ABSTRACT
In making capacity estimates and cost calculations in the manufacturing industry, many products and production systems are often involved, making the data in their totality difficult to grasp. Introducing the concept of the characteristic part, which is a fabricated part seen as representative of all parts produced in terms of demand, setup time, cycle time, average batch size and total number of batches involved, makes the calculations required much more manageable and much less time-consuming. The article takes up how the characteristic part is defined and how it can be used in calculating production capacity, system utilization and manufacturing costs.

Keywords: characteristic part, manufacturing cost, degree of occupancy, production capacity, production relocation, group technology.

1. INTRODUCTION
In today’s manufacturing system, companies often produce a large variety of products, making visualization and planning difficult. This article addresses the possibility to plan the manufacture design and do cost calculation on one or a few parts representing the whole production system regarding setup time, cycle time, average batch size, total number of batches involved and losses in performance. The part used is called a characteristic part and is a fictive part composed by the production parameters from the products produced in the actual manufacturing system.

It is common in the industry, when making estimation for new equipment investments or production relocations, to select one or a few exciting products from the product portfolio for calculating production capacity, degree of occupancy and manufacturing costs. These products are often high volume products and are manufactured involving most of the processes within the system. Using information from just a few products there is a risk that valuable information is not taken into consideration. Some problems occurring when producing one type of product are not always present when producing another. One example is products produced in exactly the same processes but consisting of different materials, affecting the quality rate, cycle time and production rate. An alternative when investing in new equipment is to do estimations on all products produced but by use of the characteristic part it is possible to do calculations on one or a few products, making the amount of data easier to grasp and also take the production performance for all products into consideration.

The article proposes a methodology for calculating the characteristic parameters for a fictive part representing a range of products manufactured in a defined set of equipment (cell or line). This together with models for calculating the degree of occupancy is used for analysing the possibility to use the characteristic part methodology to describe manufacturing costs. The term characteristic part is here defined as a product representing all of the parts belonging to a particular product family that can be manufactured in a given production line. The purpose of the proposed concept is to facilitate planning and preparation in connection to production system design and production relocation. The use of the characteristic part concept can also support the comprehensive planning needed when pronounced fluctuations in the market occur.

2. LITERATURE STUDY
To cope with the large variety of customer demands and with customization, companies could adopt a Group Technology (GT) approach for production [1, 2, 3]. When using the principles of GT the company group products with similar geometries, processes and functions together and connects these to specific machines and processes also called machine cells. There is no requirement that every product has to be handled in all machines within the cell. According to Asktin and Subramantan [4], GT make the production environment more economic and productive, with easier inventory control and reduction in material handling, work-in-process and throughput. The idea of the characteristic part is to use GT to group the correct products together and then do the comprehensive calculations. The concept of GT has been used before for calculating the economic lot size [5] and for scheduling the production to find the optimal set-up time [6].

A characteristic part can be compared in some respects with a complex part. A complex part is a detail composed of all the quality demand that occur in the group when GT is employed. In some cases the complex part is the most advanced product produced in the group and in some cases it is too complex to be genuine and only exists on a theoretical basis. The characteristic
A lot of research work has been done regarding production performance and cost. The reason for using a complex part is for planning a machine to be used when only small adjustments are needed in changing parts during production [7].

Askin and Subramantan [4] describe a heuristic cost model for determining the manufacturing cost and maximizing the machine utilization when using product families and GT. The model takes the following costs into consideration: 
- set-up costs, 
- variable production costs, 
- production-cycle inventory costs, 
- work-in-process inventory costs, 
- material handling costs and fixed machine costs.

The major differences and similarities between the model presented by Askin and Subramantan and the one employed in the present article are those shown in Table 1.

The basic concept of characteristic part is based on previous research in production performance and cost in discrete manufacturing system presented in [8] by J.-E. Ståhl et al.

### LIST OF SYMBOLS

Below are the different parameters used in the equations that are listed.

- \( f_{\text{BD}} \) Batch factor
- \( h_{\text{year}} \) Hours per year and shift
- \( k \) Costs per part
- \( k_{A} \) Equipment costs
- \( K_{\text{EUH}} \) Maintenance of tools
- \( K_{B} \) Material costs per part
- \( K_{\text{C,CHP}} \) Characteristic (Ch.) annual costs of producing a part
- \( K_{\text{C,ChP}} \) Annual costs for producing a part
- \( K_{\text{D,ChP}} \) Ch. costs per part
- \( K_{\text{dp}} \) Hourly machine cost during production
- \( K_{\text{CS}} \) Hourly machine cost at downtimes and for adjustments
- \( K_{\text{CUH}} \) Costs of equipment maintenance
- \( K_{\text{d}} \) Salary cost
- \( K_{\text{tee}} \) Annual cost of free capacity
- \( K_{\text{GUH}} \) Costs of maintenance of material handling equipment
- \( K_{\text{N}L} \) Handling and storage costs
- \( K_{\text{mean}} \) Average costs per part
- \( K_{\text{Rw}} \) Costs of reworking
- \( K_{\text{SD,ChP}} \) Ch. total annual manufacturing costs
- \( n_{\text{c}} \) Cost factor
- \( MD \) Market demand
- \( MD_{\text{ChP}} \) Ch. market demand
- \( n \) Number of complete shifts
- \( n_{p} \) Nominal batch size
- \( N_{\text{B,ChP}} \) Ch. nominal batch size
- \( N_{\text{m}} \) Manufactured batch size
- \( N_{\text{M,ChP}} \) Ch. manufactured batch size
- \( n_{\text{b},\text{ChP}} \) Ch. number of batches per part
- \( n_{\text{e}} \) Number of equivalent machines
- \( n_{\text{b},\text{tot}} \) Total batches manufactured
- \( n_{\text{op}} \) Number of operators during manufacturing
- \( n_{\text{A}} \) Number of batches connected to a specific tool
- \( n_{\text{part}} \) Number of different parts within a family
- \( p \) Interest
- \( PC_{\text{ChP}} \) Ch. production capacity
- \( q_{p} \) Relative rate reduction
- \( q_{\text{ch},\text{ChP}} \) Ch. rate of reduction
- \( q_{o} \) Rejection rate
- \( q_{\text{ch},\text{ChP}} \) Ch. rejection rate
- \( q_{s} \) Downtime proportion
- \( q_{s,\text{ChP}} \) Ch. downtime proportion
- \( t_{\text{no}} \) Nominal cycle time per part
- \( t_{p} \) Production time per part
- \( t_{\text{p},\text{ChP}} \) Ch. production time per part
- \( T_{\text{free}} \) Free capacity time
- \( T_{\text{free,b}} \) Time available for each batch
- \( T_{\text{p}} \) Production time for a batch
- \( T_{\text{pb}} \) Ch. production time for one batch
- \( T_{\text{pb},\text{tot}} \) Hours needed for production
- \( T_{s} \) Required production time
- \( T_{\text{plan}} \) Total paid and planned production time during a given period
- \( T_{\text{PB,ChP}} \) Production time required for manufacturing the characteristic part
- \( T_{\text{SU}} \) Time needed for adjustments
- \( T_{\text{SU,ChP}} \) Ch. time needed for adjustments
Utilization rate in the case of a reduced occupancy $U_{RP}$.

Development factor: change in cycle time $x_p$.

Development factor: change in set-up time $x_{p, su}$.

4. METHOD

The aim of this article is to show that it is possible to use the characteristic part and still get accurate results compared to when calculating on all products produced. The comparison is done through use of mathematical simulations based on data from the Swedish industry. The calculation will take the following in consideration:

- Market demand $MD$ for each of the different products produced in a production line.
- Batch size $N_0$ and batch size compared to customer demand.
- Production capacity.
- Degree of occupancy in the production, $U_{RP}$.
- Differences in paid and planned production time, $T_{plan}$.

In selecting a paid and planned production time ($T_{plan}$) for a particular production line or production section in which some family of parts ($j$) is manufactured, it can sometimes be practical to compute the costs of a characteristic part. The concept of a characteristic part can be used in such contexts as the following:

- Computation of the production time per year needed $T_{plan}$ for producing different parts or families of parts.
- Conducting comprehensive production analyses in connection with the planning of new production lines.
- Analysis of the degree of occupancy $U_{RP}$ that takes place or is to be expected.
- Computation of the consequences of changes in demand.
- Computation of key performance indicators for different batches or different families of parts.

When setting up a new factory the analysis above is of high interest. It is important to know how much time that is needed in order to produce the number of parts corresponding to the market demand. The aim is know the needed numbers of personnel and equipment based on the needed capacity in the new factory.

The article has the following structure: the first part provides a description of how the characterization is done and shows the equations and the parameters used for the characterization. After that comes a presentation of how to relate to batch size in comparison to market demand. Section 6 and 7 gives the degree of occupancy, capacity and cost calculation for determining the characteristic performance and cost for the manufacturing system and the parts it produce. Section 8 gives the results corresponding to the list above, based on the equations given in Section 5 to 7 and data collected from the Swedish manufacturing company. The article ends with conclusions and a shorter discussion.

5. CHARACTERISTIC PART

A characteristic part (index $ChP$) is a fictitious part seen as representative of all parts produced in terms of the demand $MD_{ChP}$, setup time $T_{su,ChP}$, cycle time $t_{0,ChP}$, average batch size $N_{0,ChP}$, and total number of batches $n_{b,tot}$ involved. Table 2 shows possible ranges for different characteristic data for different kind of parts used for creating the characteristic part. The characteristic data (see examples in Table 2) this requires is computed on the basis of average or weighted average values of by use of equation 1 – equation 13. The relationships involved that are taken up below apply under the assumption that the batch size $N_0$ for each part is constant. If the batch size for a given part varies, the computations are based on the average batch size. The characteristic annual demand $MD_{ChP}$ for a given part is computed as the average of the demand for the part in question, one that belongs to a particular family of parts.

$$MD_{ChP} = \frac{\sum_{j=1}^{n_{part}} MD_j}{n_{part}}$$  \hspace{1cm} (1)

where $n_{part}$ is the number of different parts that the respective characteristic part includes.

The schematic configuration of the characteristic part is shown in Figure 1. A characteristic part can be used to present a product, a group of different parts, one product family or several product families, depending on the system. In this article the characteristic part represent a product family.

</table>
3.1. Characteristic production times

The characteristic setup time $T_{su,ChP}$ is weighted by the number of sets-ups that occur for the part in question.

$$T_{su,ChP} = \frac{\sum_{j=1}^{n_{part}} MD_j}{N_{0,j}}$$

(2)

The number of set-ups for a given part per year is computed as the product of and product specific annual demand $MD_j$ for the part in question using a family of parts consisting of $n_{part}$ different details.

$$t_{0,ChP} = \frac{\sum_{j=1}^{n_{part}} MD_j \cdot t_{0,j}}{\sum_{j=1}^{n_{part}} MD_j}$$

(3)

3.2. Characteristic batch size

The characteristic batch size $N_{0,ChP}$ is computed as the average of the batch size $N_{0,j}$ for the respective part in the family to which it belongs.

$$N_{0,ChP} = \frac{\sum_{j=1}^{n_{part}} N_{0,j}}{n_{part}}$$

(4)

The total number of batches that are manufactured can be computed using equation 5.

$$n_{b,jot} = \frac{\sum_{j=1}^{n_{part}} MD_j}{N_{0,ChP}}$$

(5)

3.3. Characteristic production capacity

The production time required $T_{plan}$ for manufacturing a family of parts consisting of $n_{part}$ different details can be computed using equation 6.

$$T_{plan} = T_{set,ChP} + \frac{t_{0,ChP} \cdot MD_{ChP} \cdot n_{part}}{(1-q_{0,ChP})(1-q_{b,ChP})(1-q_{f,ChP})}$$

(6)

The production capacity for the characteristic part $PC_{ChP}$ can be computed as:

$$PC_{ChP} = \frac{T_{plan} - T_{set,ChP} \cdot n_{set}}{t_{0,ChP} \cdot (1-q_{0,ChP})(1-q_{b,ChP})(1-q_{f,ChP})}$$

(7)

3.3. Batch size

An important decision to be made in series production is the selection of batch size in light of the demand for the part or product in question. In some cases there is reason to distinguish between the batch size $N_{0,M}$ and the quantity of the product in question delivered to the customer $N_0$. The numerical relationship between $N_{0,M}$ and $N_0$ is expressed in terms of the batch factor $f_{N_0}$ which can also be used in connection with describing the characteristic part.

$$f_{N_0} = N_{0,M} / N_0$$

(11)

The number of parts per batch $n_b$ and the total number of batches $n_{b,jot}$ can also be expressed as a function of the batch factor $f_{N_0}$ by use of equation 12.

$$n_b = \frac{MD}{f_{N_0} \cdot N_0}$$

(12)

$$n_{b,jot} = \frac{MD_{ChP} \cdot n_{part}}{f_{N_0} \cdot N_{0,ChP}}$$

(13)

6. DEGREE OF OCCUPANCY IN THE PRODUCTION SYSTEM

An increased degree of occupancy reduces equipment costs per part. For the needs that a given annual order volume represents to be met, a certain number of planned hours of production time are required. The cost model presented earlier [8,12,13] gives the part costs of a defined product and analysis how different parameters effect the final part costs. The previous cost model was designed for calculations considering a product or a small group of similar products, resulting in that the calculations having to be conducted for all the products in the production line. The cost model in its present version describes the economic consequences of failing to reach the level of planned production time needed in order to satisfy the demand that exist for a given part or family of parts.

Increasing the degree of occupancy of a particular production system in the manufacture of a given part reduces the part costs involved through the investment costs being distributed over a larger number of production hours ($T_{plan}$) than before.

The degree of occupancy indicates the extent to which a production time of given length, the costs of which are already determined in advance, is made use of. If one fails to utilize all of the capacity being paid for, this
results in an overcapacity also referred to as free capacity. From a production standpoint, this can be regarded as representing a downtime, even if the equipment is functioning just as it should. A certain amount of free capacity in the manufacturing system is often desirable nevertheless, through its enabling a smooth transition from one batch to another to take place. An degree of occupancy $U_{RP}$ of about 96 – 97 % is thus often advantageous [13] based on interview with Swedish industry.

4.1. Degree of occupancy and capacity

The degree of degree of occupancy $U_{RP}$ of the manufacturing facilities this represents can be computed using equation 14. The selection of paid and planned production time $T_{plan}$ here usually takes place stepwise in the form of computing the number of complete shifts $n$ times the number of hours per year and per shift that are involved $(n h_{year})$ [8, 12, 13].

$$U_{RP} = \frac{T_{pb, tot}}{T_{plan}} = \frac{T_{plan} - T_{free}}{T_{plan}} = 1 - \frac{T_{free}}{T_{plan}} \tag{14}$$

The free capacity of the manufacturing facilities can be expressed in terms of the degree of degree of occupancy of them, using equation 15 below [8, 12, 13].

$$T_{free} = \frac{1 - U_{RP}}{U_{RP}} \cdot T_{plan} \tag{15}$$

If a company shows full degree of occupancy of its equipment four of five working days a week and no degree of occupancy of it on the 5th day, $U_{RP}$ is computed as $(5-1)/5 = 0.80$, the degree of degree of occupancy thus being 80 %. If the time available through overcapacity is distributed equally across all of the batches in relation to the production time $T_{pb}$, the additional time thus available for the free capacity in the manufacturing system is often advantageous [13].

The degree of degree of occupancy $U_{RP}$ of the manufacturing facilities can be computed as follows by use of equation 19 [8, 12, 13].

$$T_{pb} = T_{su} + \frac{N_0 \cdot t_0}{(1-q_s)(1-q_p)} \tag{19}$$

A particular level of annual market demand (MD) for a given part requires, for the manufacturing system involved, some specific number of production hours $T_{pb,tot}$ which can be computed by use of equation 20.

$$T_{pb,tot} = T_{su} \cdot \frac{MD}{N_0} + \frac{t_0 \cdot MD}{(1-q_s)(1-q_p)} \tag{20}$$

The ratio of the demand for the part MD to the average batch size $N_0$ gives the number of set-ups and number of batches per part, $n_0$ that would take place. Each of the parameters employed in the equation represents the average value of it during a one-year period.

The total time per year for use of a given production line or machine that would be needed for producing a particular part in the quantity foreseen can be computed using equation 21.

$$T_{plan} \geq T_{pb,tot} = \frac{T_{su} \cdot \frac{MD}{N_0} + \frac{t_0 \cdot MD}{(1-q_s)(1-q_p)}}{U_{RP} \cdot 60} \tag{21}$$

4.3. Degree of occupancy

The degree of degree of occupancy $U_{RP}$ can be expressed, in line with equation 14 presented earlier, on the basis characteristic data with use of equation 22. The parameter $n_{set}$ indicates the number of machines or production lines similar to one another in their capabilities that can be used to manufacture the characteristic part in question.

$$U_{RP} = \frac{n_{set} \cdot T_{pb,tot}}{n_{set} \cdot T_{plan}} \tag{22}$$

7. CHARACTERISTIC PART COST

If account is to be taken of the reduction in the degree of degree of occupancy involved, the costs of producing a part can be computed by use of equations presented
The total annual costs of the parts in their entirety, \( K_{\text{tot}, \text{ChP}} \), can be obtained by multiplication of this by \( n_{\text{part}} \), the number of parts involved.

\[
K_{\text{tot}, \text{ChP}} = K_{\text{ChP}} \cdot n_{\text{part}} = \frac{k_{\text{ChP}} \cdot MD_{\text{ChP}} \cdot n_{\text{part}}}{MD_{\text{ChP}} \cdot n_{\text{part}}} = \frac{K_{\text{tot}, \text{ChP}}}{MD_{\text{ChP}} \cdot n_{\text{part}}} \tag{29}
\]

### 8. RESULT

Using the equation presented here and data collected from a Swedish manufacturing company regarding batch sizes, cycle times, performance parameters, set-up times and annual market demands for different products, different relationships between parameters have been investigated. The figures in this section show how it is possible to do analysis regarding production planning when doing investment in a new factory using the characteristic part. A comparison between the characteristic manufacturing cost and the manufacturing cost based on the different products are made.

#### 8.1 Batch size

The use of equation 6 is exemplified in Figure 2, in which the total batch time \( T_{\text{planning}} \) is described as a function of the batch factor \( f_{\text{bl}} \), with use of the downtime rate \( q_{S} \) as the parameter. In the diagram, the batch factor \( f_{\text{bl}} = 1.0 \) is marked by a vertical line. For \( f_{\text{bl}} < 1.0 \) the production time required increases in relation to the nominal batch size \( (N_{0} = N_{\text{bl}}) \), whereas for \( f_{\text{bl}} > 1.0 \) it decreases. In the examples the total production time is shown as a function of the batch factor \( f_{\text{bl}} \) for each of 3 different downtime rates \( q_{S} \), as based on the characteristic part in question (solid lines), and the sum of the production times for the parts as a whole, reported by means of the discrete symbols that are shown, where \( n_{\text{part}} \approx 45 \).
8.2 Degree of occupancy analysis

The relationship between the part costs $k$ (equation 18) and the degree of degree of occupancy $U_{RP}$ is shown in Figure 3 for three different levels of paid and planned production time per year $T_{plan}$. The part cost is highly depending on to what extend the machines are utilized.

Figure 3: Examples of part costs $k$ as a function of the degree of degree of occupancy $U_{RP}$ for different paid production time levels per year $T_{plan}$.

Use of this equation 21 is exemplified in Figure 4, in which the paid and planned production time $T_{plan}$ is presented as a function of the annual demand $MD$, both in the case of full degree of occupancy, $U_{RP} = 1.0$, and the degree of occupancy of 0.9 and 0.8.

Figure 4: Examples of paid and planned production time $T_{plan}$ shown as a function of demand $MD$.

Figure 3 and Figure 4 shows how important the knowledge of the degree of occupancy is. The level affects both the part cost and the needed hour to be able to deliver the correct numbers of parts responding to the market demand.

8.3 Time planning

Figure 5 and Figure 6 exemplify the relationships between different production parameters for a family of parts. For the case in question, one can note that the setup time $T_{su,j}$ increases with the cycle time $t_0,j$ and that an increase in the annual demand $MD$ tends to result in an increase in the nominal batch size $N_{0,j}$ selected. In all four cases the location of the characteristic part is marked with a blue square. The figures give the relationship between the characteristic parts and the parts it represent, showing that the characteristic part is an average part regarding production parameters.

Figure 5: Examples of how the setup time $T_{su,j}$ can vary for a family of parts, with different values for the cycle time $t_0,j$ (left) and for the nominal batch size $N_{0,j}$ (right).

Figure 6: Examples of how the relationship between the cycle time $t_0,j$ and the nominal batch size $N_{0,j}$ (left) and between the annual demand $MD$ and the nominal batch size $N_{0,j}$ (right) can vary within a family of parts.

The use of equation 22 is exemplified in Figure 7 for three different levels of the paid and planned production time, $T_{plan} = 3200$, 4800 and 6400 h/year, respectively. A degree of degree of occupancy $U_{RP} > 1.0$ means that overtime is needed to achieve the production goals that have been set. This kind of analysis could be very useful when estimating the production capacity.

Figure 7: Examples of the degree of degree of occupancy $U_{RP}$, shown as a function of the batch factor $f_{N0}$ (left) and of the demand $MD_{ChP}$ (right).

8.4 Characteristic manufacturing cost analysis

An example of computations of the distribution both of the part costs $k_j$ (left) and of the total annual costs $K_{0,j}$ (right) for a family of some 40 different parts is presented in Figure 8. The characteristic part costs $K_{ChP}$ and the characteristic annual costs $K_{0,ChP}$ are shown by the vertical columns.
Figure 8: Examples of the statistical distribution of the part costs $k_j$ and of the total manufacturing costs per year $K_{b,j}$, as well as of the characteristic costs involved.

On the basis of the values used in this case, the total sum of the characteristic part costs multiplied by the number of parts involved is 11.99 MSEK and the total manufacturing costs for all of the different products is 12.00 MSEK. The error in using a characteristic part in this case is less than 0.1%.

Figure 9 presents examples of the part costs, shown as a function of the batch factor $f_{N0}$, computed by use of equation 25, the discrete symbols in their entirety representing all of the parts involved, the continuous lines showing the results of computations based on the characteristic data. The computations were carried out here for two different levels of the downtime rate $q_S$. By increasing $f_{N0}$ the total set-up time decreases making the part cost decrees.

Figure 9: Examples of the part costs $k_j$ shown as a function of the batch factor $f_{N0}$ for two different downtime rates $q_S$.

Under conditions in which both the size of the series of parts $N_0$ that is manufactured and the total demand for the parts $MD_{Tot} = \Sigma MD_j$ are constant, the part costs $k_j$ are dependent in a straightforward way on the annual demand for the parts in question $MD_j$. An increase in the total demand leads to an increase in the length of time altogether that the equipment is made use of per year. This provides the basis for computations regarding the degree of occupancy of the equipment $UR_P$. In general terms, there is also a reduction in equipment costs as use of the equipment increases, through the basic investment in the equipment being distributed over a greater number of production hours. Figure 10 exemplifies changes that occur in the characteristic part costs as a function of the level the annual characteristic demand $MD_{ChP}$ for the parts in question. The discontinuities in costs that are evident in the figure can be explained in terms of the assumed length of the intervals between successive renovations of the equipment when the production time that is planned being allowed to vary.

Figure 10: Examples of the characteristic part costs $k_{ChP}$, shown as a function of the annual characteristic demand $MD_{ChP}$, for $f_{N0} = 0.25, 1.0$ and 10, respectively, together with examples of the total production time needed for producing the family of details in question in its entirety, $T_{plan}$, for $f_{N0} = 0.25, 1.0$ and 10, respectively and for values of the planned production time involving 1, 2 and 3 work shifts per day, the latter shown by the horizontal lines.

The y-scale located at the right in Figure 10 indicates the total production time $T_{plan}$ needed per year, this providing a basis for planning of the production time $T_{plan}$ required, in line with equation 21. The effects of the batch factor $f_{N0}$ on the total production time needed in the case at hand are shown in the figure. Figure 11, in turn, exemplifies how the characteristic part cost $K_{ChP}$ can vary under conditions in which the paid and planned production time is constant. When this is the case, the degree of occupancy $UR_P$ increases with the demand $MD_{ChP}$ since if the degree of occupancy is reduced, for example, a part of the free time is added to the batch time.

Values of $UR_P$ somewhat larger than 1.0 are often dealt with as involving overtime, due to the equipment costs being distributed then across a greater number of parts. This effect is illustrated in Figure 11 (the red curve). If, as is frequently the case, no account is taken, in computing the machine costs here, of the increase in machine costs that occurs under such circumstances, the part costs appear to remain constant when the level of the demand increases (the blue horizontal line). In the case at hand, no account was taken of the extra salary costs that came about when overtime was involved.
Figure 11: Examples of the part costs $k_{ChP}$ and $U_{RP}$, shown as a function of the demand $MD_{ChP}$, for each of three different levels of paid and planned production time, $T_{plan} = 3200$ h (red), $4800$ h (blue) and $6400$ h (black).

Figures 11-12 illustrate that reductions in demand $MD$ affect part costs negatively, as shown in Figure 12. The effects of reduced demand can be analyzed by use of cost derivatives, as described in [8, 12, 13]. A change in demand of 10% might tend to affect the manufacture of all or virtually all parts and families of parts. It can be practical under such conditions to base analyses of the situation on characteristic parts.

Figure 12: Examples of the part costs $k_{ChP}$, shown as a function of the demand $MD_{ChP}$, for $URP > 1.0$, both with (the red curve) and without (the blue horizontal line) adjustment for the added machine-time costs ($k_{CP}$ and $k_{CS}$) caused by the increase in total production time.

9. CONCLUSION

In industry it is usual to make calculations and estimations in connection with production design and planning on one or a few existing products representing the product range. With use of the characteristic part it is possible to take all products into consideration. Figure 2, 5, 6, 8, 9 demonstrate how calculations using the characteristic part relate to the product range it represents. It has been shown here that it is possible to use a characteristic part when making capacity estimates and cost calculations. In Figure 3, 4, 7, 10-12 ways of analysing the data are shown. The simulations can be used in order to analyse the needed production hours and how the batch size and market demand affecting the part cost, giving the company information to use when making decisions on investment. However the model is based on production data that could be difficult to collect if the company in question possesses no adequate production monitoring systems and is unable to estimate the specific production conditions to each part. Any type of capacity calculations or estimates not using this kind of performance data is not likely to be correct.

There are both global and characteristic parameters that could be used in calculations. In the present case the number of parts $n_{part}$, the number of batches of each part $n_{b}$ and the total number of batches $n_{b, tot}$ are global, meaning it is not possible to manipulate the numbers and still get an adequate result.

Figure 2 illustrates the fact that the characteristic part (with its index $ChP$) can be used under appropriate conditions for describing the total production time required for each of the different parts. When rather large changes occur, such as in the relationship of market demand $MD_{0}$ and batch size $N_{0,j}$ to one another, there tend to be rather large differences between the results of computations pertaining to the characteristic part and those pertaining to each and every part. The use of a characteristic part in this article is based on the fact that all the parts involved belong to the same family and that the same machine and the same operations can be used in machining all of them.

10. DISCUSSION

There has been a study of the economically optimal automation level [14], relating to this its representing a further development of the model presented in [8, 12, 13]. It is possible to combine the model there with the one presented in the present paper. This makes it possible to combine calculations of the optimal automation level with that of a characteristic part, making the planning of the production system more efficient. A situation when this kind of investigation could be very useful is when a company analyses different alternatives for relocating manufacturing sites. With the presented calculations a company would be able to do an in depth analysis of the needed capacity and final manufacturing costs based on each alternative’s special condition. This makes it possible to compare different system both old and new ones, which is necessary in order to make a well based decision. This is in line with Park’s and Son’s statement. “A decision to install a new manufacturing system requires a comparison of the manufacturing performance of the old and new systems” [15, p. 2].

Future work could aim at construct a model for calculating the optimal batch size, on the basis of the characteristic part. A basic approach that could be taken here has been reported in [16], by J-E. Ståhl.
