of pressure towards the skin can influence the result considerably (Jerosch-Herold 2005, Lundborg & Rosen 2004).

The recently described STI-test (shape/texture-identification) is a standardised test based on active touch with identification of shapes and textures of increasing difficulty (Rosén & Lundborg 1998).

The model instrument (*Model Instrument for Outcome After Nerve Repair*) mentioned earlier, based on subjective as well as objective measures, focusing on the totality, take into account sensory, motor and pain/discomfort aspects. This model correlates well the patient's opinion of the impact of the nerve injury on activities of daily living (ADL) (Rosén & Lundborg 2000).

Factors influencing the outcome

The outcome from nerve repair is much dependent on prevailing conditions as well as the technique that is used. However, the outcome from peripheral nerve surgery varies considerably among patients, even when conditions as well as surgical techniques are virtually identical. Various factors are known to influence the outcome from nerve repair.

Age

Although the outcome from nerve repair is disappointing in adults (Allan 2000, Jerosch-Herold 1993, Jerosch-Herold 2000, Kallio & Vastamäki 1993, Rosén *et al.* 2000) it is well known that children usually achieve superior functional results (Lundborg & Rosen 2001). Although factors as generally shorter regeneration distance in children and that the regeneration capacity in general can be expected to be better, the better adaptability of the brain in children with a superior ability of central adaptation to the new pattern and afferent impulses presented by misdirected axons have usually been proposed as an explanation. There seems to be a critical age period for recovery of functional hand sensibility with the best results being seen in those younger than the age of 10 years, followed by rapid decline levelling out after late adolescence (Lundborg & Rosen 2001). Interestingly, there is a striking

analogy between this pattern and the pattern illustrating the scores of immigrants on a grammar test, plotted against the age at which they start to learn a new language (Lundborg 2004, Lundborg & Rosen 2001). Thus, the critical period for regaining discriminative tactile capacity after nerve repair is analogous to a corresponding critical period for acquisition of a second language, indicating a strong learning component in acquisition of functional sensibility as well.

Cognitive brain capacities

Specific cognitive capacities of the brain such as verbal learning capacity and visuo-spatial logic capacity can help to explain variations in the recovery of functional sensibility in adult after nerve repair (Rosén *et al.* 1994). Verbal learning capacity and visuo-spatial cognitive capacity have been shown to play a significant role for recovery of functional sensibility in median an ulnar nerve repair in adults.

Timing of repair

It is generally agreed that freshly transected nerves should be repaired acutely with no or minimal delay (Birch & Raji 1991, Diao & Vannuyen 2000, Lundborg 2004, Trumble & McCallister 2000). Early repair will substantially reduce the postoperative nerve cell death (Ma *et al.* 2003) and at this time nature landmarks such as epineurial blood vessels can still be used to ensure a correct matching of the nerve ends. With increasing preoperative delay the results become progressively worse as a result of fibrosis of the distal nerve segment, atrophy of Schwann-cells and progressive loss of neurons.

Type of nerve

The type of nerve that is injured considerably influences the outcome. If a pure motor nerve is injured the risk for mismatch between motor axons and sensory axons is eliminated thus

optimising the accuracy in reinnervation. For pure sensory nerves, such as a digital nerve the situation is analogous.

Level of injury

After nerve transection there is an initial delay followed by sprouting and axonal outgrowth. A nerve outgrowth rate of at most 1-2 mm per day in humans have been suggested as likely (Buchthal & Kühl 1979). In digital nerve injuries there is only a short distance separating the regenerating axons from their distal targets while injuries at upper arm level create different situations with longer time before regeneration of the hand occurs. Median nerve lesions at wrist level may require 3-4 months before the first signs of reinnervation in the hand occur.

Type of injury

A crush lesion always results in better functional outcome as compared to total severance of a nerve trunk (Lundborg 2004). The initial delay is shorter and the growth of axons proceeds as a faster rate after a crush injury as compared to a nerve transection. The Schwann-cell basal lamina are still in continuity and can thus guide the axons back to their original peripheral targets. The correct peripheral reinnervation of the crush injuries are reflected in a perfect restoration of the original cortical representational areas corresponding to the reinnervated body part (Merzenich & Jenkins 1993).

The role of the brain in nerve repair

Clinical experience show that the outcome from nerve repair in adults is often disappointing and far from satisfactory, especially with respect to recovery of tactile discrimination (Allan 2000, Jerosch-Herold 1993, Jerosch-Herold 2000, Kallio & Vastamäki 1993, Lundborg *et al.* 2004, Moberg 1991, Rosén 2000, Wynn-Parry 1986). Introduction of microsurgery and refined surgical repair techniques have not led to dramatically improved results (Lundborg

2000b, Lundborg 2003, Lundborg 2004). Thus, there are good reasons to look for explanatory factors in the central nervous system in addition to the cellular and biochemical events which are associated with degeneration and regeneration in the peripheral nervous system. A nerve injury in the upper extremity is followed by profound functional reorganisational changes in brain cortex, mainly due to misdirection of regenerating axons. A major component in rehabilitation after nerve injury should therefore be to focus on the relearning process which is required to learn the “new language spoken by the hand”.

What happens in the brain after nerve injury and repair?

A nerve injury in the hand or arm represents a sudden de-afferentiation with immediate and longstanding influence on the cortical hand representation as well as the representation of adjacent cortical territories (Chen *et al.* 2002, Kaas *et al.* 1983, Merzenich *et al.* 1983, Wall *et al.* 1986, Wall *et al.* 2002). After a median nerve transection there is a silent “black hole” in the somatosensory brain cortex corresponding to the median nerve projectional areas.

Rapidly, adjacent cortical areas expand and occupy the former median nerve territory (Merzenich *et al.* 1983, Silva *et al.* 1996). These changes which happen within minutes are probably based on unmasking of normally occurring but inhibited synaptic connections. They will last over the initial post injury period before regenerating axons have reached the hand. During this period the hand is without sensation and there is no sensory input from median innervated areas. In the following text this period will be named *phase 1*.

Although our microsurgical nerve repair techniques have been refined to an optimal level there is still a great extent of misorientation of regenerating axons at the repair site. Thus, the skin areas of the hand will, to a large extent, not be reinnervated by their *original* axons. Instead they may be reinnervated by axons originally innervating other parts of the hand. The result is significant reorganisational changes in the cortical territory where the median nerve

is normally represented. The originally well-organised hand representation is changed to a mosaic-like pattern (Florence *et al.* 1994, Jain *et al.* 1998, Kaas & Florence 1997, Wall *et al.* 1986) and the median nerve does not recapture all of original territory. The former well defined individual cortical representation of separate fingers disappears and changes into distorted discontinuous islands. Surfaces of the skin with normally well-defined cortical representations such as the thumb, a segment of a finger, or a palmar pad, now become represented across multiple cortical patch-like areas, sometimes overlapping (Lundborg 2004, Wall *et al.* 1986). This knowledge is based primarily on primate experiments, but analogous findings have been made also in humans on basis of fMRI techniques (Hansson & Brismar 2003). In the following text this period, representing beginning reinnervation of the hand, is named *phase 2*. After a median nerve injury at wrist level the phase 2 usually begins 3-4 months after nerve repair.

Sensory re-education and sensory relearning – current concepts

Following nerve injury and repair a relearning process is required for recovery of functional sensibility. Due to misdirection of axons and the consequence remapping of the cortical hand representation “the hand speaks a new language to the brain” (Dellon 1981, Dellon *et al.* 1974, Lundborg 2004, Wynn-Parry & Salter 1976). This new language has to be interpreted by the brain, a process which can be achieved by sensory relearning through sensory re-educational programs. It is not known how such programs influence the functional cortical organisation (Florence *et al.* 2001). The functional improvement seen after training may be based either on normalisation of the distorted hand map or it can be due to adaptations in higher brain centres with a capacity to decipher the distorted hand map.

Learning is a key word in the rehabilitation process after all injuries. New sensory and motor codes are presented to the brain that has to cope with this for purposeful sensory-motor interaction and functional use. The extensive cortical reorganisational changes which occur

after nerve repair requires a relearning process in order to adapt to the new and distorted afferent sensory input when familiar objects are touched – the mind does not understand the new “sensory code” associated with specific textures and shapes. To facilitate and enhance this process, specific programs for sensory re-education are routinely used in adult patients for regaining tactile gnosis, starting once touch can be perceived (Callahan 1995, Dellon 1997, Dellon 1981, Dellon *et al.* 1974, Rosén 2003, Wynn-Parry & Salter 1976). According to these strategies, the brain is reprogrammed on the basis of a relearning process (Lundborg 2004). First, the perception of different *touch modalities* and the capacity to *localise touch* is trained, followed by touching and exploration of items, presenting *shapes and textures* of varying and increasing difficulty with the eyes open and closed. In this way an alternate sense (vision) assists the training and improves the deficient sense (sensation).

However, the sensory re-education programs that are used today were designed in the 1970s and 1980s and have not been changed much since then. They do not have a solid scientific base and are not updated in view of evolving concepts of learning mechanisms, cortical remodelling and brain plasticity. They are not taking into account the time factor in view of the rapid cortical reorganisational changes which follow a changed sensory input (Rosén 2003, Rosen & Lundborg 2004).

New strategies in sensory re-education and sensory relearning

According to routine sensory re-education protocols the sensory training starts at first in *phase 2*, that is when beginning reinnervation of the hand has started and when the cortical reorganisational changes resulting from the nerve injury are well manifested. The cortical hand representation has since long disappeared and is occupied by expanding adjacent cortical areas. In our current and evolving protocols for sensory re-education we focus on the *timing*

of initiation of the training program with emphasis on new training concepts not only in *phase 2* but also in *phase 1*, i.e. early after nerve injury and repair, long before hand reinnervation has started. The strategy is to activate the cortical area representing the damaged nerve, hereby diminishing the cortical reorganisation aiming at a maintenance of the cortical representation of the denervated body part.

Phase one

Maintaining the cortical hand map

Background

Nerve transection results in a rapid disappearance of the corresponding cortical representation. For instance, a combined median and ulnar nerve injury is followed by disappearance of the cortical hand representation followed by a rapid expansion of the adjacent cortical hand territories. In our treatment regimen in *phase 1*, we focus on maintaining the cortical hand representation by using the brains capacity for *visuo-tactile and audio-tactile interaction*. Activation of motor neurons – “mirror neurons” in premotor cortex by the mere observation of hand motor actions is a well known phenomenon which is believed to play a fundamental role in both action and understanding and imitation (Rizzolatti & Craighero 2004, Rizzolatti *et al.* 2001). Activation of somatosensory cortex by visual observation of touch has been demonstrated with reference to the lower extremity (Keysers *et al.* 2004) and does occur also with observation of a hand being touched (Avikainen *et al.* 2002, Grezes *et al.* 2003, Hansson *et al.* 2005). Premotor cortex may be activated also by reading or listening to action or words (Hauk *et al.* 2004). It is well known that the brain has a multimodal capacity meaning that specific neurons and association cortical areas respond to stimuli provided by touch as well as vision and hearing (Bavelier & Neville 2002). In analogy, an interesting principle is activation of somatosensory cortex by listening to the

friction sound of a hand being touched or a hand touching various textures (Lundborg & Rosen 2003, Lundborg *et al.* 2005).

Training concepts (phase one)

- *Visuo-tactile interaction and mirror training*

The patient's observation of his hand being touched by the therapist is an important component of early sensory training which might activate the cortical hand area due to visuo-tactile interaction. The effect can be further enhanced by using mirror training. We use a mirror placed transversally in front of the patient with the nerve injured hand hidden behind the mirror, the healthy hand being reflected in the position of the injured hand (Ramachandran *et al.* 1995, Ramachandran & Hirstein 1998). Touching the healthy hand gives an illusion of touching the nerve-injured hand. In these training sessions the patient often gets a perception of the tactile stimuli in the nerve-injured non-sensate hand by the combined mirror illusion and the true touch of the healthy hand.

- *Audio-tactile interaction and the use of Sensor Glove*

We use a Sensor Glove System with microphones mounted dorsally at fingertip levels in a glove connected to earphones – via a miniature stereo processor. With this system “the patients can listen to what the hand feels”. Thus, auditory stimuli substitute for absent tactile stimuli – specific and typical friction sounds are associated with touching of various textures.

In a clinical randomised prospective study run at five hand centres in Sweden patients with median nerve injuries were randomised either to a group using the Sensor Glove from the first postoperative day or a group not using the glove but subjected to routine sensory re-educational programs. Preliminary results, obtained from one year follow-up shows that tactile discrimination, as assessed in the STI-test and hand dexterity,

assessed by the Sollerman-test showed a significantly better recovery in the group using the Sensor Glove (Lundborg & Rosen 2003, Rosen & Lundborg 2003).

Phase two

Enhancing the effects of sensory re-education

Background

The brain's capacity for rapid redistribution of cortical resources as a component of brain plasticity has been well described in the literature in rehabilitation of stroke patients. For instance, it has been shown that selective anaesthesia of ventral roots of C5-C8 (motor innervation of shoulder and elbow) results in enhanced motor function of the hand (innervation C8-C11 (Muellbacher *et al.* 2002)). The mechanism is that de-afferentiation of specific cortical area (shoulder and elbow representations) allows expansion of adjacent cortical representational areas (the hand). In analogy cutaneous de-afferentiation of the forearm would hypothetically result in expansion of the adjacent cortical hand representation.

Training concepts (phase two)

Cutaneous de-afferentation of the forearm

- In our treatment regime we perform anaesthesia of the forearm proximally to the nerve injured hand with the purpose of allowing expansion of the cortical hand representation. Cutaneous anaesthesia of the volar part of the forearm is induced by EMLA-crème twice a week for two weeks. This is combined with intense classic sensory training. In a double blind, randomised clinical study on patients treated for median or ulnar nerve injuries the EMLA-group showed a significantly improved tactile discrimination as compared to the control group (Rosén *et al.* 2005), subjected to sensory training only, when assessed at two and four weeks after the last EMLA-treatment.

Functional outcome after nerve repair

Following nerve repair at distal forearm level of major nerve trunks the fingers may be without sensibility for up to six months before reinnervation at finger level occurs. Using the diagnosis specific outcome instrument *Model Instrument for Outcome after Nerve Repair* (Rosén & Lundborg 2001), a reference interval for the outcome with the estimated 95% predicted values for the outcome show ongoing improvements up to five years after the nerve repair.

In spite of the use of microsurgical techniques for nerve repair median, ulnar or combined injuries lead to long lasting disabilities in terms of lost fine sensory and motor functions, and in addition pain and discomfort from hyperaesthesia and cold intolerance that can be very problematic with large impact on activities of daily living (ADL) (Carlsson *et al.* 2003, Jaquet *et al.* 2001, Rosén 1996). The individuals' ability to experience and interact with the surrounding world is hereby disturbed.

Five years following surgery a mean Functional Symptom Score of 19 (0=no disability, 100=max disability) on the DASH (Disability of the Arm Shoulder and Hand) questionnaire has been reported (Jaquet 2004). In a recent Dutch study 59% of patients with median or ulnar nerve repairs returned to work within one year with an average time off work of 31 weeks (Jaquet 2004). Substantial costs for the society are also generated in terms of sick leave. A mean cost of 51000 Euro for a median nerve repair has been calculated (Rosberg *et al.* 2005).

In addition to the large number of peripheral and central factors including active and conscious use of the hand in activities of daily life, combined with high motivation by the patient, is since long reported to be a factor of great importance for useful return of functional sensibility (Callahan 1995). Bruyns *et al.* found that high education, high compliance to hand therapy and an isolated injury predict quicker return to work in patients with median and/or

ulnar nerve injuries (Bruyns *et al.* 2003). A recent meta-analysis showed that age, site, injured nerve and delay significantly influence the prognosis after nerve repair (Ruijs *et al.* 2005).

The surgeon's ambition is to use repair techniques, which brings a maximal number of nerve fibres into peripheral cutaneous territories. There are however at least three strong indications that *central nervous factors* associated with cortical re-modelling represent a major reason for the inferior functional outcome following nerve repair: 1) children up to the age of 10-12 usually present excellent recovery of functional sensibility in contrast to adult patients. This critical "age-window" for perfect sensory recovery presented by children corresponds well to what is known from other types of learning processes, for instance the ability for acquisition of a second language (Lundborg & Rosen 2001); 2) cognitive functions are important explanatory factors in adults for variations in recovery of tactile discrimination (Jaquet 2004, Rosén *et al.* 1994); 3) The peripheral repair technique in median nerve lesions has not been found to influence the functional outcome in a clinical randomised study at a five year follow-up (Lundborg *et al.* 2004). Silicone tubular repair, leaving a short distance between the nerve cuts, was compared with the outcome from routine microsurgical repair in a clinical randomised prospective study, comprising 30 patients with median or ulnar nerve injuries in the distal forearm. Postoperatively, the patients were assessed regularly over a 5-year period with neurophysiological and clinical assessments. After 5 years there was no significant difference in outcome between the two techniques except that cold intolerance was significantly less severe with the tubular technique. The most significant improvement of perception of touch occurred during the first postoperative year, while improvement of motor function could be observed much later (Rosén *et al.* 2000). In the total group there was however an ongoing improvement of functional sensibility throughout the 5 years after repair although there was no further impairment in nerve conduction velocity or amplitude after the two first years (Lundborg *et al.* 2004). This supports that the central nervous factors

associated with the cortical remodelling after a nerve repair are important, and that efforts to improve the results from nerve repair in the future must address the brain as well as the peripheral nerve.
