A Comprehensive Model for Ultrawideband Propagation Channels

Andreas F. Molisch, Fellow, IEEE, Kannan Balakrishnan, Member, IEEE Dajana Cassioli, Member, IEEE, Chia-Chin Chong, Member, IEEE Shahriar Emami, Senior Member, IEEE, Andrew Fort, Member, IEEE Johan Karedal, Student Member, IEEE Juergen Kunisch, Member, IEEE, Hans Schantz, Member, IEEE, and Kazimierz Siwiak, Senior Member, IEEE

Abstract— This paper describes a comprehensive statistical model for UWB propagation channels that is valid for a frequency range from 3-10 GHz. It is based on measurements and simulations in the following environments: residential indoor, office indoor, built-up outdoor, industrial indoor, farm environments, and body area networks. The model is independent of the used antennas. It includes the frequency dependence of the pathloss, as well as several generalizations of the Saleh-Valenzuela model, like mixed Poisson times of arrival and delay dependent cluster decay constants. The model can thus be used for realistic performance assessment of UWB systems. It was accepted by the IEEE 802.15.4a working group (WG) as standard model for evaluation of UWB system proposals.

I. INTRODUCTION

Ultrawideband (UWB) communications systems have many attractive properties, including low interference to and from other wireless systems, low sensitivity to fading, easier wall-and floor penetration, and inherent security [1], [2], [3]. UWB communications originally started with the spark-gap transmitter of Hertz and Marconi. However, it was not until the 1990s that the interest was renewed. The pioneering work in [4], [5], [6], [7] developed the concept of time-hopping impulse radio (TH-IR) systems. In 2002, the frequency regulator in the USA allowed unlicensed UWB transmission (subject to the fulfillment of a spectral mask), and other countries are expected to follow suit. One of the most promising applications for UWB are sensor networks, where the good ranging and geolocation capabilities of UWB [8] are particularly useful. The data rates for those applications are typically low (<1 Mbit/s). Recognizing these developments the IEEE has established the standardization group 802.15.4a, which is currently in the process of developing a standard for these applications.

The ultimate performance limits of any communications system are determined by the channel it operates in. For a UWB system, this is the UWB propagation channel, which differs from conventional (narrowband) propagation in many respects. The performance of a system thus can only be evaluated when realistic channel models are available. A considerable number of papers has been published on the measurement and modeling for specific environments (see [11] for an overview), but none of them has gained widespread acceptance for system testing purposes.

In the present paper, we present a general model for UWB channels that is valid for the high-frequency range (3 – 10 GHz) in a number of different environments, based on measurements and simulations of the authors [12], [13], [14], [15] and other papers in the open literature. The model has been developed by the authors during their work for the 802.15.4a group, and was accepted by that body as the official model for comparing different system proposals for standardization. The value of the present paper is thus twofold:

• It represents a model for UWB channels that is accepted by an official standardization body for the purpose of selecting among physical layer proposals, and is available for large number of environments.
• It includes a number of refinements and improvements beyond what the authors and others had previously presented in the literature, specifically:
  - frequency dependence of the pathloss, and thus implicitly the distortions of each separate multipath component (MPCs);
  - modeling of the number of clusters of multipath components in the Saleh-Valenzuela model as a random variable;
  - a power delay profile that models a "soft" onset, so that the first arriving paths can be considerably weaker than later MPCs; this is critical for accurate assessment of ranging capabilities of UWB;
  - a new model for body area networks that includes correlated lognormal shadowing.

The remainder of the paper is organized as follows: in Sec. II, we present the generic channel model structure, especially discussing the refinements compared to previous literature. Section III describes the actual parameterization in different environments, while Sec. IV concentrates on the channel model for body area networks, which has a slightly different underlying structure. Section V shows some example results for power delay profiles and other parameters characterizing the delay dispersion. A summary concludes the paper.
II. GENERIC CHANNEL MODEL

A. Environments

The following environments have the most importance for sensor network applications, and are the ones for which the model is parameterized

1) Indoor residential: these environments are critical for "home networking", linking different appliances, as well as safety (fire, smoke) sensors over a relatively small area. The building structures of residential environments are characterized by small units, with indoor walls of reasonable thickness.

2) Indoor office: some of the rooms are comparable in size to residential, but other rooms (especially cubicule areas, laboratories, etc.) are considerably larger. Areas with many small offices are typically linked by long corridors. Each of the offices typically contains furniture, bookshelves on the walls, etc., which adds to the attenuation given by the (often thin) office partitionings.

3) Outdoor: while a large number of different outdoor scenarios exist, the current model covers only a suburban-like microcell scenario, with a rather small range. Many small obstacles (silos, animal pens), with large distances in between, are present. The delay spread can thus be anticipated to be smaller than in other environments.

4) Industrial environments: are characterized by larger enclosures (factory halls), filled with a large number of metallic reflectors. This is anticipated to lead to severe multipath.

5) Agricultural areas/farms: for those areas, few propagation obstacles (silos, animal pens), with large distances in between, are present. The delay spread can thus be anticipated to be smaller than in other environments.

6) Body-area network (BAN): communication between devices located on the body, e.g., for medical sensor communications, "wearable" cellphones, etc.

The measurements and simulations that form the basis of the model in the different environments cover different frequency ranges. For the use within the IEEE standardization, they are defined to be used for the whole 2 – 10 GHz range. However, from a scientific point of view, they should only be used in the frequency range for which the underlying measurements are valid; those frequency ranges are specified in Sec. III. A similar statement is true for the distance between transmitter (TX) and receiver (RX) over which the model should be used.

B. Pathgain

We define the frequency-dependent path gain (related to wideband path gain [16], [17]) in a UWB channel as

\[ G(f, d) = E \left\{ \int_{f - \Delta f/2}^{f + \Delta f/2} |H(f, d)|^2 df \right\} \]

(1)

where \( H(f, d) \) is the transfer function from antenna connector to antenna connector, \( \Delta f \) is chosen small enough so that diffraction coefficients, dielectric constants, etc., can be considered constant within that bandwidth, \( d \) is the distance between transmitter and receiver, and the expectation \( E \{ \} \) is taken over the small-scale and large-scale fading.

To simplify computations, we assume that the path gain as a function of the distance and frequency can be written as a product of the terms

\[ G(f, d) = G(f)G(d). \]

(2)

The frequency dependence of the channel path gain is modeled as [18], [19]

\[ \sqrt{G(f)} \propto f^{-n} \]

(3)

The distance dependence of the path gain in dB is described by the conventional power law

\[ G(d) = G_0 - 10n \log_{10} \left( \frac{d}{d_0} \right) \]

(4)

where the reference distance \( d_0 \) is set to 1 m, \( G_0 \) is the path gain at the reference distance. The path gain exponent \( n \) depends on whether a line-of-sight (LOS) connection exists between the transmitter and receiver or not.

The path gain also depends on the antenna gains and efficiencies. Since these also contain a frequency dependence, the following equation is used for computing the total received power (this includes several simplifications and assumptions not reproduced here for space reasons - for details see [20]):

\[ G(f) = \frac{1}{2} G_0(TX-ant)(f) G_0(RX-ant)(f) \left( \frac{f/f_c}{1-2(n+1)} \right)^{-2(n+1)}(d/d_0)^n. \]

(5)

The total path gain shows random variations (due to shadowing), which are lognormally distributed, so that Eq. (4) is replaced by

\[ G(d) = G_0 - 10n \log_{10} \left( \frac{d}{d_0} \right) + S \]

(6)

where \( S \) is a Gaussian-distributed random variable with zero mean and standard deviation \( \sigma_S \).

C. Power delay profile (PDP)

The impulse response (in complex baseband) of the SV (Saleh-Valenzuela) model is given in general as [21]

\[ h_{\text{discr}}(t) = \sum_{l=0}^{L} \sum_{k=0}^{K} a_{k,l} \exp(i\phi_{k,l}) \delta(t - T_l - \tau_{k,l}), \]

(7)

where \( a_{k,l} \) is the tap weight of the \( k^{th} \) component in the \( l^{th} \) cluster, \( T_l \) is the delay of the \( l^{th} \) cluster, \( \tau_{k,l} \) is the delay of the \( k^{th} \) MPC relative to the \( l^{th} \) cluster arrival time \( T_l \). The phases \( \phi_{k,l} \) are uniformly distributed, i.e., for a bandpass system, the phase is taken as a uniformly distributed random variable from the range [0,2\pi]. Deviating from the standard SV model, he number of clusters \( L \) is modeled as Poisson-distributed with probability density function (pdf)

\[ \text{pdf}_L(L) = \frac{(L)^L \exp(-L)}{L!} \]

(8)

1For the simulations within the 802.15.4a standardization, the shadowing is not to be taken into account.
so that the mean $T$ completely characterizes the distribution. This modification gave better agreement with some of the experimental results used in this study.

By definition, we have $\tau_{0,l} = 0$. The distributions of the cluster arrival times are given by a Poisson process

$$p(T_l|T_{l-1}) = \lambda_l \exp[-\lambda_l (T_l - T_{l-1})], \ l > 0$$

(9)

where $\lambda_l$ is the cluster arrival rate (assumed to be independent of $l$). The classical SV model also uses a Poisson process for the ray arrival times. Due to the discrepancy in the fitting for the indoor residential, indoor office, and outdoor environments, we propose to model ray arrival times with mixtures of two Poisson processes as follows

$$p(\tau_{k,l}|\tau_{k-1,l}) = \beta \lambda_1 \exp[-\lambda_1 (\tau_{k,l} - \tau_{k-1,l})] + (\beta - 1) \lambda_2 \exp[-\lambda_2 (\tau_{k,l} - \tau_{k-1,l})], \ k > 0$$

(10)

where $\beta$ is the mixture probability, while $\lambda_1$ and $\lambda_2$ are the ray arrival rates.

For some environments, most notably the industrial environment, a "dense" arrival of multipath components was observed, i.e., each resolvable delay bin contains significant energy. In that case, the concept of ray arrival rates loses its meaning, and a realization of the impulse response based on a tapped delay line model with regular tap spacings is to be used.

The next step is the determination of the cluster powers and cluster shapes. The PDP (mean power of the different paths) is exponential within each cluster

$$E[|a_{k,l}|^2] \propto \Omega_l \exp(-\tau_{k,l}/\gamma_l)$$

(11)

where $\Omega_l$ is the integrated energy of the $l$th cluster, and $\gamma_l$ is the intra-cluster decay time constant.

The cluster decay rates are found to depend linearly on the arrival time of the cluster,

$$\gamma_l \propto k_{\gamma} T_l + \gamma_0$$

(12)

where $k_{\gamma}$ describes the increase of the decay constant with delay.

The mean (over the cluster shadowing) mean (over the small-scale fading) energy (normalized to $\gamma_l$) is the intra-cluster shadowing. In general an exponential decay

$$10 \log(\Omega_l) = 10 \log(\exp(-T_l/\Gamma)) + M_{\text{cluster}}$$

(13)

where $M_{\text{cluster}}$ is a normally distributed variable with standard deviation $\sigma_{\text{cluster}}$.

For the NLOS case of some environments (office and industrial), the shape of the power delay profile can be different, namely (on a log-linear scale)

$$E[|a_{k,l}|^2] \propto (1 - \chi \cdot \exp(-\tau_{k,l}/\gamma_{\text{rise}})) \cdot \exp(-\tau_{k,l}/\gamma_1)$$

(14)

Here, the parameter $\chi$ describes the attenuation of the first component, the parameter $\gamma_{\text{rise}}$ determines how fast the PDP increases to its local maximum, and $\gamma_1$ determines the decay at later times.

D. Small-scale fading

The distribution of the small-scale amplitudes is Nakagami

$$p(x) = \frac{2}{\Gamma(m)} \frac{m^m}{\Omega^m} x^{2m-1} \exp\left(-\frac{m}{\Omega} x^2\right),$$

(15)

where $m \geq 1/2$ is the Nakagami m-factor, $\Gamma(m)$ is the gamma function, and $\Omega$ is the mean-square value of the amplitude. A conversion to a Rice distribution is approximately possible [22]. The $m$ parameter is modeled as a lognormally distributed random variable, whose logarithm has a mean $m_0$ and standard deviation $\sigma_{m_0}$. For the first component of each cluster, the Nakagami factor is modeled differently. It is assumed to be deterministic and independent of delay

$$m = \bar{m}_0$$

(16)
A uniformly distributed phase is ascribed to all MPCs. Note that this passband representation is different from both [10] and [9], which used a (real) baseband model.

### III. Model Parameterization

The parameters of the model are extracted by fitting measurement data to the model described in Sec. II.2 The model for residential environments was extracted based on measurements that cover a range from 7 – 20 m, up to 10 GHz [13]. For office environments, the model was based on measurements that cover a range from 3 – 28 m, 2 – 8 GHz [14]. For outdoor, the measurements cover a range from 5 – 17 m, 3 – 6 GHz [15]. The derivation of the model and a description of the simulations (for the farm area) can be found in [23]. The model for industrial environments was extracted based on measurements [12] that cover a frequency range from 3 – 10 GHz and a distance range from 2 – 8 m, though the pathloss also relies on values from the literature [26].

From a scientific point of view, the parameterization is valid only for the range over which measurement data are available. Note, however, that for the comparison purposes within the IEEE 802.15.4a standardization group, the parameterization is used for the whole 2 – 10 GHz range, and also for all distances of interest.

### IV. Body Area Network

Section II presented a generic channel model representing typical indoor and outdoor environments for evaluating 802.15.4a systems. However, simulations and measurements of the radio channel around the human body indicate that some modifications are necessary to accurately model a body area network (BAN) scenario. Due to the extreme close range and the fact that the antennas are worn on the body, the BAN channel model has different path loss, amplitude distribution, clustering, and inter-arrival time characteristics compared with the other application scenarios within the 802.15.4a context.

Analysis of the electromagnetic field near the body using a finite difference time domain (FDTD) simulator indicated that in the 2 – 6 GHz range, no energy is penetrating through the body. Rather, pulses transmitted from an antenna diffract around the body and can reflect off of arms and shoulders. Thus, distances between the transmitter and receiver in our path loss model are defined as the distance around the perimeter of the body, rather than the straight-line distance through the body. The amplitude distributions measured near the body are also different: the lognormal distribution turned out to be best. In addition, the uncorrelated scattering assumption is violated for systems where both the transmitter and receiver are placed on the same body. Our simulations and measurements in an anechoic chamber indicate that there are always two clusters of multi path components due to the initial wave diffracting around the body, and a reflection off of the ground (more clusters could occur in an indoor environment due to reflections from walls etc., but this is not included in the model). Thus, the number of clusters is always 2 and does not need to be defined as a stochastic process as in the other scenarios. Furthermore, the inter-cluster arrival times are also deterministic and depend on the exact position of the transmitters on the body. To simplify this, we have assumed a fixed average inter-cluster arrival time depending on
Implementing this model on a computer involves generating \( N \) correlated lognormal variables representing the \( N \) different bins, and then applying an appropriate path loss based on the distance between the antennas around the body. This can be accomplished by generating \( N \) correlated normal variables, adding the pathloss, and then converting from a dB to linear scale as follows:

\[
Y_{\text{dB}} = X \cdot \text{chol}(C) - M - G_{\text{dB}}
\]

(17)

\( X \) is a vector of \( N \) uncorrelated, unit-mean, unit-variance, normal variables. To introduce the appropriate variances and cross-correlation coefficients, this vector is multiplied by the upper triangular cholesky factorization of the desired covariance matrix \( C \). The means (a vector \( M \)) of each different bin and the large scale path loss (\( P_{\text{dB}} \)) are subtracted.

The path gain can be calculated according to the following formula:

\[
G_{\text{dB}} = -\gamma(d - d_0) + G_{0,\text{dB}}
\]

(18)

with \( \gamma \) in units of dB/meter. The parameters of this path loss model extracted from the simulator and measurements are summarized in Table I. The means and variances of the lognormal distribution describing the amplitude distributions of each bin are given in Table I; the covariance matrices \( C \) are not reproduced here for space reasons; they can be found in [20].

The parameterized channel models can be used to generate ensembles of impulse responses, which in turn are employed to test the performance of different UWB transceiver structures. In the following, we present some example realizations, as well as parameters that allow insight into the effects of the impulse response on Rake receivers, which are used for combining different MPCs in both impulse-radio based systems and direct-sequence spread spectrum systems.

The impulse responses in different environments have some noticeable differences between them. Figure 1 depicts a typical impulse response in a residential NLOS environment in Fig. 2. In this example, we first observe that the first arriving MPC is strongly attenuated, and the maximum in the instantaneous power delay profile \( |h(\tau)|^2 \) occurs only after about 50 ns. This is especially significant for ranging geolocation applications, since the ranging requires the detection of the first path, not of the strongest path. Detection of such a weak component in a noisy environment can be quite challenging.

A key parameter for Rake receivers is the number of "significant" MPCs. By this, we mean the number of MPCs that are

\begin{table}[h]
\centering

\hline
\( \gamma \) & 107.8 dB/m \\
\hline
\( d_0 \) & 0.1 m \\
\hline
\( G_0 \) & -35.5 dB \\
\hline
\end{tabular}
\caption{Pathloss model for BAN.}
\end{table}
within a certain dynamic range (e.g., 10 dB) of the strongest path in CM1 (residential LOS) and CM6 (outdoor NLOS). The above figures are only a small sample of the results that can be obtained with this channel model. Extensive simulations of some 20 different systems have been performed as part of the IEEE 802.15.4a standardization activities.

VI. SUMMARY AND CONCLUSIONS

We have presented a comprehensive model for UWB propagation channels that was accepted as standardized model by IEEE 802.15.4a. The model is based on a large number of measurement and simulation campaigns, and includes the most important propagation effects in UWB channels, including the frequency selectivity of the pathloss, stochastic interarrival times of the MPCs, and a soft onset of the power delay profile in some NLOS situations. The model allows to test a wide variety of UWB transceivers in a unified and reproducible way.
